INDEX FOR VOLUME XXXIII

JANUARY 1 TO JUNE 30, 1911

Explanatory Note.

Illustrated articles are marked with an asterisk (*). Book notices are denoted by a dagger (†). Cross references to a particular initial word may apply to any cognate word beginning in the same way. Thus, a reference from "Oil" to "Lubricant" would relate equally to "Lubricating," "Lubrication" or "Lubricator." The cross references condense the matter and assist the reader, but are not to be regarded as conclusive. So, if there were a reference from "Boiler" to "Furnace" and if the searcher failed to find the required article under the latter word, he should look through the "Boiler" entries, or others that the topic might suggest, as he would have done had there been no cross reference. Letters are indexed under title or subject, general articles under writer's name as well. Not all articles relating to a given topic necessarily appear under the same entries.

POWER

NEW YORK, JANUARY 3, 1911

WE HAVE just passed a period of uplift, so to speak. Perhaps each of us who has been bowling merrily along, doing those things which he ought not to have done and leaving undone those things which he ought to have done, pulled up for a deep breath two mornings ago and solemnly swore, "Never again!"

This is all right and quite natural, for we have just put behind us another milestone; we are just one page nearer to the end of the chapter.

Changing the numerals from 1910 to 1911 drove home a realization of lost opportunities which we meant to improve, but which, somehow, we did not.

And so, with rustling ostentation, we "turn a new leaf," with the high resolve to "make up for lost time," to "brace up" and to do numerous other things plainly beneficial to ourselves. The doing of all these things probably amounts to nothing more than our simple duty; yet we feel uplifted, chastened, better men.

If the case is a usual one, this higher-thought thing wears off in the course of a few days, and the erstwhile better man is indulging in the same old sins of commissions and omissions.

This is mainly the result of force of habit.

This paper is made up of a consolidation of "Power" "The Engineer" "The Engineer's Review" "Science and Industry" "Steam" and "Steam Engineering"

Good resolutions are good resolutions—nothing more.

And of what use are good resolutions except to be broken?

* * *

Man is the victim of habit.

Think it over!

Does habit decide that three meals a day is the proper "caper"—then man eats three meals straightway.

Does habit decide that man shall wear his hair short—then man wears his hair short forthwith.

After a habit has been handed down for a generation or two it is given the pleasanter name of custom. The two habits just mentioned have borne the name custom so long that the bare thought of departing from either seems almost a sacrilege.

Study is a habit, neglect of duty is a habit. "Cussin'" is a habit, and so is surliness.

Forget about those impossible good resolutions and start sincerely to work on your habits. Start *today*, continue *tomorrow* and keep the work up *throughout the year*.

Break up a bad habit and institute a good one. Stick to this policy, and at the end of the current year you will find it hard indeed to draft a set of good resolutions.

Let all your habits be good ones!

Setting Horizontal Tubular Boilers

By S. F. Jeter

Directions for constructing the setting of a horizontal tubular boiler, together with the dimensions of different parts of the setting for various sizes of boiler, and the number of bricks required.

The usual method of purchasing a horizontal tubular boiler is to pay a stipulated price for the boiler, front, attachments, etc., delivered f.o.b. cars on the nearest railroad siding to the boiler room. From this point the purchaser usually makes a contract for the removal of the boiler to the plant and setting it in brickwork, or else turns the job over to his engineer to superintend, and hires a mason by the day to do the necessary brickwork. It frequently happens that in the small plant, which may be located in an out of the way place, that skilled masons cannot be procured, and even where brick masons are plentiful it is frequently difficult to procure one skilled in furnace work. A mason may be first class on general building work, without being able to lay up furnace work that will stand. Although it is impossible to give exact directions for doing such work, the principal features and requirements necessary to secure a good and lasting setting may be pointed out.

Foundations

The first thing that is necessary to secure a setting that will remain tight and free from cracking is a good foundation, which should be prepared before the arrival of the boiler. The manufacturer of the boiler should furnish a setting plan which will give the dimensions of the setting walls, and from this the proper dimensions and location of the foundation walls may be obtained. If a setting plan is not furnished, correct dimensions may be obtained from Table 1, used in connection with Fig. 1. In using these dimensions for a boiler already built, particular attention should be paid to the note, relative to the variations in the several dimensions as may be required, due to the hight of front, length of grate bars or the dimensions of the covering for the rear connection that are furnished, and which may not conform to the sizes given in the table. Also for flush fronts, on account of the depth of the extension sheet varying from that given for P in the tables, several dimensions on such settings would require modification of the figures given. The dimension Q for flush fronts is given uniformally two inches greater than P so that ample protection from the furnace heat may be afforded the extension sheet. It is impossible to give exact directions regarding the depth of foundations or the width of footings necessary, as these points depend entirely upon the nature of the soil at each plant. Formerly, stonework was used almost exclusively for building foundations, but now concrete is in general use. Where the soil is very bad and capable of supporting only light loads, a bed of concrete, properly reinforced and extending entirely over the space occupied by the setting, makes a very satisfactory foundation. It should be remembered that in arranging a foundation for boilers supported on columns, that the load on the portions of the foundations beneath the columns is more concentrated than in the case of lug-supported boilers resting directly on the brickwork, and it is necessary that additional width to the footings be provided at the base of the columns. It cannot be too strongly emphasized that the foundation must be capable of holding the boiler and setting practically rigid, for no matter how well the brickwork is set above it, a weak

Note.—In using this table for setting boilers, particular attention must be paid to the fact that dimensions F, J, M and N must conform to the dimensions of the front furnished with the boiler and dimensions K and L with the grates furnished. On flush fronts dimensions Q, R and S depend on dimension P, and these dimensions must be changed to conform to any changes that may be necessary in P. The column giving the number of common brick required refers to the overhanging-front style of setting, and for flush fronts these should be added [illegible] brick, depending upon the size of boiler.

foundation will cause the walls to crack and also may cause stresses on the pipe connections to the boiler that are apt to result in a serious accident.

Unloading

When the boiler arrives at its destination it should be carefully unloaded and transported to the site of erection. In handling a boiler, one should remember that it is usually made up of a number of plates riveted together and that the tightness of each tube depends upon two expanded joints; therefore, the boiler cannot be handled as if it was a chunk of pig iron. The writer has seen a boiler deliberately dropped from the side of a flat car, and the mechanic superintending the job expressed surprise that a block on which it happened to land had dented the shell. The nozzles are most likely to be damaged in handling; and pipes or bars should never be stuck in the tubes to aid in moving the boiler.

Placing the Boiler in Position

It is best to place a boiler in the correct position with the front in place before commencing the brickwork; if the boiler is to be supported on lugs resting on the brickwork it should be placed about a half inch higher than the desired final position, to allow for lowering on the brickwork when the supports are removed. When a boiler is to be hung from beams it can be placed in the correct position at once. None of the weight should be carried by the boiler front, and to insure against this ½ to ¾ inch clearance should be left between the bottom of the shell and the front. Ample clearance between the front and shell is especially important in the lug-supported type in order to allow for settling.

The front end of a boiler should be placed about 1 inch higher than the rear to aid draining through the blowoff pipe when washing out; this also allows an extra inch depth of water over the rear tube ends, which is a precaution against damage from low water. To level a boiler crosswise it is necessary to consider two points, the top line of tubes and the faces of the steam nozzles. Every boiler manufacturer endeavors to have the face of the steam nozzle parallel to a line across the tops of the tubes; but owing to the fact that the nozzle is finished in a lathe and then riveted to the boiler shell, the surface of the flange is sometimes out of true with the top line of tubes. Usually slight differences of this kind can be taken up in the packing of the joint, but if the top line of tubes and the face of the nozzle are out enough to prevent a proper joint being made, the boiler should be set so that the tubes are level crosswise and a special flange used to fit the nozzle to bring the main steam pipe vertical. Many engineers view the matter from a piping standpoint alone and endeavor to level the boiler by the face of the steam nozzle; this, however, is not correct, because the short length of surface at the top of the steam nozzle precludes accurate leveling from this point, and also because it is of more importance that the tops of the tubes be level than the flange of the nozzle. The angularity of the nozzle face can be remedied by the use of a special mating flange, but the tops of the tubes across the boiler not being level means a higher water line and consequently a reduction of steam space which cannot be remedied.

Blocking or barrels placed beneath the shell are generally used to hold a lug-supported boiler in position while the setting walls are being built; however, barrels are preferable to blocking, as they are less in the way of the brick masons. Two heavy oil barrels in good condition can be depended upon to support a 66-inch by 16-foot boiler, if the blocking below them and on top is arranged so that the load is distributed evenly over all the staves. Additional barrels should be used for larger boilers and the blocking on the top arranged so that the load will be distributed evenly between the barrels. If good barrels are not available, a cribwork of blocks placed under the front and rear ends of the shell will serve the purpose. In placing such supports care should be used in the arrangement of the blocking so that it will not interfere with the building of the setting walls.

Materials Required

Some masons still use common lime mortar in building boiler settings, but a much better and more lasting job can be obtained by adding cement to the bonding mixture. First, regular lime mortar is made, using three-quarters of a cubic yard of good, sharp sand to one barrel of lime. After this has been made up in the usual manner, a mixture of sand and cement is made, using two barrels of sand to one barrel of cement (four bags of cement); this mixture of sand and cement is added to the lime mortar and it is then ready for use. This quantity of material should make enough mortar to lay about one thousand brick. If all the mortar cannot be used at once, the sand and cement mixture should only be added to such portion of the lime mortar as will be required for immediate use, as it is difficult to keep it in proper condition for use over night after the cement has been added. Fire clay is the only bonding material that should be used in laying the firebrick and for this purpose it should be mixed with water to about the consistency of buttermilk, so that the bricks may be dipped in it and rubbed together when laying them. About two barrels of fire clay are required to lay one thousand brick.

The temperatures attained in the furnaces of return-tubular boilers are generally moderate, and it does not require a specially high grade of firebrick to withstand the heat; but there is more need of mechanical strength to withstand the wear incidental to the rubbing of the fire tools and breaking off clinkers. On this account a medium grade of firebrick, costing about $22 to $25 per thousand, will be generally found most suitable. Firebrick that are made especially with a view to resisting the very high temperatures are usually mechanically weak and soft and they are also the most costly. For arches in dutch ovens, where there is no danger of hitting the brick with the fire tools, the higher grade of brick generally gives the best service. The common brick used for setting should be well burned and selected for strength rather than beauty.

To estimate the number of common brick required for a boiler setting, figure the number of cubic feet of wall that is to be laid with this kind of brick and multiply by 23; the result will be the number of brick required. In making calculations for the number of brick, no deductions should be made for openings in the setting walls for cleaning doors, etc.; for the waste from breakage and cutting will require all of the extra brick figured in this way. Where fire lining is laid 4½ inches thick and with every sixth course a header, eight firebrick should be figured for each square foot of wall surface lined in this manner. If the lining is to be 9 inches thick and with every sixth course tied to the common brick with a header, fifteen brick should be figured for every square foot of wall surface lined.

		49½

Thickness of Wall

Draftsmen usually specify a nominal thickness for the walls on a setting; and often the brick mason (who does not know how much change may be made without affecting the work) is troubled in endeavoring to meet the given dimensions without cutting the brick. For standard-sized brick, Table 2 gives about the proper wall thicknesses to specify, so that they may be laid without cutting the brick.

The sizes of common brick vary slightly with each locality; but the standard is 8¼x4x2 inches and the standard size for firebrick 9x4½x2½ inches. Although the standard sizes of firebrick are so different from the common brick, they lie together correctly because the firebrick are laid brick to brick, while the common brick have about ½ inch of mortar between them.

Design of Setting Walls

Return-tubular boilers are usually set with an air-spaced wall, as illustrated in Fig. 1. Many claims are made as to the benefits derived from such construction, one of the chief being that it lessens the radiation losses by keeping down the temperature of the exposed wall surface. The air space does reduce the temperature of the outer wall surface, but introduces other losses that probably outweigh the gain in economy due to this feature, and it is very doubtful if this form of construction, from an economical standpoint, is better than a solid wall.

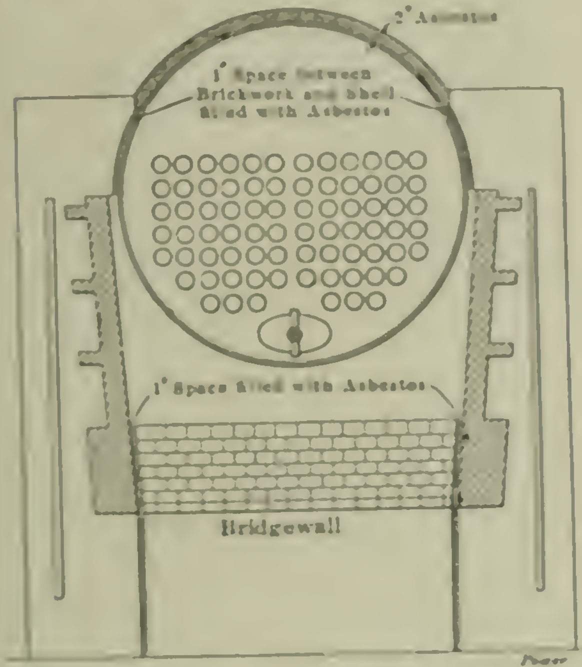

Fig. 2. Showing Clearance at Ends of Bridgewall and Around Shell

The chief advantage of the air-space construction is that when properly built it tends to prevent the cracking of the outer wall surface and, therefore, makes a better looking setting. One very important point in the design of setting walls, to prevent cracking, is the method used to join the ends of the bridgewall with the side walls. Usually a mason will build the two at the same time, and tie the bridgewall rigidly to the side walls. This method of construction is almost certain to result in cracked side walls, because the bridgewall expands when heated and pushes out the side walls. With the wall having an air space this does not necessarily show on the outer wall unless the two are tied together at this point.

There are two ways of preventing trouble from the expansion of the bridgewall. One is to leave the ends of the bridgewall about an inch away from the side walls, as shown in Fig. 2, packing the space with asbestos or mineral wool. The elasticity of the packing allows for the expansion of the bridgewall and it prevents the space from becoming clogged with ash and cinders. The other way to accomplish the same purpose is to build a recess about 4½ inches deep in the side walls having the same shape as a vertical section of the bridgewall, and build the ends of the bridgewall into this recess, leaving 1½ inches of clearance at each end for expansion; this method of construction is shown in Fig. 3.

There are many different ideas regarding the proper shape to be given to bridgewalls and the correct distance that should be left between the top of the wall and the shell of the boiler. The chief function of a bridgewall is to limit the length of the grate surface by presenting a barrier beyond which the spreading of the fuel is prevented; it also aids in mingling the unburned gases and air, so as to cause complete combustion before reaching the tubes. The exact shape or hight of the bridgewall does not greatly affect the attainment of these functions, but it may play an important part in tending to cause or prevent trouble at the girth seams due to overheating. Where girth seams are located in the vicinity of the bridgewall, the top of the wall should be so shaped and of such a distance below the shell that the products of combustion will not impinge directly against the seam. A distance of at least 10 or 12 inches should be left between the top of the bridgewall and the shell to prevent overheating of the sheets, even in the absence of seams; and the top of the bridgewall should be built straight across and not follow the contour of the shell as is sometimes done. All the bricks on top of the bridgewall should be laid as headers, as illustrated in Figs. 1 and 3, so that they may be better able to resist being dislodged by the fire tools. It is much better to rake the top of the bridgewall as shown in Figs. 1 and 3 instead of trying to cut the brick to make them present a smooth slope; for when the bricks are cut, clinker adheres more tenaciously to the cut surfaces than it does to the original surface of the brick.

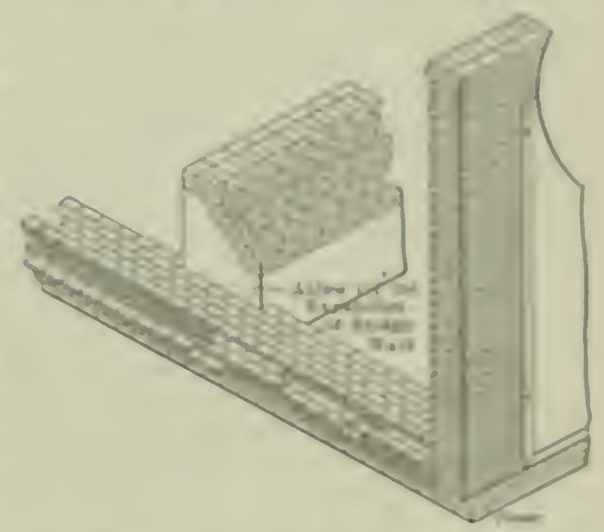

Fig. 3. Method of Allowing for Expansion of Bridgewall

The side walls of a boiler are generally battered as shown in Fig. 1, and this is good construction, especially for a lug-supported boiler; for in making repairs to the lining on the side walls of the furnace the firebrick may be removed and still leave ample support for the boiler.

Combustion Chamber

The combustion chamber at the rear of the bridgewall is a very important feature of the setting, tending to aid complete combustion, especially if bituminous coal is used. The rear slope of the bridgewall should be built vertical and the space behind it down to about the level of the floor should be left open as in Fig. 1, and not filled up and paved as in Fig. 4, which is common practice. The deep combustion chamber at the rear of the bridgewall tends to cause a whirl in the air and gases passing over it and greatly aids in their proper mixture. It also affords storage capacity for the fine ash and cinder that is carried beyond the bridgewall. The practice of filling the space behind the bridgewall to conform to the contour of the shell, as is sometimes done, cannot be too strongly condemned, for it seriously interferes with the accessibility for inspection of the most important surfaces of the boiler, and is certain to prevent complete combustion, if bituminous coal is

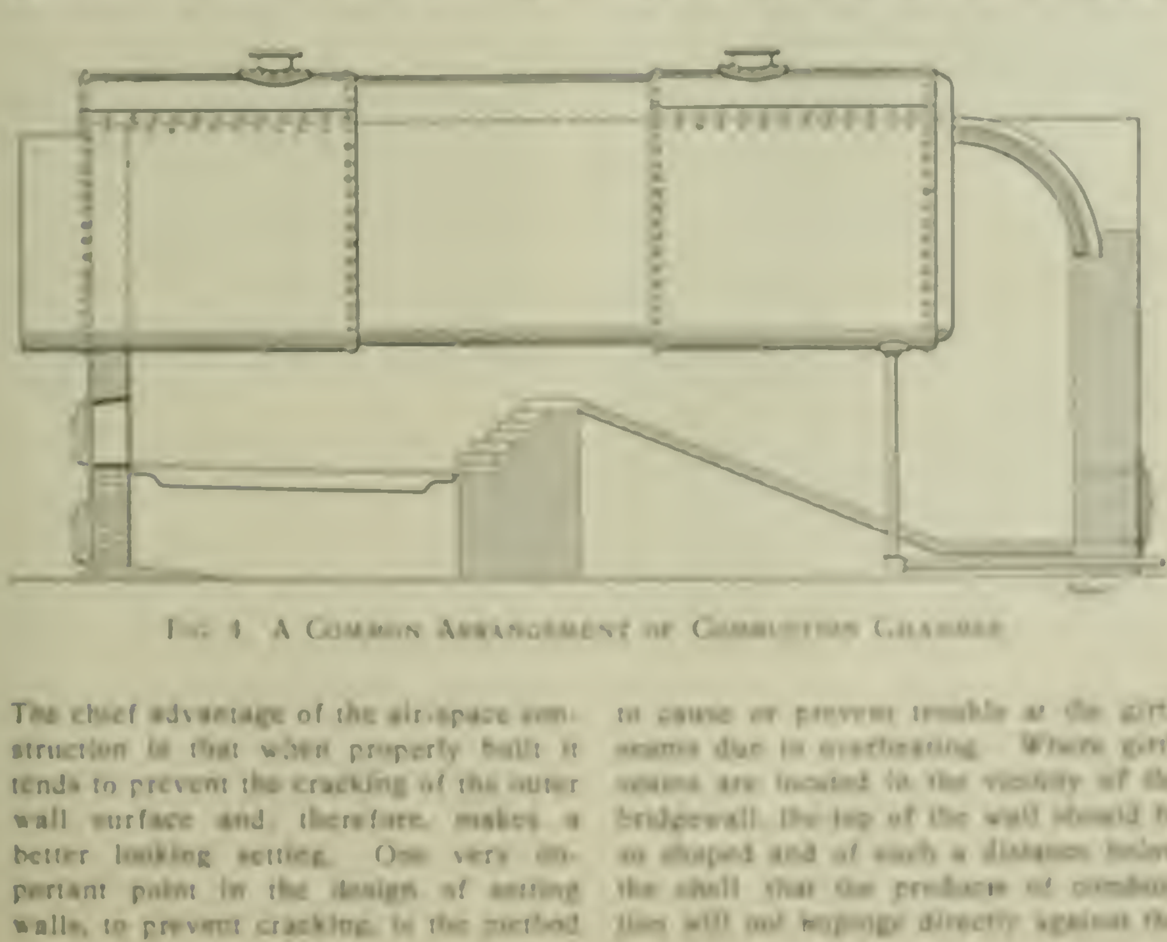

Fig. 4. A Common Arrangement of Combustion Chamber

used. Convenience in cleaning out the combustion chamber is obtained by arranging the bottom of this chamber as illustrated in Fig. 1; so that the blowoff pipe passes out below the paving, and the cleanout door, which is usually located in the rear wall, is placed on a level with the paving so that no obstacle is offered to raking out the ashes. The blowoff pipe should be placed in a brick trough, the bricks on top being arranged so that they may be readily removed for inspection. This arrangement also admits of the blowoff pipe being placed above the boiler-room floor without interfering with free access to the cleanout doors. The vertical section of the blowoff pipe should be protected from the direct impingement of the flames by slipping a pipe sleeve over it; or a form of protection which is equally as good, with the blowoff pipe accessible for inspection, may be made by laying loose firebrick in front of the pipe in the form of a V.

Firebrick Lining

The amount of wall surface that is required to be lined with firebrick is largely a matter of opinion; some engineers prefer to line all of the inner surfaces that are swept by flame and heated gases; but, although this makes a good and lasting setting, it adds considerably to the cost. If the front wall and the side walls over the space indicated by the letters *W X Y Z*, Fig. 1, are lined, together with the bridgewall, and the balance of the setting is laid with good, hard, burned red brick, a satisfactory and very durable job will result. Every fifth or sixth course of firebrick should be a header course to properly bind the lining to the main wall. In laying fire lining too much emphasis cannot be put on the necessity of using the minimum amount of bonding material. Fire clay, which is the only kind of material that should be used for this purpose, should be mixed with water to the consistency of buttermilk and the bricks dipped in it and rubbed down on each other as they are laid. When too much fire clay is used between the bricks where exposed to high temperatures, the clay will fuse and apparently acts as a flux to run out the brick material, resulting in wearing away of the bricks at the joints; a condition that may be noted with improperly laid linings.

Binder Bars

Although it has been the general custom to place binder bars on side walls of settings, it is a debatable question as to whether they are of any real benefit or not, except possibly near the front and rear ends of the setting. When a boiler is set with a dutch oven, there is absolute need of binder bars or their equivalent to carry the thrust of the arch, but no such need exists with the ordinary return-tubular setting where the boiler is hung, and probably not where the boiler is supported by lugs resting on the setting walls.

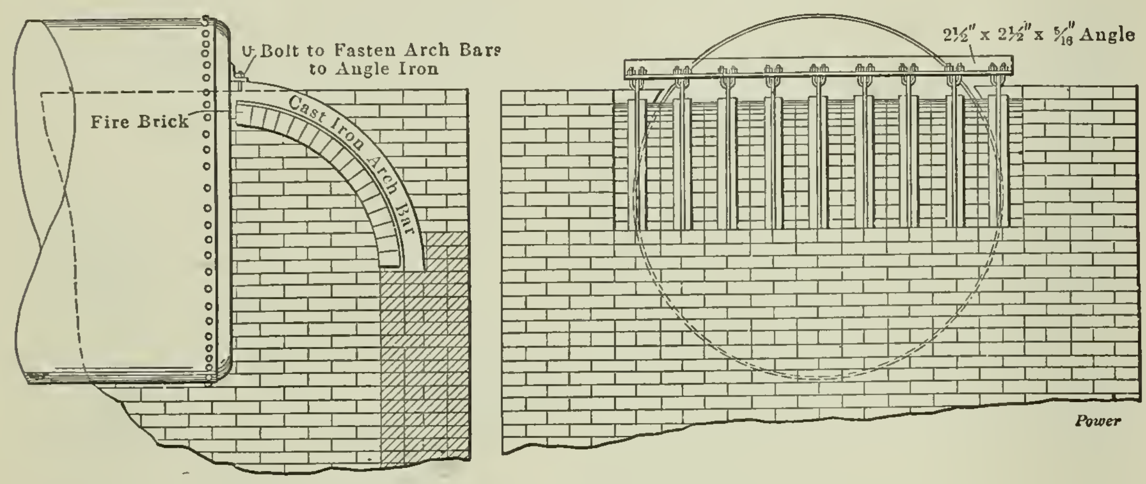

Fig. 5. Best Form of Covering for Rear Connection

Allowance for Expansion

An important point upon which depends the prevention of cracks in the walls of the setting, is the proper provision for expansion of the boiler. In supporting the boiler on lugs it is generally attempted to secure this feature, in part, by providing rollers under one pair of lugs (usually the rear lugs), as shown in Fig. 1. These rollers prevent a lengthwise thrust on the walls due to the expansion of the shell; but it is doubtful if they are of much real value because they do not provide for any movement across the setting. For instance, in a 72-inch by 16-foot boiler the longitudinal distance between the centers of the lugs is about 8 feet, while the distance between centers across the boiler is about 7 feet; hence, the movement across the setting that should be cared for is about as great as it is lengthwise, and the rollers do not aid the movement in this direction. The method of making allowance for expansion between the shell and setting is shown in Fig. 2, where a 1-inch space is left between them and the space filled with plastic asbestos or asbestos rope. The brickwork should not be allowed to touch the boiler at any point, and special care must be taken to keep it free from the rear supporting lugs, pockets usually being left in the walls for this purpose. Another point where clearance is of vital importance is around the pipe connections to the water column and the blowoff pipe, for, unless proper freedom is allowed at these points, there is danger of the pipes being broken off.

Back Connection Covering

This is one of the most difficult points about a boiler setting to keep tight. There are numerous methods of arranging the covering at this point, and one of the best ways to accomplish this, which is in common use in the West and South, is illustrated in Fig. 5. The usual arrangement of this form of covering is to have an angle-iron strap bolted to the boiler head, and the ends of the arch bars rest on the leg that extends outward; but owing to the fact that the angle is exposed to the direct heat of the gases it burns off in a short time. A better arrangement is to fasten the angle to the tops of the arch bars by means of U-bolts, so that they will all line up together. If desired the angle iron may be bolted to the boiler head, although this is not necessary. With this form of covering the arches follow the movement of the boiler head; and by covering the whole surface with plastic asbestos about 2½ inches thick, a tight job is insured. One of the desirable features of this form of covering for the back connection is that it presents a straight line across the head above the tubes, affording ample protection against overheating to the portion of the head above the water line, without interfering with the free passage of heated gases to any of the tubes.

Another method of closing in the back connection that is commonly used throughout the East, is illustrated in Fig. 6. In setting this type of arch, care must be used that the head above the water line is not exposed; and it is sometimes necessary to partially block off one or two of the outside tubes to accomplish this. In the arrangement of all types of covering for the back connection the fusible plug must be left uncovered so that it is freely exposed to the products of combustion.

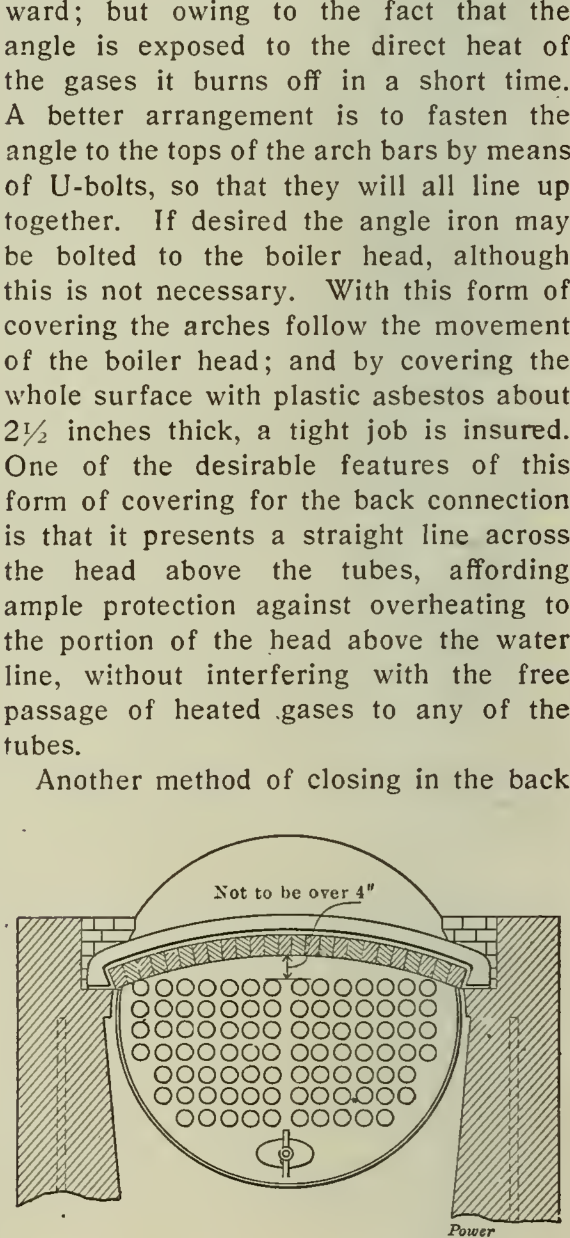

Fig. 6. Cross Arch for Covering Back Connection

Boilers Supported on Columns

Where boilers are hung from beams or channels supported on columns and more than one boiler is used, a column is often placed in the dividing wall between boilers; where this is the case too great care cannot be exercised to keep such columns from being overheated. In such cases there should be at least 13 inches of brickwork between the column and the fire and a 2-inch air space around the column, with free ventilation in this space. To accomplish this, air should be admitted near the bottom of the column through an open duct not less than 10 inches square. These requirements, where a column 8 inches in diameter is used, mean that the minimum wall thickness between the boilers at the grate level must be 38 inches.

Covering the Top of the Boiler

The best covering for the exposed surface on top of a boiler, and the one that will reduce the radiation losses to a minimum, is 85 per cent. magnesia from 2 to 3 inches thick, the outer layer being made with a hard finishing cement. A cheaper covering, but one that will resist wear better than the magnesia and still reduce the radiation losses to a low point, is made of asbestos, but it should be of good grade. The usual covering consists of a layer of bricks laid on edge; but such covering only has cheapness and durability to recommend it, as it is practically worthless as an insulator.

Cost of Setting

With common bricks at $9 per thousand and firebricks from $22 to $25 per thousand, mason's wages at 60 cents per hour and laborers at 30 cents per hour, a very accurate estimate of the cost of a boiler setting may be obtained by figuring $22 per thousand, laid, for the common brick and $45 per thousand, laid, for the firebrick. The cost, laid, will rarely exceed $25 and $50 per thousand for common and firebrick respectively.

Setting Water Columns

In setting a boiler attention should be given to the proper location of the water column; it should be placed so that the lowest gage cock is at least 3 inches above the tops of the tubes, and the lowest point of vision in the gage glass at least ½ inch above the tops of the tubes. The latter point is of great importance, for it is often a temptation for an engineer to take chances as long as he can see water in the glass, although he may realize that it is lower than safety demands and it is therefore best to prevent the water level from being seen after the lowest point for safety has been reached.

Starting Boilers

No matter how carefully a boiler setting has been built, it can be badly damaged and cracked, by carelessness in starting up. No setting which has just been completed should be operated in regular service without a thorough drying

Chimney at Queen Lane Filter Plant, Philadelphia

out, this drying is accomplished by keeping a slow fire under the boiler for at least a week, and longer if circumstances will permit. The interior of a new boiler should always be thoroughly cleaned of oil, dirt, etc., and the best way to accomplish this is to boil slowly with a strong solution of soda ash, and in this way the drying of the setting walls and the cleaning of the boiler can be accomplished simultaneously.

A Handsome Chimney

In these days when the high cost of living is a problem which baffles satisfactory solution, the industrial-plant proprietor is less than ever inclined to spend good hard cash to satisfy the artistic tastes of the members of the community where the plant is located. A chimney is bought for the amount of draft it will create and gases it will handle. The purchaser usually wants the most stack for the least money. Consequently, few chimneys are on view that have any work on them for purely ornamental purposes.

Occasionally, however, conditions may be such that the expenditure of money to produce ornamental effects in chimney and power-house design is justified. Such a set of conditions exists at the Queen Lane Filter Plant, Queen Lane and Fox street, Philadelphia. The accompanying figure is a view of the chimney at this plant. It is reputed to be the handsomest chimney in America. The plant is located in a high-class residential section of the city and any building or plant which would tend to detract from the desirability of the neighborhood would of course have a bad influence on the value of the surrounding property. For this reason it was found justifiable to go in for the esthetic in the matter of building ornamentation.

The chimney is 125 feet high and 6 feet in diameter inside. It serves six horizontal return-tubular boilers, the total rated capacity of which is 900 horsepower. The lower portion or base of the chimney is of granite and terra-cotta. The upper portion or shaft is constructed of radial brick, faced with pearl-gray blocks to match the terra-cotta ornaments of the cap and base. The round column or shaft of the chimney has a double entasis; that is, a double curvature, which is used to overcome the optical illusion which a straight shaft gives of being concaved. This is the design which was applied by the Greeks and Romans to the columns in their temples.

The general scheme of ornamentation is Italian Renaissance. The architect employed conventionalized water forms as motives of decoration, both on the chimney and the power house itself, as being indicative of the character and use of the structures. It will be noticed in the view that use is made of shells, cat tails, dolphin heads, star-fish, etc., cleverly placed as motives of decoration instead of the more commonplace garlands and flowers, etc.

In designing the ornamentation of the cap, it was necessary to give them very bold and vigorous relief, otherwise they would have been lost to view on account of the great hight; hence, the large medallions or disks, surmounted by the huge lion heads, which form so conspicuous a climax to a structure unique in the annals of chimney building.

The total cost of the chimney complete was $15,500. Under the existing circumstances it is undoubtedly true that the expenditure of this sum was justified. A radial-brick chimney of the same capacity for an industrial plant could be purchased complete for approximately $4000.

The chimney was designed by Architect William E. Groben, of Philadelphia, and erected by the M. W. Kellogg Company, contractors, New York City.

The Old Burden Water Wheel

Old overshot wheel built at Troy, N. Y., in 1851, said to be the largest in the world. It is 60 feet in diameter, 22 feet wide and at two revolutions per minute developed 600 horsepower.

One of the most interesting landmarks of Troy, N. Y., is the old Burden waterwheel. Its days of usefulness, however, are over and it is fast going to decay. The old mills for which it furnished power are in ruins and all that remains of the once busy industry are the toppled down walls, the old waterwheel and the iron penstock leading to it from a grass- and weed-covered canal. The new Burden iron works are located near the Hudson river and point to the march of progress in the steel industry; the old discarded mill indicates the primitive generation of power sixty years ago.

Henry Burden, the founder of the original Burden iron works, was the inventor of many appliances, but his greatest achievement was in designing the immense waterwheel, shown in Fig. 1, which was constructed in 1851. It is of the overshot type and was capable of developing 1200 horsepower. It is 60 feet in diameter and 22 feet wide and contains 36 buckets, each 6 feet deep. These are shown in Figs. 2 and 3.

Fig. 1. Old Burden Waterwheel Built in 1851

The axis is composed of six hollow cast-iron tubes keyed into flanges, from which diverge two hundred and sixty-four 2-inch iron rods terminating at the outer edge of the wheel.

The two axis flanges are made with bearing shafts 12 inches in diameter. The bearings in which these shafts rested are each supported by an iron frame which set on a brick foundation built between the two upright brick piers shown in Figs. 1 and 4.

Power was transmitted to jack shafts by means of small gears meshing into a toothed rim placed on the outer circumference and outside edges of the waterwheel as shown in Figs. 1 and 4. The jack shafts transmitted the power to the mill rolls by means of shaftings which extended from the flywheel and gears as shown at the left of Fig. 1.

The flow of water was governed by a rod and handwheel, the upper end of the extension rod supporting a worm which meshed with a gear, mounted on a shaft that extended from one side of the wheel to the other, on top of the flume, and supported by suitable bearings, as shown in Fig. 4.

By turning the handwheel and rod, the shaft and gear were revolved in the direction desired, and by means of gears and racks, the latter being attached to the stem of each gate in the flue, the gates were opened or shut. The water was thus regulated in flowing from the penstock to the four outlets over the buckets placed between the three metal distance pieces.

The water was brought to the wheel through an iron penstock, which extended out over the waterwheel, the water coming from the canal through the farther gate shown in Fig. 5. The second gate was for the purpose of emptying the canal.

This old waterwheel is said to be the largest in the world. When running at a speed of two revolutions a minute, between 500 and 600 horsepower was developed. A wheel of larger diameter was constructed at one time at Wales, but being of less width and depth of buckets developed less power.

Fig. 2. With the Buckets Full of Water the Wheel Revolved Toward the Foreground

The First Steam Cylinder Used in America

In a glass case in the National Museum at Washington is preserved the cylinder of the first steam engine ever run in America. The following extracts from a letter of the Hon. Joseph T. Bradley, Associate Justice of the Supreme Court of the United States, dated at Washington, September 20, 1875, to David M. Meeker, of Newark, N. J., into whose possession, we understand, the cylinder had come, contains pretty nearly all that is known in reference to this interesting relic:

"The steam engine of which this is a

portion of the cylinder was the first ever erected on this continent. It was imported from England in the year 1753 by Col. John Schuyler for the purpose of pumping the water from his copper mine opposite Belleville, near Newark, N. J. The mine was rich in ore, but had been worked as deep as hand or horse power could clear it of water.

"Colonel Schuyler having heard of the success with which steam engines—then called fire engines—were used in the mines of Cornwall, determined to have one in his mine, and accordingly requested his London correspondent to procure an engine and to send out with it an engineer capable of putting it up and in operation. This was done in the year named and Josiah Hornblower, a young man then in his twenty-fifth year, was sent out to superintend it.

"Mr. Hornblower's father, whose name was Joseph, had been engaged in the business of constructing engines in Cornwall from their first introduction in the mines there—about 1740—and had been an engineer and engine builder from the first use of steam engines in the art—about 1720.

"The engines constructed by him and his sons were the kind known as Newcomen engines, or Cornish engines. That brought to America by Josiah was of this construction. Watt had not then invented his separate condenser, nor the use of high pressure, but it is generally said that for pumping purposes the Cornish engine has still no superior.

"About 1790 the Cornish mine was worked for several years by Mr. Hornblower himself. The approach of the war in 1775 caused its operation to cease. Work was resumed, however, in 1792 and was carried on for several years by successive parties. It finally ceased altogether in this century and the old engine was broken up and the materials disposed of. The boiler, a large copper cylinder standing upright, 8 or 10 feet high and as large in diameter, with a flat bottom and dome-shaped top, was carried to Philadelphia. A portion of the cylinder was purchased by some person in Newark.

"In 1844 I met an old man named John Van Emburgh, then 100 years old, who had worked on the engine when it was in operation in 1792. He described it very minutely, and I doubt not accurately. It is from his description that I happen to know the kind of engine it was, although from the date of its construction and the use to which it was put there could have been little doubt upon the subject."

Fig. 4. Penstock and Arrangement of Gate Control

The pumps for drawing water from the lake at Chicago to dilute the sewage of the city are to be operated by electric motors. Recently, one of the triple-expansion vertical engines was replaced by a 750-horsepower motor. This motor, though but a small machine compared to the steam engine, has the same pumping capacity, namely, 40,000 cubic feet per minute. It is operated with current supplied by the hydroelectric transmission system of the sanitary district.

Gravity Turbine Oiling System

By Hugh Hughes

Description of the design and operation of a gravity oiling system for a vertical turbine. Bypasses are extensively used so as to secure flexibility of feed and continuity of operation.

Much has been written about engine-oiling systems, and much may be written on turbine-oiling systems. The simplest form of the latter is the gravity feed which in all respects resembles that employed for engines. Its possibilities, however, when applied to turbines are not fully appreciated. By arranging a few bypasses, with valves properly placed, almost any combination of feed may be obtained. Referring to the left half of the accompanying figure, *A* is the lower receiving tank; *B* the suction to oil pumps; *C* the discharge to the upper receiving tank *D*; *E* the feed to the reservoir *F*; *G* are sight feeds on the line *H* to top bearing and the line *J* to middle bearing; *K* and *L* are the returns from the top and middle bearings respectively. The greatest head of oil that that can be brought upon the upper bearing with this system is about 3 feet. If the bearing has no tendency to heat, this is quite sufficient; but it costs but very little more to pipe in the bypass *M*, by means of which the direct pressure of upper tank *D* may be brought on this bearing. The connection *N* is a bypass that will bring this pressure on the middle bearing also. If still more pressure is required, the oil pump may be made to discharge directly into the feed line through the bypass *O*.

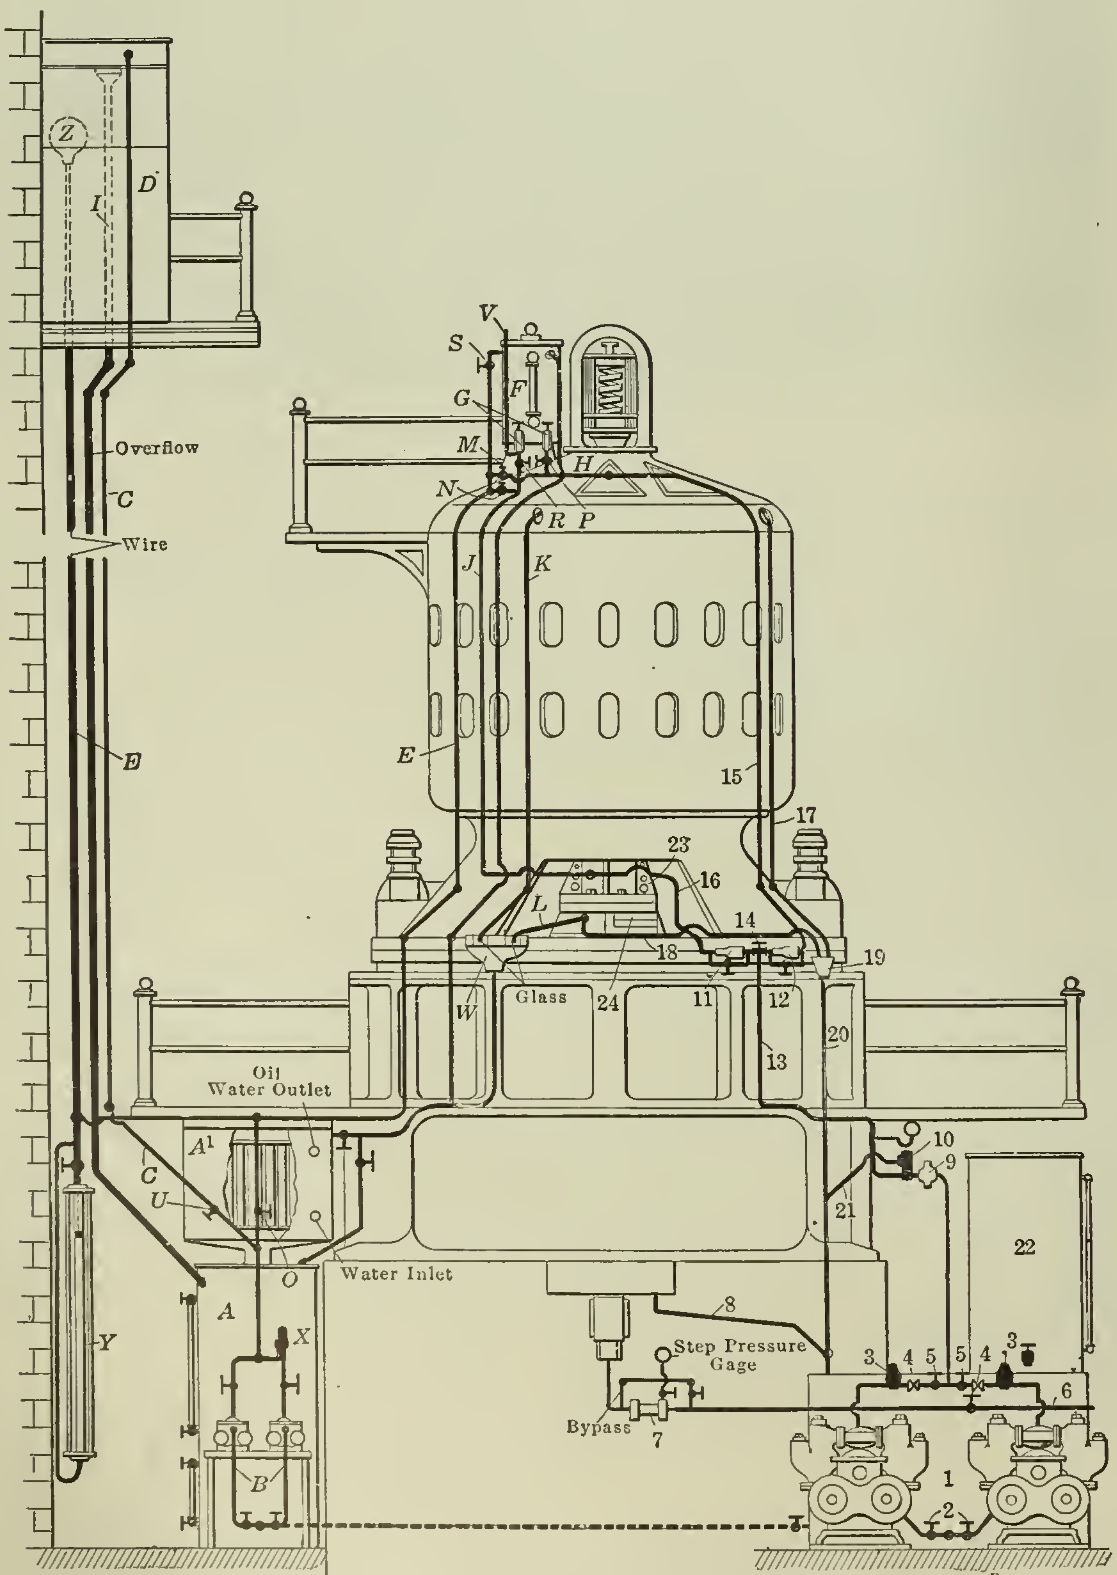

Fig. 1. Gravity Turbine-oiling System

In practice, the bypasses would be employed somewhat as follows:

To feed more oil to the top bearing, close the valve *P* and open valve *M*; to middle bearing, close the valve *R* and open *N*; to both bearings, simultaneously close the valves *P*, *R* and *S* and open *M* and *N*. If, for any reason, the upper tank *D* and the reservoir *F* are allowed to run dry, open the valve *O* and close *U*, and pump directly into the feed line, for it will take some time for the oil to reach the reservoir if allowed to follow its usual course, especially if air enters the pipe. In this dilemma, if the bypass *O* is not included in the system, draw a bucketful of oil from the tank *A*, or any other source, and empty it into the reservoir *F*; keep doing this until oil in sufficient volume is delivered to it from the top tank *D*.

Some believe that better lubrication is obtained by piping an air vent below the sight feeds as shown at *V*. Others, in cases where the flow of oil is subject to frequent stoppages, prefer to keep the reservoir *F* for emergencies only, the oil being led to a tee above the sight feeds and the reservoir outlet closed by a valve which is opened only when the regular feed stops. The returns from the bearings should be piped separately, and at some point should be open, so that the amount of oil passing through each bearing can be seen and its temperature ascertained. Some have the two returns discharge into a funnel open to the atmosphere as shown at 19. If the engine room is dusty, especially if it is subject to coal dust, it is better to have the returns discharge through oil-cup glasses with tin or brass covers as shown at *W*. It is good practice where the pump discharge is piped directly to the feed line, as through the bypass *O*, to mount a small relief valve as shown at *X*. Very often it is the case that the oil line in the glass gage of the upper tank cannot be seen from the floor below. An arrangement for indicating the quantity of oil in the tank is shown at *Y*. This is simply a glass tube piped to a continuation of the downward feed pipe. The ball *Z* floats on the surface of the oil in the tank *D*, and is guided by a short length of quarter-inch tubing. To the end of this is attached a straight piece of light wire of a length sufficient to reach the glass gage *Y*. Any dark object pendant at the end of the wire is very easily distinguished if the glass is filled with clear water. The internal piece I of the overflow pipe from tank D is screwed hand tight only, so that it can easily be removed when it becomes necessary to drain the tank. It will be noticed that the oil pumps are shown with the oil ends outward. This way of installing is preferable to the universal practice of side exposing, for one pump is as accessible for repairs as the other. With

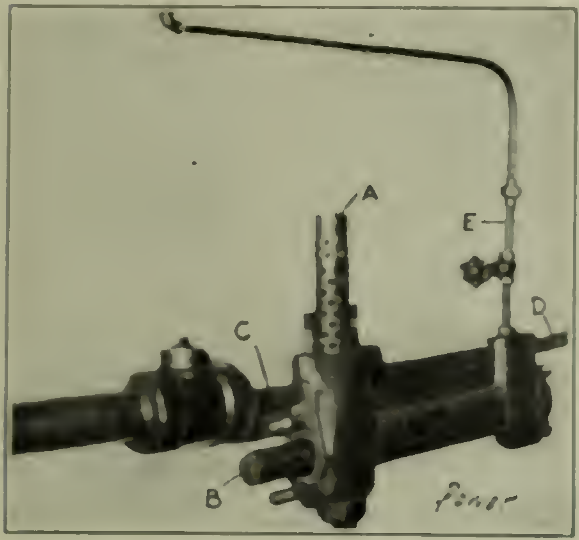

Fig. 2. The Baffler

the other arrangement, if repairs are needed to the inside pump, one must lean over the outside pump, which may be in service, and the repair man is lucky to escape without burns.

In many turbine plants oil coolers are now being installed, so that the oil is used not only to lubricate a bearing but also to cool it by carrying away the heat generated. One form of cooler is shown at A'. The water is obtained by tapping the discharge of the circulating pump. Cooling the oil condenses the vapor it may contain, which falls to the bottom of the receiving tank A. This tank should therefore be equipped with two separate sight glasses as shown, to establish clearly the true quantity of water present. When only one long glass is used the water at the bottom will be forced up in it, by the weight of the accumulating oil. I have seen a barrel of oil turned into the sewer by an attendant, who mistook the water level in the glass as indicating the water level in the tank. So far, it has been assumed that the step bearing is subject to hydraulic pressure. When oil is the balancing medium employed, it is good practice to use the same system of oiling the upper bearings as described above. The only change necessary is to substitute the larger storage tank 1 for the receiving tank A. The course of the oil to the step bearing would be from storage tank 1 through suction valves 2 to the step-bearing pump; thence under relief valve 3 through the check valve 4 and the stop valve 5 to the accumulator 6 and the baffler 7.

The oil returns from the step and guide bearings to the storage tank through the pipe 8. Valves 3, 4 and 5 are shown elevated in the figure merely to obtain space to map them. In some plants oil for the upper bearings is taken directly from the step-bearing pumps discharge, the pressure being lowered by the reducing valve 9. Tanks A and D and the pair of small oil pumps on the left-hand side are now done away with. If the top reservoir F is retained, the gravity feed is again restored on the two upper bearings; if it be removed and the feed led directly to the bearings then the relief valve 10, and the two bafflers 11 and 12, one on each feed branch, should be installed. The course of the oil now is: From the step-bearing pumps discharge through the pipe 13, to the cross valve 14, where it divides and enters the baffler 12 and the pipe 15 for the top bearing, and the baffler 11 and pipe 16 for the middle bearing. The returns 17 and 18, from the top and middle bearings respectively, enter the funnel 19, from which to the storage tank they have pipe 20 in common. The relief-valve discharge is at 21.

With such a system it is in line with good practice to have a reserve tank 22 to be used for sudden emergencies or to replenish storage tank automatically. In some plants where the turbine is run continually, and much vapor is present in the oil, the storage tank is in duplicate and each is used alternately, thus allowing time for the oil to cool and the water to settle and be drawn out from one while the other is in service. The storage tank should be placed at as great a distance below the step bearing as it is possible in order to allow for some head for the oil return. Some oil step bearings are provided with a small pipe open to the atmosphere and entering the space between the oil and the carbon packing to facilitate the flow of the return oil and prevent its intermixture with the condensed steam used to seal the vacuum. This can also be somewhat aided and air prevented from entering the return by piping it on the principle of an ejector to the common return 20 as shown in the figure. The down-flowing oil in this pipe, if the connections are properly made, will have a tendency to siphon out the waste oil from the guide bearing.

Fig. 2 shows an adjustable baffler. A is the strainer, B the baffler screw, C is the oil inlet and D the oil outlet; E is a pressure-gage connection. At the other end of the baffler screw B is an adjusting screw the head of which, when the baffler is in place, rests against the cover on the outlet side of the baffler chamber. The more this bolt is backed out of the baffler screw, the more will the oil pressure be reduced. If manipulation of this screw does not give the desired flow of oil a piece may be sawed off the end of the baffler, or one having a coarser thread may be substituted. As a rule, the baffler is designed to reduce the pressure about 25 per cent., though this depends materially on the viscosity of the oil. Altogether it is an ingenious contrivance for causing trouble if not regularly inspected.

Most readers have seen in Power sectional cuts of the upper and lower bearings of a Curtis turbine, and some have conceived the idea that they are very complicated affairs. Fig. 3 shows these members for a 2000-kilowatt turbine when stripped of all supports. A drip pan, which is generally bolted to the bearing support, and an oil deflector cast on the turbine shaft to throw the waste oil by centrifugal force into the drip pan would about complete the bearing. The part A is the top bearing, which fits tightly into the top bracket of the turbine. The governor and governor hood must be removed to get at it. Oil enters the bearing through the small holes B and leaves around the bottom or by the row of upper holes C. The parts D are the two halves of the middle bearing, which are locked together by an outer shell, also in halves and bolted together. These locking bolts are to be seen at 23 in Fig. 1, while 24 is the drip pan mentioned. The part E, Fig. 3, is the shaft lining.

A description of the newer styles of bearings will be found in back numbers of Power. If a bearing has a tendency to throw oil into the generator fields, or if steam escapes from around the high-pressure carbon packing and commingles with the oil in the drip pan of the middle bearing, felt washers held gently against the shaft by sheet-iron straps should be secured to the bottom of the oil pans or top of the bearing brackets. In some places

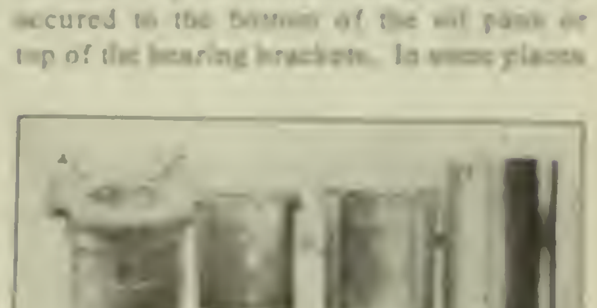

Fig. 3. Parts of Upper and Lower Bearings

a practice is made of oiling the high-pressure carbon rings upon starting the turbine. An oil cup, secured to a pipe which ends as close as possible to the shaft, is filled with freshly mixed graphite and cylinder oil. While the turbine is slowly revolving and more or less air is being drawn in around the carbon bearing, the mixture is let out of the cup. Oil feed, however, must be used sparingly as it is liable to gum the carbon packing rings and cause them to stick in their receptacles.

Modern Steam Superheaters

By Warren O. Rogers

A general description of the few successful types of American superheater, dealing with their features of design and application to various types of boiler, flooding and control of the furnace gases passing over the members.

Less than ten years ago hundreds of engineers held the opinion that, although the water consumption of a steam engine would be reduced by superheating the steam, the extra fuel required would offset the saving in the water consumption. But when the facts are fully considered there can be no doubt in the minds of those who have taken the trouble to inform themselves that, with a properly designed plant, the superheater will add to the economy.

In 1860, when the question of superheating was first taken up, the pressure carried in steam boilers ranged from 25

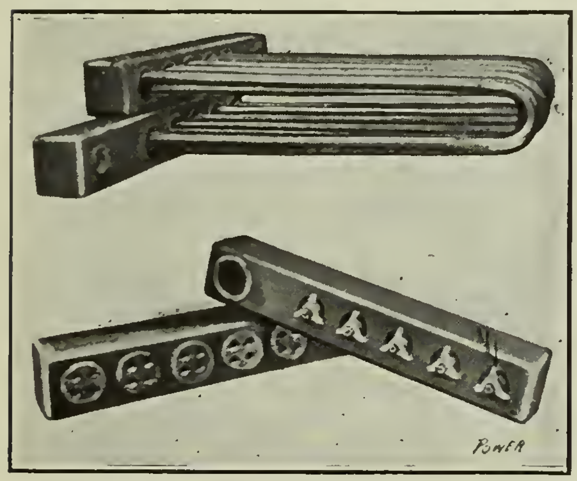

Fig. 1. Header and Tubes of Parker Superheater

to 50 pounds per square inch. With these low pressures tallow was found to answer very well for cylinder lubrication, but the use of superheated steam brought trouble to the engineer, because the high temperature of the steam dried up and decomposed this animal oil.

About this time, however, engine builders began building compound engines which demanded higher boiler pressures, and as this demand was met, the desirability of superheating the steam decreased. Furthermore, this increase in steam pressure made the use of superheated steam all the more difficult. For this reason superheating was practically abandoned for a period of thirty years.

About 1890 superheating was taken up by engineers in European countries, and was carried on successfully, especially by the Germans. The problem was solved by using a high-grade mineral oil for lubricating purposes, together with valves and cylinders of suitable design. The demand for superheated steam brought out the superheater, of which there are several types made in this country that give very satisfactory results.

There has been, and still is, a difference of opinion as to how high steam should be superheated. A common range

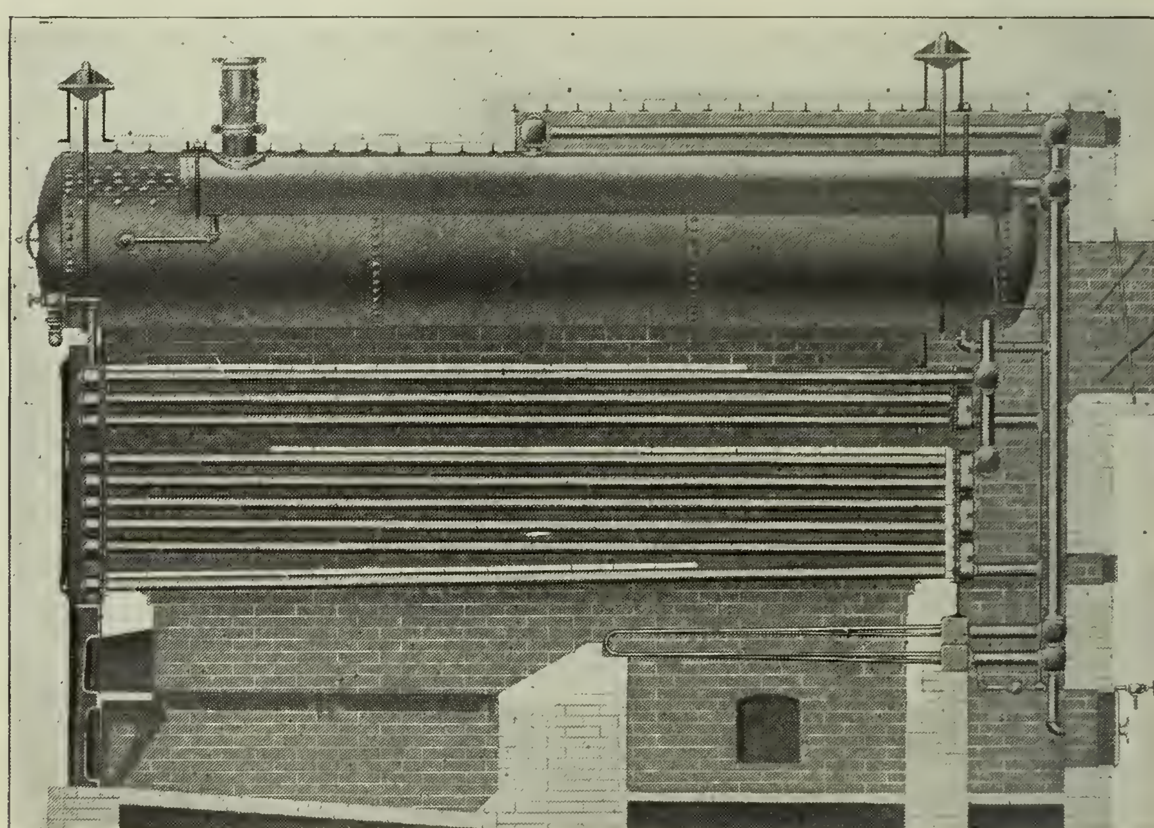

Fig. 2. Parker Superheater as Applied to a Parker Down-draft Boiler

is from 100 to 200 degrees of superheat, and 150 degrees is considered a maximum figure by many engineers.

A common objection to using superheated steam is that it has been the cause of many ills which are not encountered when using saturated steam. Packing troubles, however, have been practically eliminated; lubrication of the valves and piston can be satisfactorily maintained, and troubles from failure of pipes and fittings are being greatly reduced. As to the superheater itself, one company that has made superheaters for fifteen years has never been called upon to make a single repair due to damage from excessive temperatures.

A superheater contained within the boiler setting is perhaps the most efficient type when the steam is not to be superheated more than 200 degrees. Such superheaters require no additional space in the boiler room, unless it is an in-

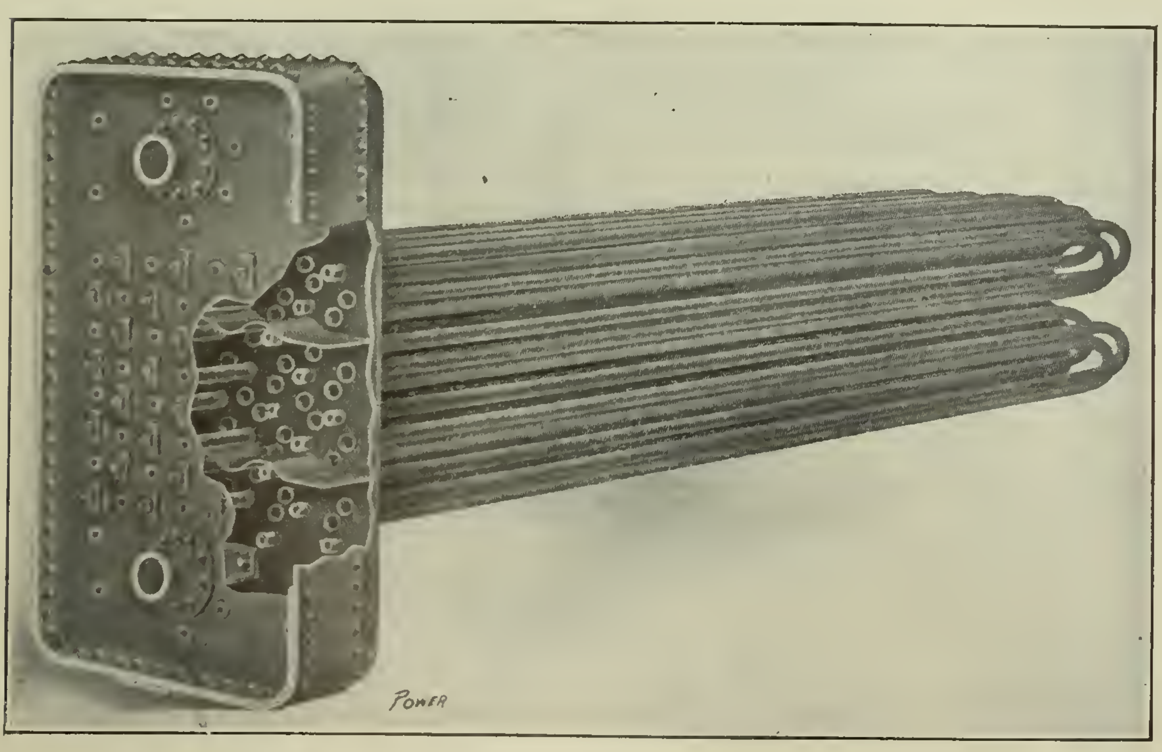

Fig. 3. Details of Tube and Header Construction in Heine Superheater

creased hight in the boiler setting, and the amount of piping required is very small. A superheater so arranged is, however, subject to the fluctuating temperatures of the furnace, for, if the boiler is forced, the superheater is correspondingly affected by the increased temperature of the furnace gases. It is also subjected to the cooling effects of air admitted through the fire doors, which naturally cools the gases passing to the uptake.

Cast iron, which was at one time largely used in the construction of superheaters, is gradually being replaced by stronger metals, especially where high steam pressures are concerned. At best it is a treacherous metal when subjected to temperature changes, and cannot compare to point of safety with forged steel, cast steel and drawn-steel sections.

In this article several types of superheaters will be taken up and attention given to their principles of design, methods of attaching to the boiler, flooding, and their general characteristics.

Fig. 4. Heine Boiler and Superheater

Parker Superheater

This superheater, which is used in connection with the Parker down-flow boiler, consists of a number of seamless drawn-steel tubes of small diameter, the number and length being proportioned to the degree of superheat desired. The tubes are bent into U forms and are expanded into steel headers. The general design of the headers and U tubes is shown in Fig. 3; front and back views of the headers are also shown.

An unique feature of this superheater is the use of the superheater drum or separator between the superheater and the steam nozzle. This prevents carrying the flooding water into the steam line, and saves the heat that would be wasted by draining the superheater.

Connection is made from the lower head of the superheater to the steam space of the steam drum of the boiler by a tube expanded into malleable-iron fittings. The top superheater header is connected to the steel superheater drum in a similar manner. At the end of the drum farthest from the superheated-steam inlet is the steam outlet from which connection to the steam main is made. This drum, which is shown in Fig. 2, acts as a separator, and has sufficient capacity to handle all of the water discharged from the superheater and connections when getting up steam in a cold boiler, or when putting a banked boiler on the line, the circulating water being returned directly to the superheater from the drum. The superheater is fitted with a drain connection for returning all excess water to the boiler drum. Thus the superheater automatically floods itself with the water of condensation when the fires are banked and requires no special attention in this regard.

Fig. 2 shows the general appearance and arrangement of this type of superheater. It is placed near the fire and thus requires only a small amount of heating surface.

All of the hot gases from the burning fuel must pass to the rear of the boiler before passing up among the boiler tubes, owing to the baffle wall placed on the upper side of the lower row of tubes for the greater portion of their lengths. This brings the superheater practically in the direct path of the heated gases.

The superheater is located near the bottom row of boiler tubes where more

Fig. 5. Sectional View, Showing Path of Gases

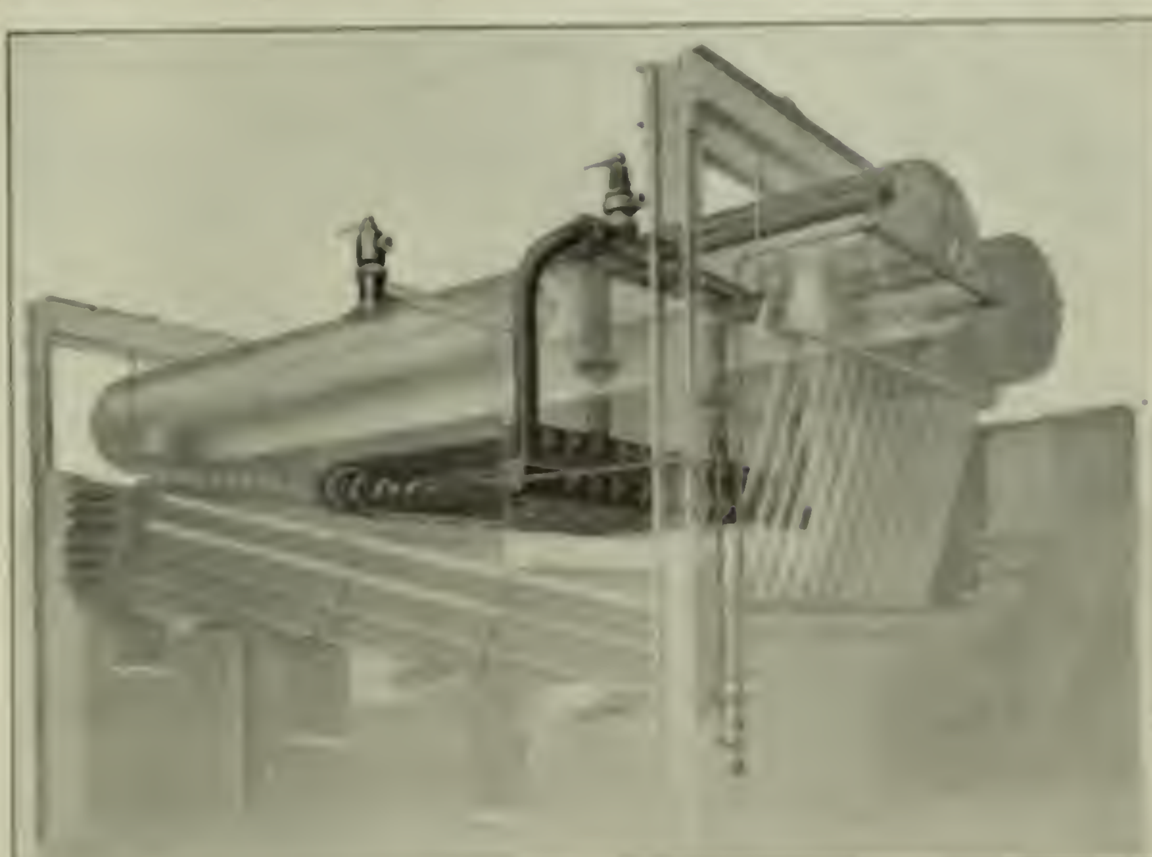

Fig. 6. Phantom View of Babcock & Wilcox Superheater Attached to a Boiler of the Same Make

of the steam is generated, and any change in the condition of the fire affects the boiler and superheater simultaneously, maintaining a remarkably uniform degree

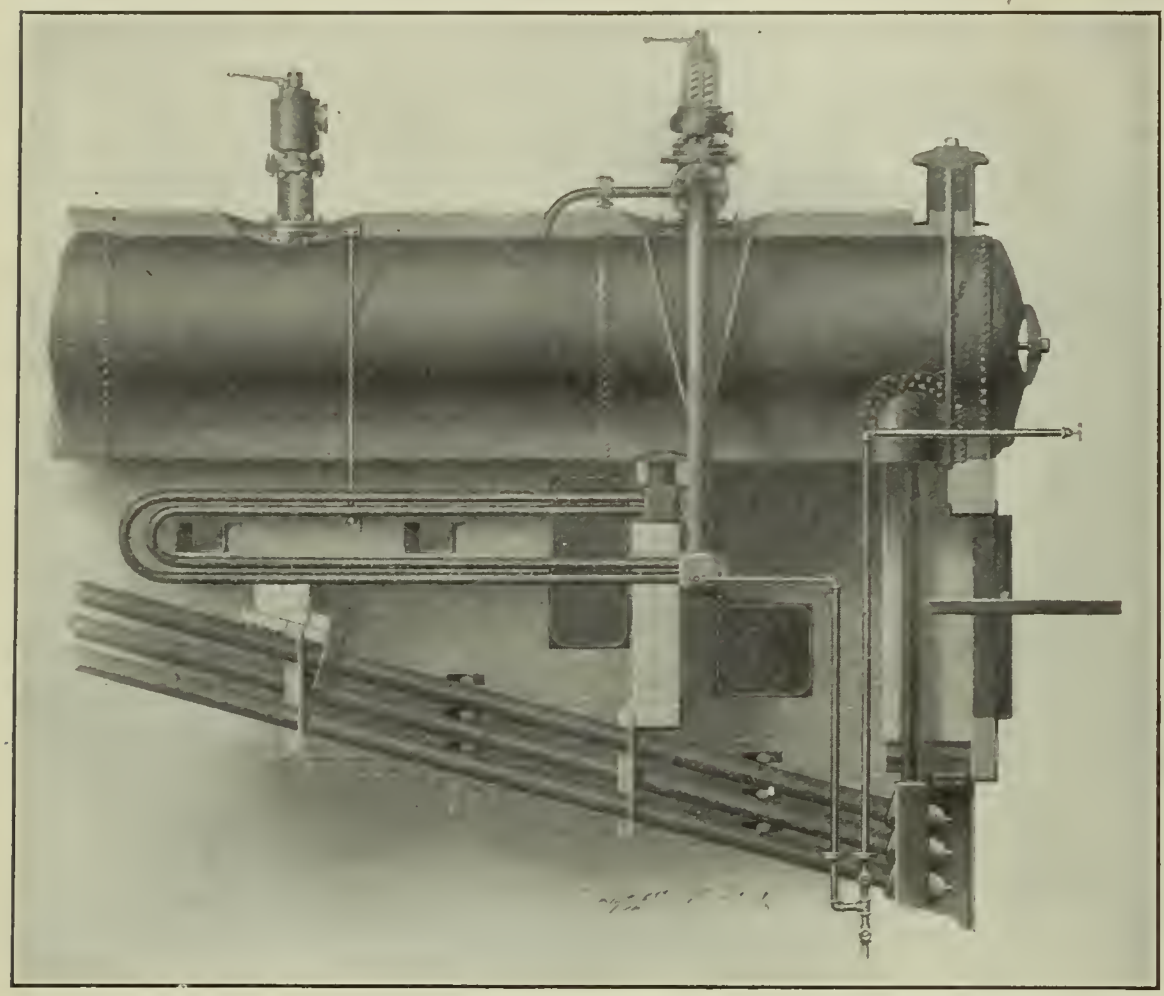

Fig. 7. Showing Position of Headers and Flooding Arrangement

of superheat. Another advantage of this location is that the size of the boiler setting is not increased, and there are no losses due to radiation and air leakage.

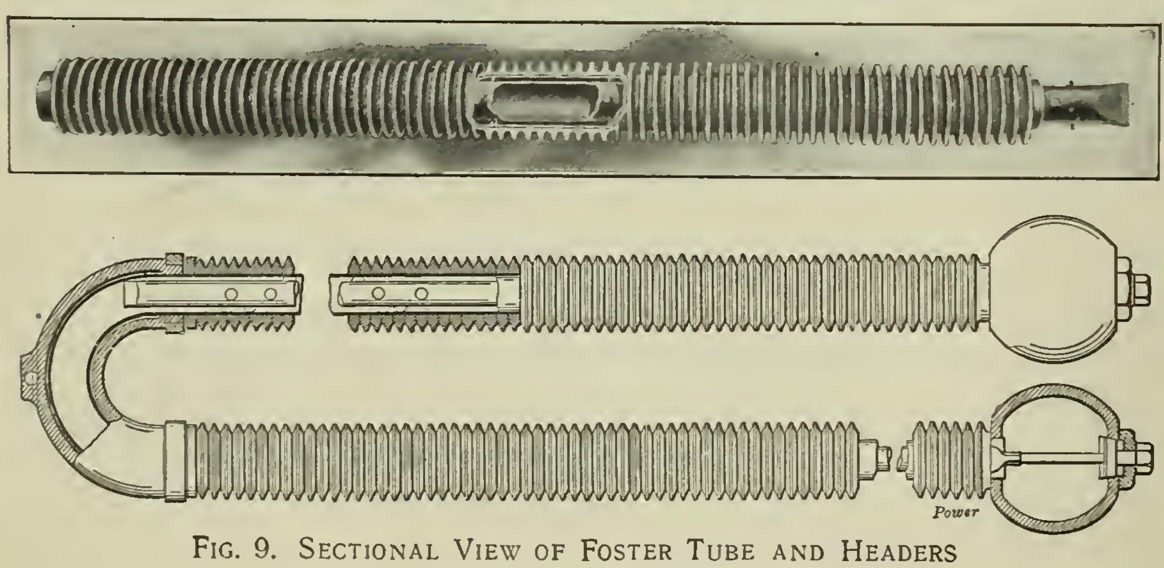

Fig. 9. Sectional View of Foster Tube and Headers

By placing the superheater in the path of the hottest gases passing from the furnace their temperature is reduced, and this results in cooler gases passing to the economizer and up the stack. If the superheater were placed in the flue it would not reduce the temperature of the gases so much on account of the smaller difference between the temperature of the steam and the escaping gases. One of the reasons for the uniformity of superheat in this superheater is that the steam and water of the Parker boiler are separated by a diaphragm and the boiler never primes.

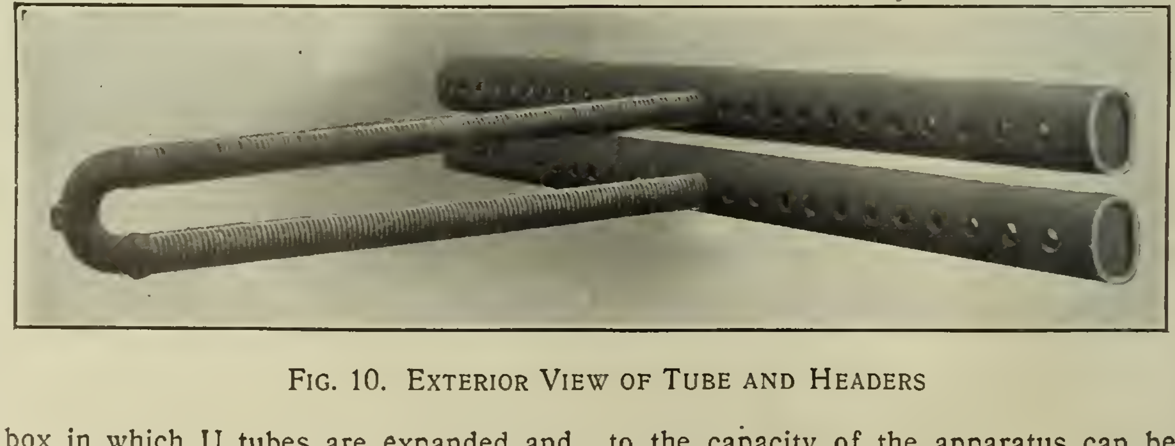

Fig. 10. Exterior View of Tube and Headers

Heine Superheater

Although the members of a superheater may be similar in construction, a difference is found in the design of the header. This is particularly noticeable in the Heine superheater, made by the Heine Safety Boiler Company.

This superheater consists of a header box in which U tubes are expanded and the flat sides of the header are strengthened by staybolts. The interior of the header box is divided into three compartments by means of sheet-iron diaphragms, as shown in Fig. 3. These diaphragms cause the steam to change its direction of travel four times in passing through the U tubes before entering the steam pipe leading to the main steam header.

This type of superheater and method of setting is shown in Fig. 4. It is located at the side of the boiler drum toward the front, and just above the last

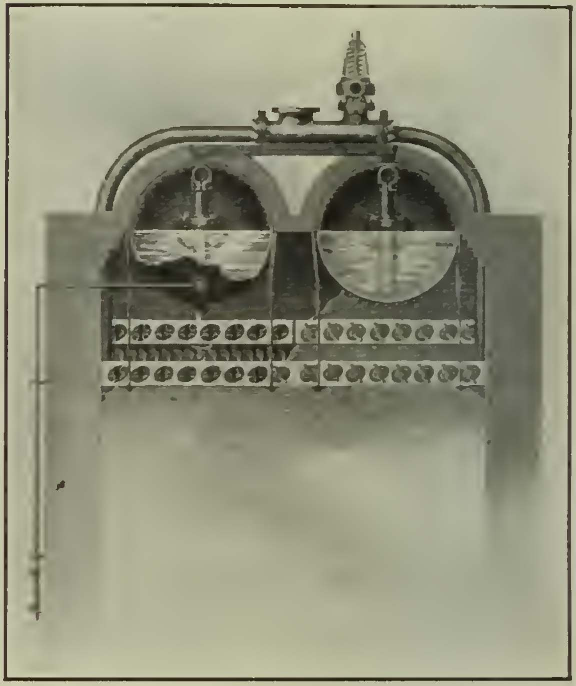

Fig. 8. End View of Manifolds in Brickwork

passage of the boiler gases. It is incased in brickwork which is lined with firebrick on the roof.

In order that the hot gases may be carried direct from the furnace to the superheater a small flue is built in the side wall of the boiler setting. In this flue the hot gases make two passes around the superheater tubes, as shown in Fig. 5. The flow of gases is controlled by a damper placed at the outlet end of the flue. When the damper is closed the circulation of the hot gases is stopped and when the heat from the gases in the flue in which the superheated is located, has been absorbed, saturated steam only is delivered to the steam main. Owing to this method of controlling the hot gases, various degrees of superheat up to the capacity of the apparatus can be obtained.

The saturated steam-outlet connection

from the boiler is made to the lower end of the superheater box, and the steam, after passing through the tubes, goes to the main steam header.

Owing to the location of the superheater above the boiler, and having no connection to it below the water line, the tubes are never flooded, nor is it necessary, on account of the complete control of the gases by the damper, which is easily operated by thermostatic control.

FIG. 12. HEADERS AND PLUGS

The exterior surfaces of the superheater tubes are smooth and such accumulations of soot as stick to them do not seriously interfere with the transmission of heat, as provision has been made by which the soot is removed by means of a blower introduced through the hollow staybolts passing from one header plate to the other. By this means the tubes of the superheater are cleaned without interfering with its operation or that of the boiler.

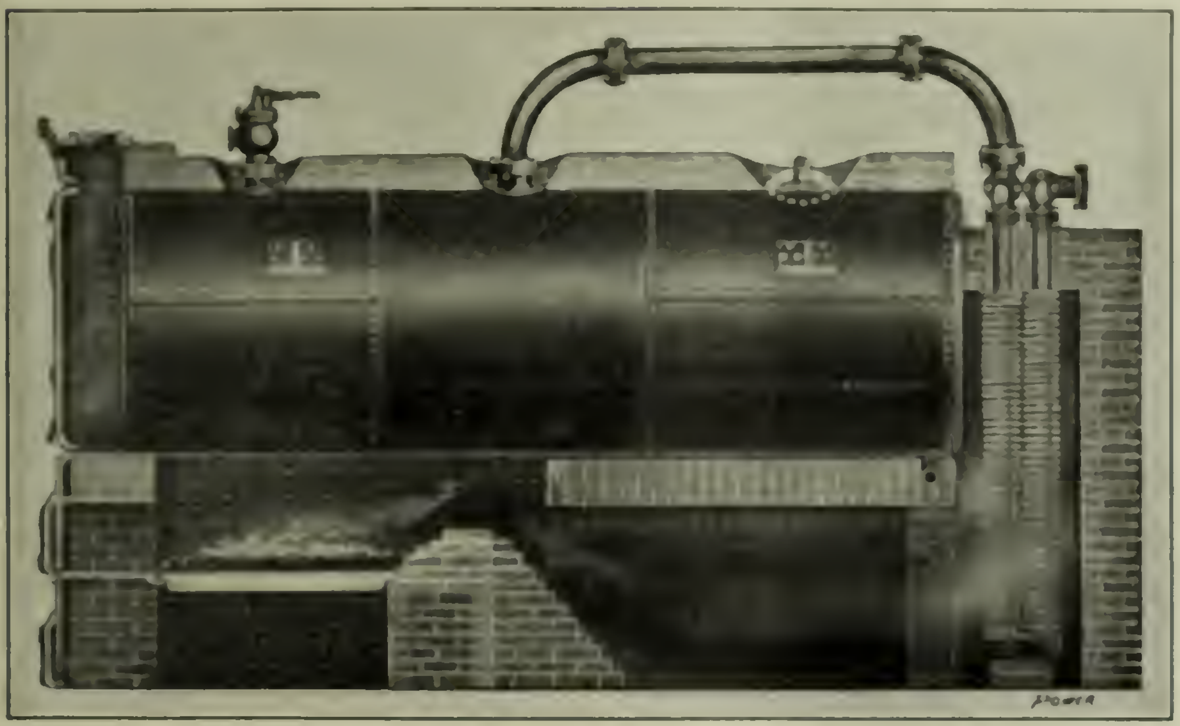

FIG. 13. FOSTER SUPERHEATER IN REAR COMBUSTION CHAMBER OF RETURN-TUBULAR BOILER

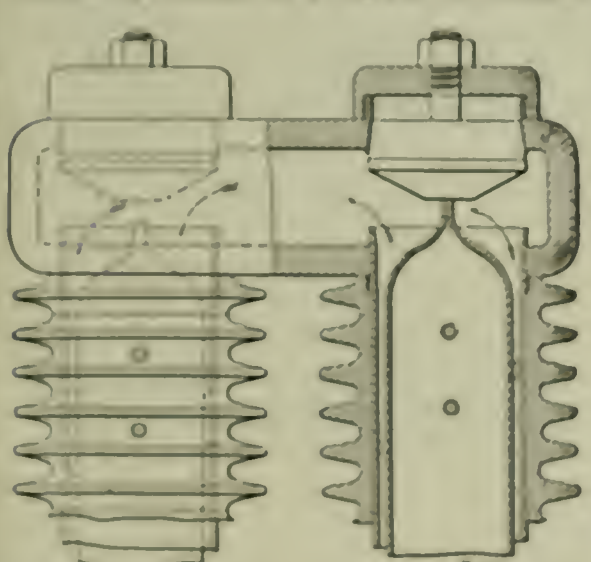

FIG. 11. SECTIONAL VIEW THROUGH RETURN HEADER

BABCOCK & WILCOX SUPERHEATER

A design of superheater that has found favor, and is extensively used, is the type made by the Babcock & Wilcox Company. It is made entirely of wrought steel and is so constructed that no joints are in the direct current of the hot gases. The superheater is made up of 2-inch No. 8 gage seamless steel tubes bent to a U form, and of square headers or manifolds of forged steel, into which the tube ends are expanded. The tubes are arranged in clusters of four, and an oval handhole opening is made in each header opposite each cluster of tube ends. A finished seat is formed on the inside of the header around each handhole, and a wrought-steel handhole cap having a fixed stud with a threaded end, is used for closing each opening; the joint is made tight by a gasket. The stud of the cap passes through a forged-steel guard, and a wrought-steel nut secures the cap in place against the gasket on the inside of the header. No cast-iron parts or screwed joints are employed in the construction of this superheater.

When used in connection with the Babcock & Wilcox boiler, the superheater is placed in the triangular space below the steam and water drums and above the inclined tubes, as shown in Figs. 6 and 7. It is supported independently of the brickwork by hangers from the drums of the boiler, in a position where it is accessible for inspection and does not in any way interfere with the cleaning or repairing of the boiler.

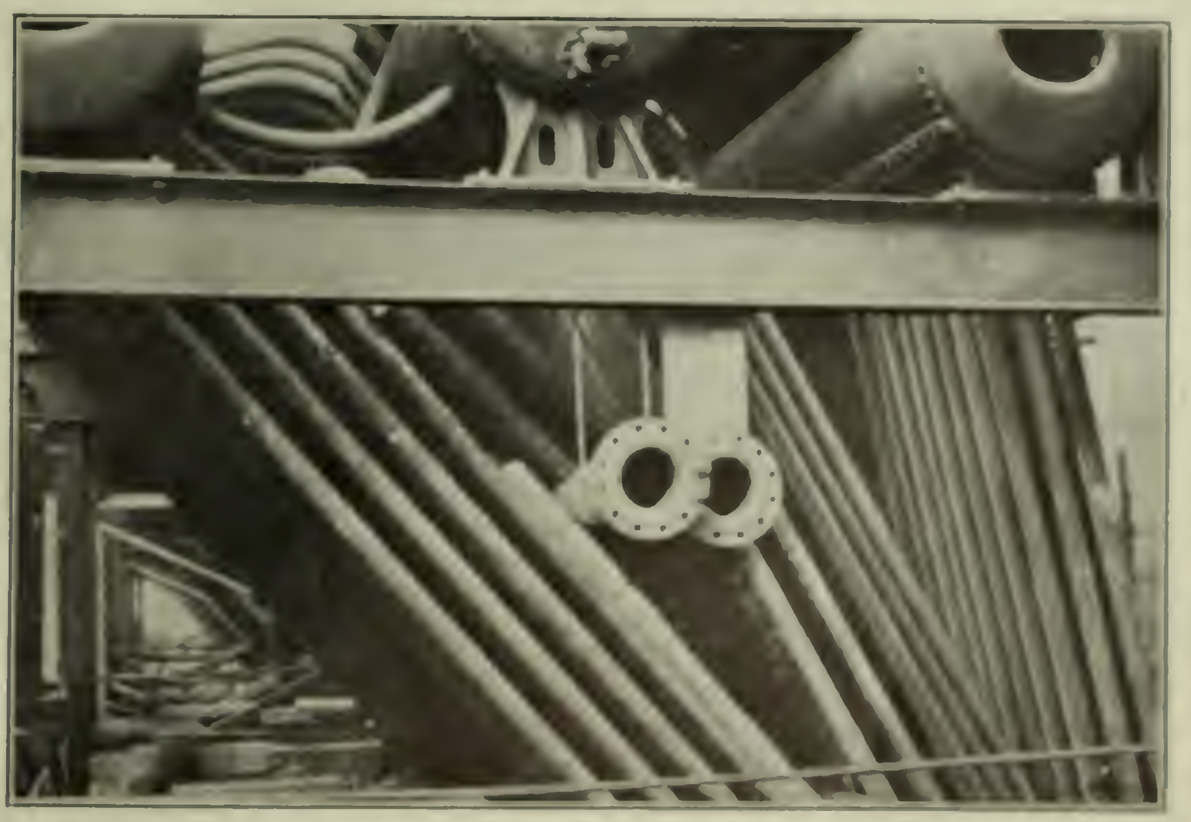

FIG. 14. SUPERHEATER ATTACHED TO STIRLING BOILER

Both manifolds are built into the brickwork of the hanging bridgewall over the second set of baffles, as shown in Fig. 8. The tube ends and handholes are thus protected, while the space back of the hanging bridgewall affords access to all handhole fittings. If necessary, the tubes can be rerolled or replaced with no more trouble than would be experienced in a like operation on the boiler. The U form of the tubes and the fact that the expanded joints are out of the path of the hot gases insure against stresses tending to cause leaky joints. As a consequence, the necessity for rerolling a superheater tube is of very rare occurrence.

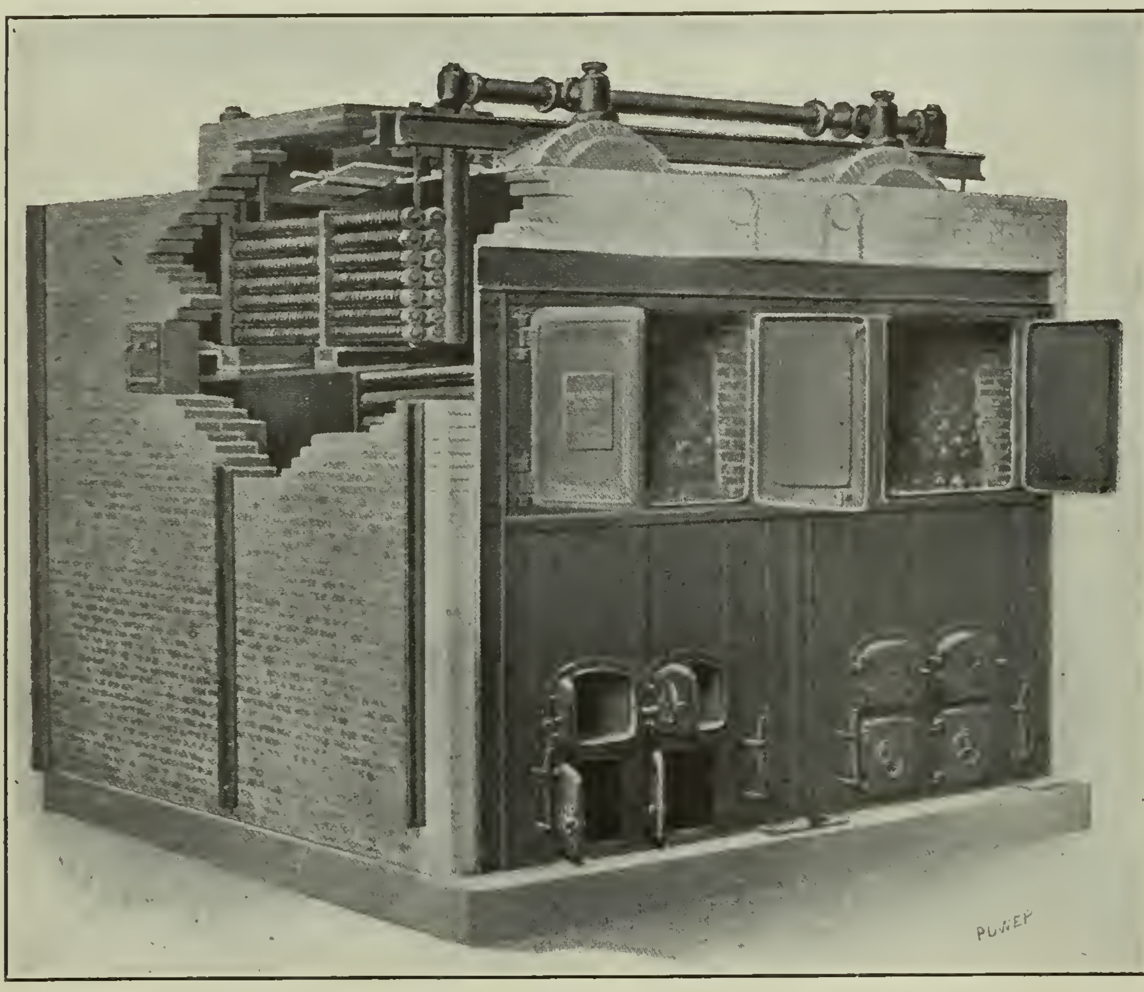

Fig. 15. Franklin Boiler and Foster Superheater

The upper box or manifold is connected to the steam space of each drum by a steel pipe passing through the bottom of the drum and fixed in position by an expanded joint in the superheater header and by a pad riveted to the drum. Outlet pipes are attached to the lower superheater header and, passing around the steam and water drums are connected over the top of the boiler by a heavy flanged fitting to the main steam outlet.

In addition to the safety valves connecting directly to the boiler drums, a special steel-body safety valve, made to withstand the action of the superheated steam, is connected to the outlet fitting. In order to give access to each expanded joint of the connecting pipes, circular handhole openings, closed by inside caps, are placed in the superheater headers. This superheater is supplied with external flooding pipes connected at one end to the rear head of a steam and water drum below the water line and to the end of the bottom superheater header, Fig. 7. These pipes are arranged so that the superheaters may be drained before cutting the boiler into the steam line. In operation, the steam is taken from the steam space in the boiler drum through dry pipes and enters the superheater through the inlet pipes. The steam is uniformly distributed through the upper manifolds and passes through the tubes to the lower manifolds. The superheater safety valve on the outlet fitting is set to open before the safety valves on the boiler drums so that when the load is suddenly thrown off the boiler the superheated safety valve opens and causes a flow of steam through the superheater until the fires can be checked, thus preventing excess superheat. By means of the external flooding piping the superheater can be flooded when steam is being raised on the boiler, thus protecting it from any possible overheating during this period.

Owing to the position the superheater occupies in the setting an even flow of heated gases over the heating surface is insured, and at the same time the area of the gas passage is not reduced so as to affect the operation of the boiler. As the external surfaces consist only of smooth, seamless tubes, there are no recesses in which ashes and soot may collect to any considerable extent, and at any time the tubes can be thoroughly cleaned with a steam jet from a lance passed through the dusting doors in the side walls of the setting.

The entire heating surface of the front pass of the boiler is between the superheater and the furnace, and wide variations of temperature are avoided in the chamber in which the superheater is located, such fluctuations of superheat that do occur being relatively unimportant.

Foster Superheater

At least four attributes should be incorporated in the design of a superheater. These are freedom from liability to burn, proper distribution of steam circulation, accessibility for inspection, both internally and externally, and provision for freedom of expansion and contraction.

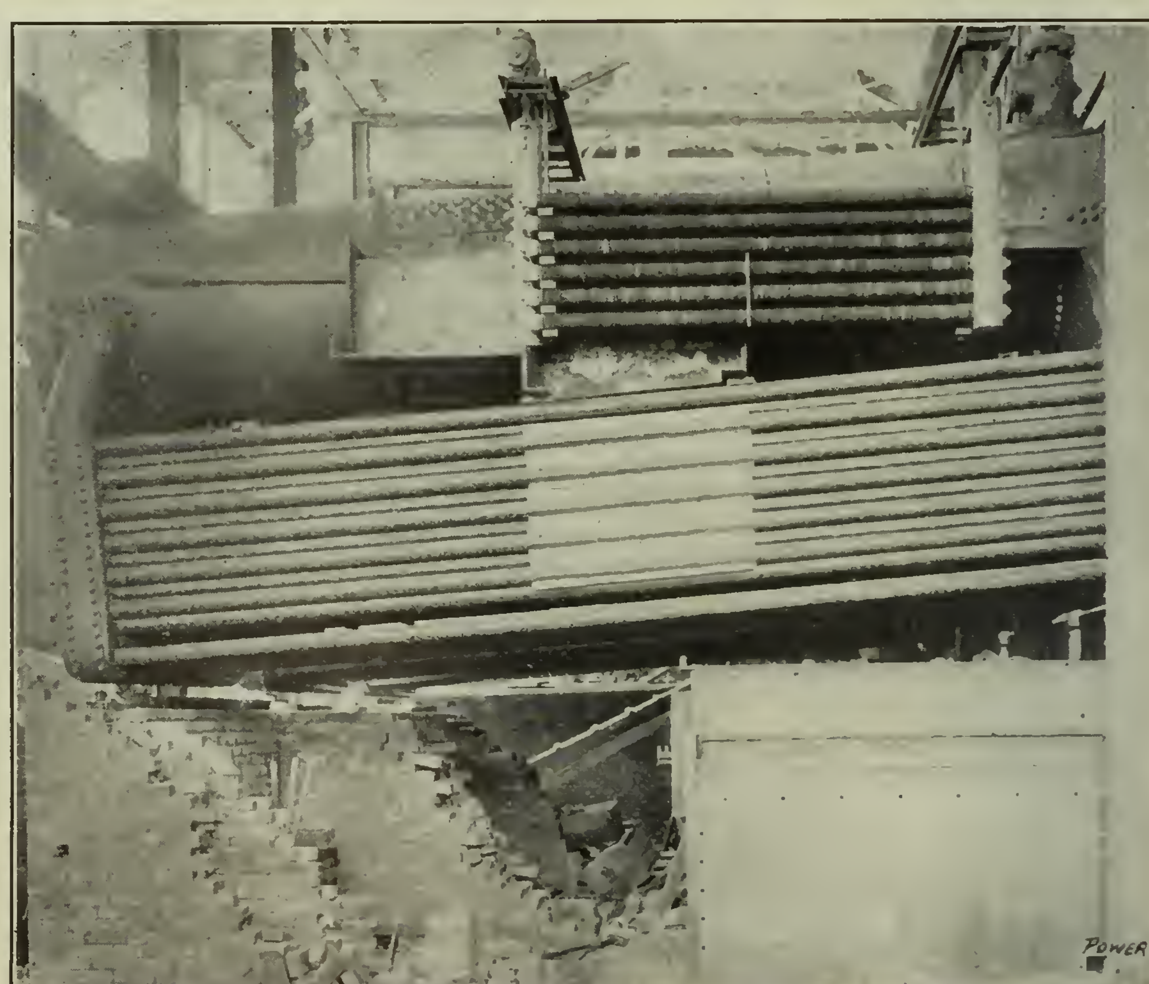

Fig. 16. Heine Boiler and Foster Superheater

The various designs of superheater have characteristics distinctly their own. One design that differs materially from all others is the Foster. It is a combination of annular cast-iron flanges and seamless-steel tubes. The elements or tubes are straight and are generally placed parallel to each other. A manifold joins the elements at one end and the other end of each element is joined to a return header, as shown in Figs. 9 and 10.

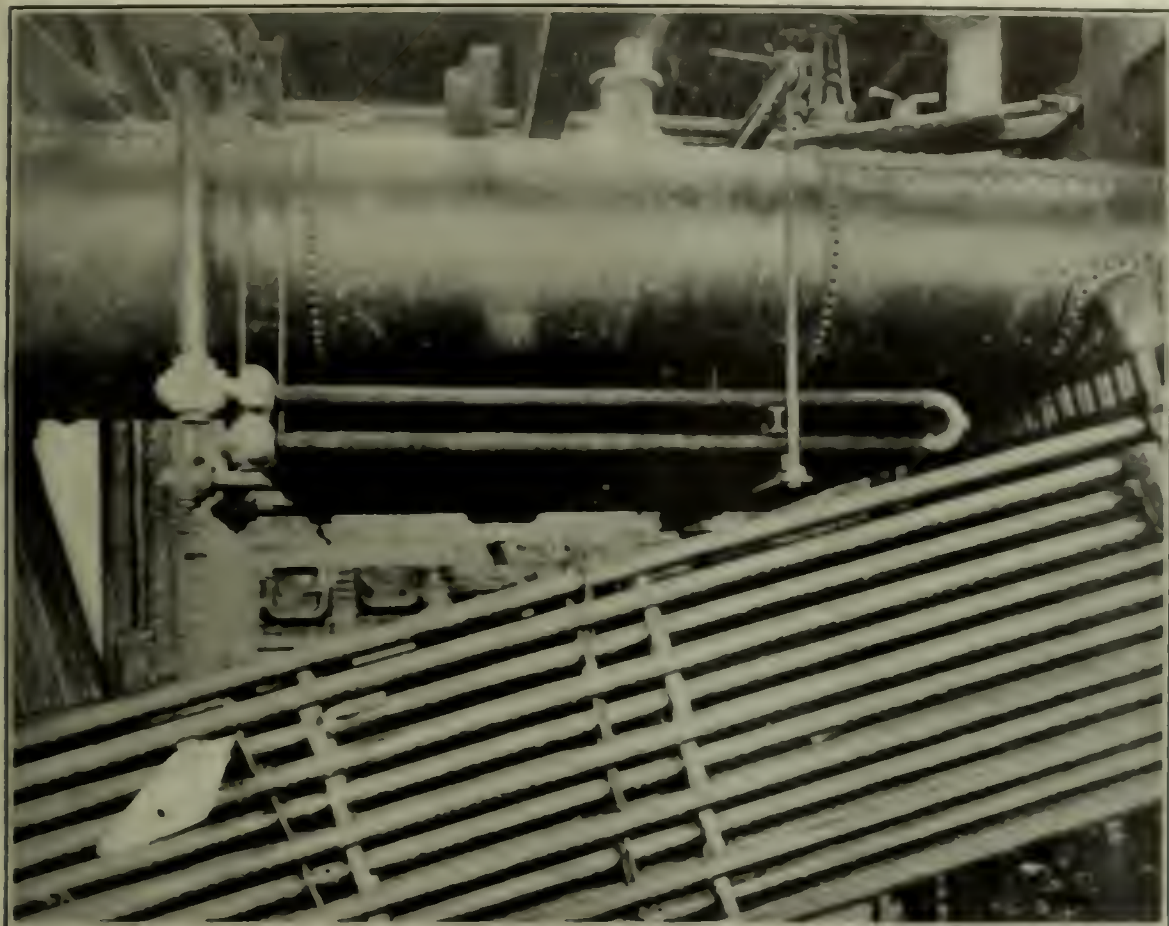

FIG. 17. BABCOCK & WILCOX BOILER AND FOSTER SUPERHEATER

The construction of the combination casting and steel tubing is shown in Fig. 9. The cast-iron flanges fit over the steel tube and are used to protect the tubes from the high temperature of the furnace gases. As the cast-iron rings are shrunk on the tubes, the rings and tubes practically act as a unit. An additional benefit derived from using cast-iron rings is that they act as a reservoir of heat, and are therefore capable of continuously imparting practically the same amount of heat to the superheater, thus maintaining a constant temperature of steam regardless of the ordinary fluctuation in the temperature of the hot gases.

Inside of the steel tubes of each element is a wrought-iron tube. It is kept central in the outer tube by knobs spaced through the length of the inner tube. This feature is shown in Fig. 9. Steam, however, does not enter this inner tube, as it is closed at both ends, as shown in Fig. 11, which is a cross-section through a return header. An exterior view of the same header and handhole plugs is shown in Fig. 12. The purpose of this inner tube is to force the steam as it passes the superheater to go between the inner and outer tubes in a thin sheet. This causes the steam to cling to the heating surface of the outer tube in its passage through each element.

No provision is made for flooding this superheater, and all the protection necessary to guard against burning the elements when getting up steam is found in the covering of cast iron.

This design of superheater is adaptable for use with any type of boiler. In Fig. 13 it is shown attached to a return-tubular boiler. The elements are set on end, and the steam connections are made at the top. The number of elements are determined by the size of boiler and the degree of superheat desired. The superheater is placed in the chamber at the rear end of the boiler, and in order that the greatest amount of heat may be imparted to the superheater, a firebrick arch is constructed in the combustion chamber, as shown. The path of the gases is over the bridgewall, under the arch and through and around the superheater member before entering the tubes of the boiler. This arrangement is not only suitable for new return-tubular boilers, but also for boilers of the same type that have been in service for some years and cannot carry with safety the necessary steam pressure demanded by the engine. As the temperature of superheated steam does not change the pressure, a boiler generating saturated steam can be made to deliver steam to an engine at a high temperature, but low pressure, by using a superheater.

Where this superheater is used in connection with a water-tube boiler, its shape will vary as the design of the boiler dictates. When used with a Stirling boiler the superheater is suspended by means of suitable U-bolts to the I-beams of the boiler support. The members are placed between the first and second banks of tubes in an inverted position. That is, the return bend is placed at the top and the header at the bottom. The general arrangement is shown in Fig. 14. This brings the superheater in the direct path of the hot gases as they pass from the first to the second bank of tubes. The steam connection from the steam drum to the superheater is placed outside of the setting, likewise the pipe running

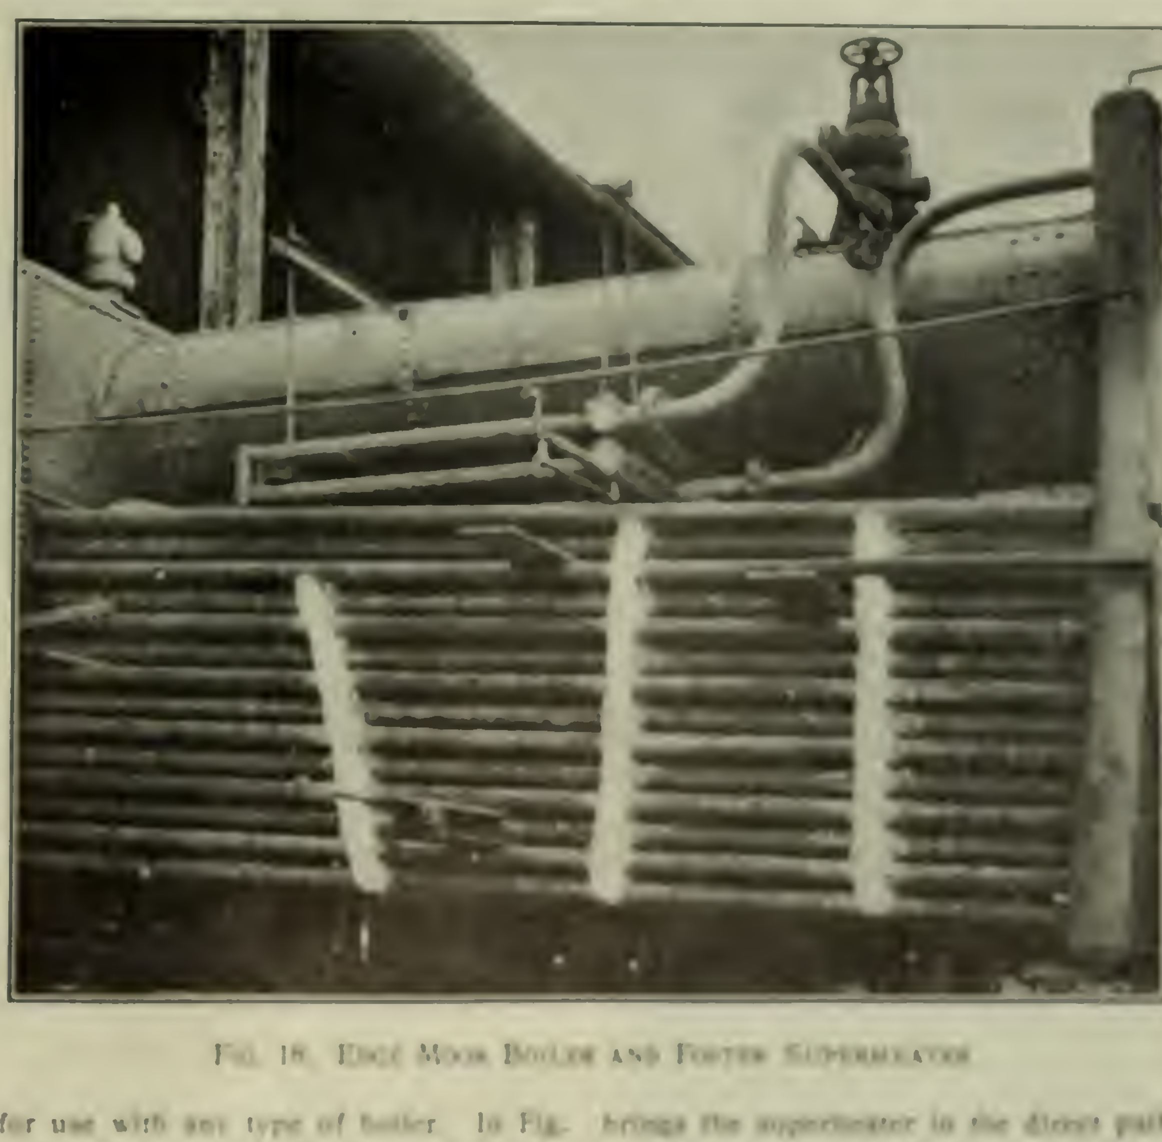

FIG. 18. EDGE MOOR BOILER AND FOSTER SUPERHEATER

from the superheater to the steam main.

This type of superheater is not always made with return bends. What is termed a return header, Figs. 11 and 12, is used with some types of boiler, the design having much to do with the type of header used in connecting the elements.

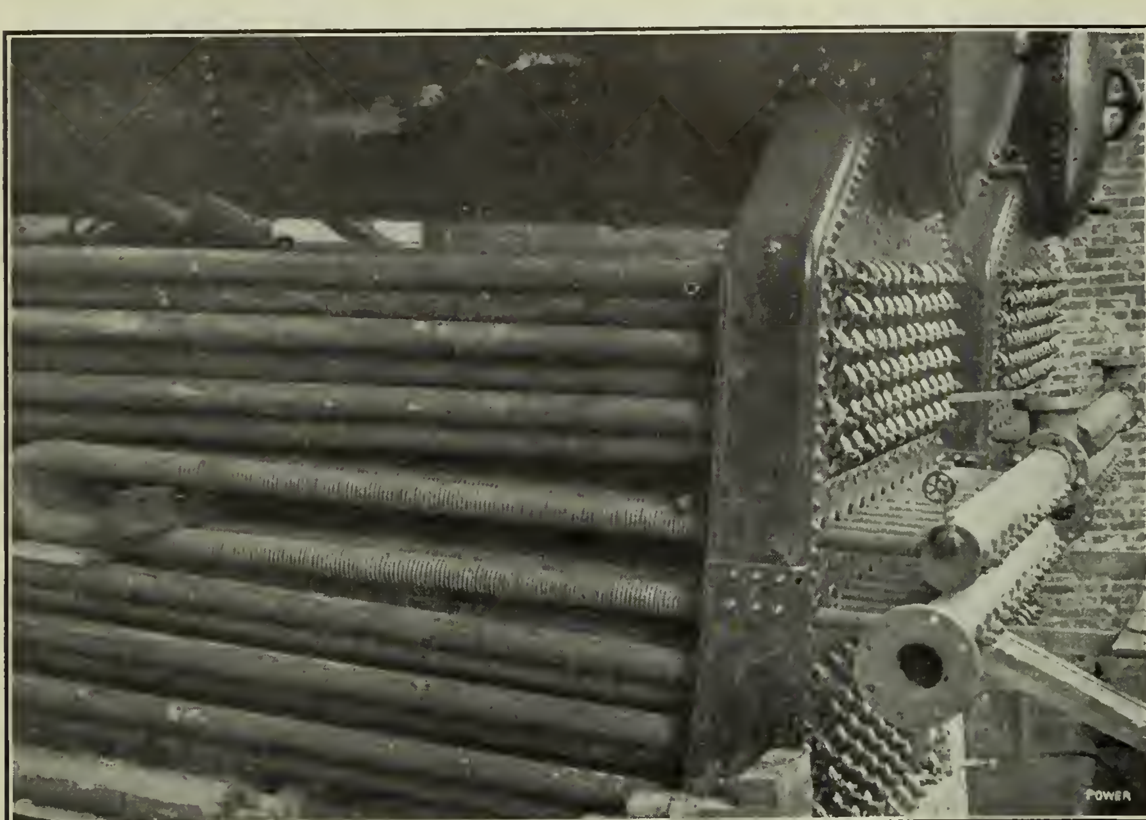

Fig. 19. Casey-Hedges Boiler and Foster Superheater

A Franklin water-tube boiler, Fig. 15, is equipped with this same design of superheater header, as shown in Figs. 11 and 12. Owing to the close proximity of the drum to the tubes it is necessary to place the superheater at the front end and along the side of the drum. The superheater is arranged in a separate chamber, which is divided into two compartments by means of a vertical baffle running transversely across the superheater tubes. The bottom of the rear compartment of the superheater chamber is connected by means of a flue in the side walls of the setting directly with the combustion chamber a little to the rear of the bridgewall. The bottom of the forward compartment of the superheater chamber is in direct communication with the area provided for the passage of the gases passing through the boiler underneath the boiler drums. The circulation of the gases through the superheater chamber is then into the chamber by way of the flue in the side walls, upward among the superheater tubes in the rear compartment, and downward among the superheater tubes in the front compartment of the superheater chamber, from which they issue and join the gases passing through the boiler on their way to the stack. A damper arranged above the vertical baffle in the superheater chamber controls the amount of gases passing through, and consequently the degree of superheat. The amount of hot gas made to pass directly past the superheater is controlled by a damper placed above the top member of the superheater.

Practically the same arrangement of the superheater is made with the Heine boiler, Fig. 16, and other similar designs of boilers, where the superheater is generally suspended from the I-beams by means of suitable bolts.

Fig. 17 shows the method of attaching the superheater to a Babcock & Wilcox boiler. As it is placed central to the longitudinal length of the boiler between the tubes and the drum it lies in the direct path of the hot gases as they leave the first section of tubes and enter the second nest of tubes between the first and steam drums of the boiler is made with second baffle walls. A connection from the the lower header of the superheater on one side of the drum. The steam, after passing through the coils, escapes through a pipe leading from the top header, and on the opposite side of the boiler from the inlet pipe to the main steam header. It is connected to similar types of boilers in practically the same manner. Figs. 18 and 19 show the superheater applied to an Edge Moor and Casey-Hedges boiler, respectively.

Fig. 20. Wickes Vertical Boiler and Foster Superheater

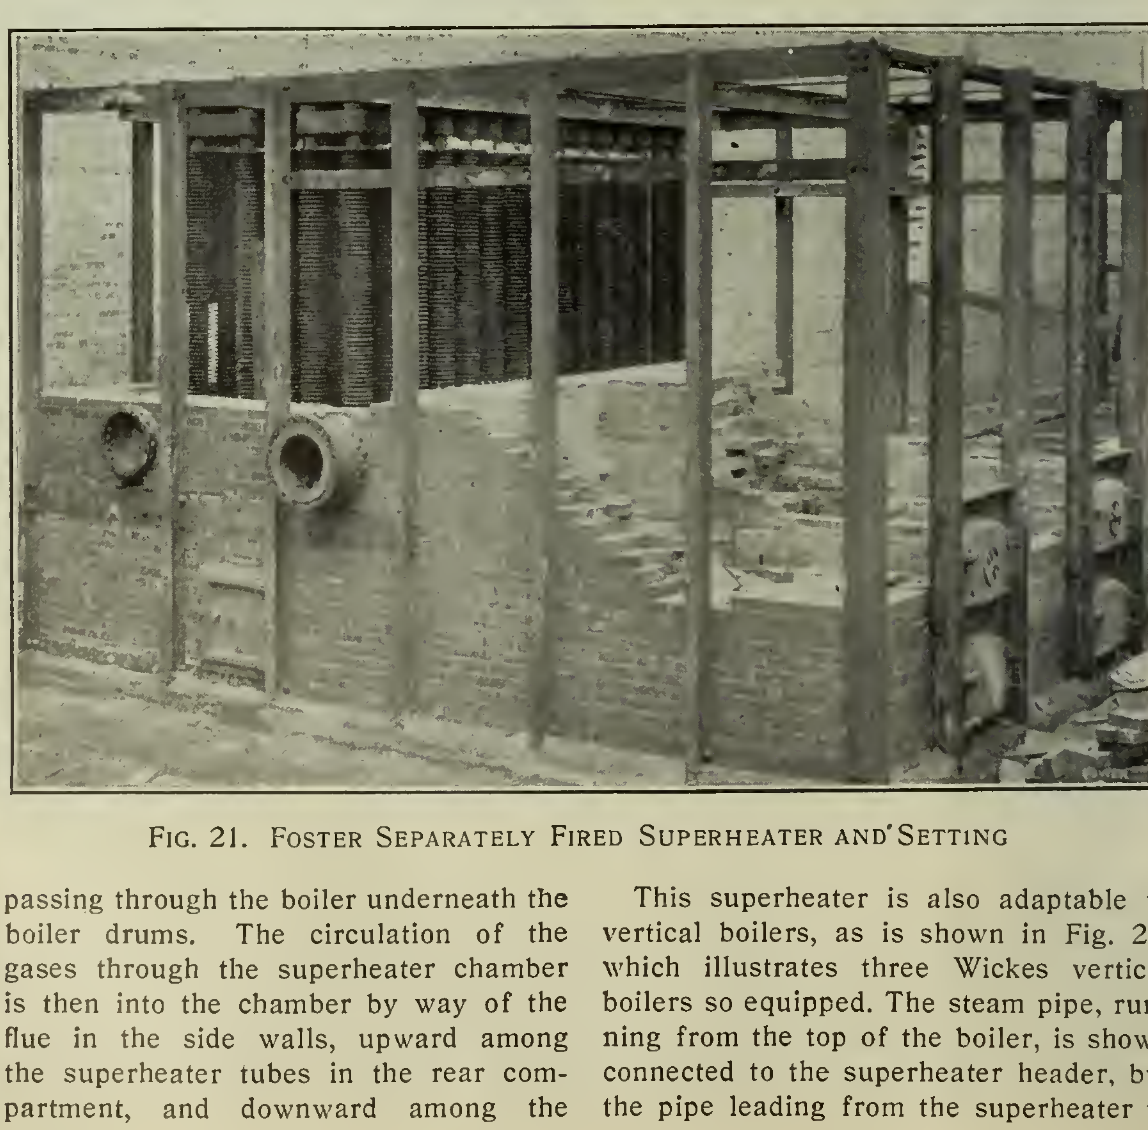

Fig. 21. Foster Separately Fired Superheater and Setting

This superheater is also adaptable to vertical boilers, as is shown in Fig. 20, which illustrates three Wickes vertical boilers so equipped. The steam pipe, running from the top of the boiler, is shown connected to the superheater header, but the pipe leading from the superheater to the steam main is not indicated, the connection being shown flanged. The members of the superheater are arranged vertically. The return headers serve as a means of support, which is accomplished by rods being bolted to a cross piece under each return header. The upper end of the bolts pass through holes in an angle piece that is riveted to the boiler.

This superheater is adaptable to separate firing, that is, obtaining the heat for superheating the steam from a furnace separate from the boiler furnace. This design is illustrated in Fig. 21, which shows the method of constructing the framework and the arrangement of the superheating members in relation to the furnace. In steel mills this type of superheater can be operated by waste heat from the various furnaces.

The Steam Turbine in Germany

By F. E. Junge and E. Heinrich

A study of the losses which occur in turbines of the Curtis and Rateau types, with an example from practice on a combination turbine.

Special Discussion of Curtis and Rateau Principles

After having given a general idea in the article in the December 20 number of the methods of investigation we proceed now to the special discussion of the economic qualities of the Curtis and Rateau systems, respectively, by determining, as far as this is possible today by calculating, the losses occurring in each.

Calculation of Losses

(1) By far the largest part of all losses is caused by friction, shock and eddy currents in nozzles and blades. This loss was determined in equation 2 as

$$R = (1 - \eta_i) h_a \qquad (2)$$

wherein R = loss in heat units per pound of steam, η_i indicated efficiency and h_a available energy of the stage.

(2) *Work absorbed by friction and windage of the rotating wheels.* By the friction between the wheel disks and the surrounding medium a certain amount of work is consumed. Moreover, those blades upon which the live steam does not impinge act as a fan, causing a circular motion of the steam whereby work is again absorbed. Of course, it is not possible to determine the exact amount of this loss by calculation. We profit, therefore, by the results of experimental research, so far as they have been condensed in formulas. For our purpose here we employ the formula of Lasche (Stodola, fourth edition, page 129), which is applicable for admission diameters of from 900 to 1200 millimeters, or 2.95 to 3.94 feet, with length of blades ranging from 10 to 50 millimeters, or 0.394 to 1.97 inches. In this formula the friction and windage expressed in kilowatts for a wheel not inclosed in a casing, and working without admission of steam but in the medium steam, is

$$N_{kw} = \beta \cdot 10^{-6} D_m n^3 L_m \gamma \qquad (5)$$

wherein D_m is admission diameter; L_m mean length of blades; n, number of revolutions per minute; γ, specific weight of steam.

If metric units are employed (D and L in meters, γ in kilograms per cubic meter) the coefficient β becomes

17. [illegible] for wheels with one row of buckets,
29. [illegible] for wheels with two rows of buckets,
[illegible] for wheels with three rows of buckets,
[illegible] for wheels with four rows of buckets.

If British units are employed (D and L in feet, γ in pounds per cubic foot) the coefficient β becomes

26.1 for wheels with one row of buckets,
30.5 for wheels with two rows of buckets,
41.7 for wheels with three rows of buckets,
63.2 for wheels with four rows of buckets.

Recalculated in B.t.u. per second and considering that 1 kilowatt = 737.3 foot-pounds per second and 1 B.t.u. = 78 foot-pounds, this equation reads:

$$V = \frac{737.3}{778} \beta \cdot 10^{-6} D_m n^3 L_m \gamma =$$
$$0.948 \beta \cdot 10^{-6} D_m n^3 L_m \gamma \qquad (6)$$

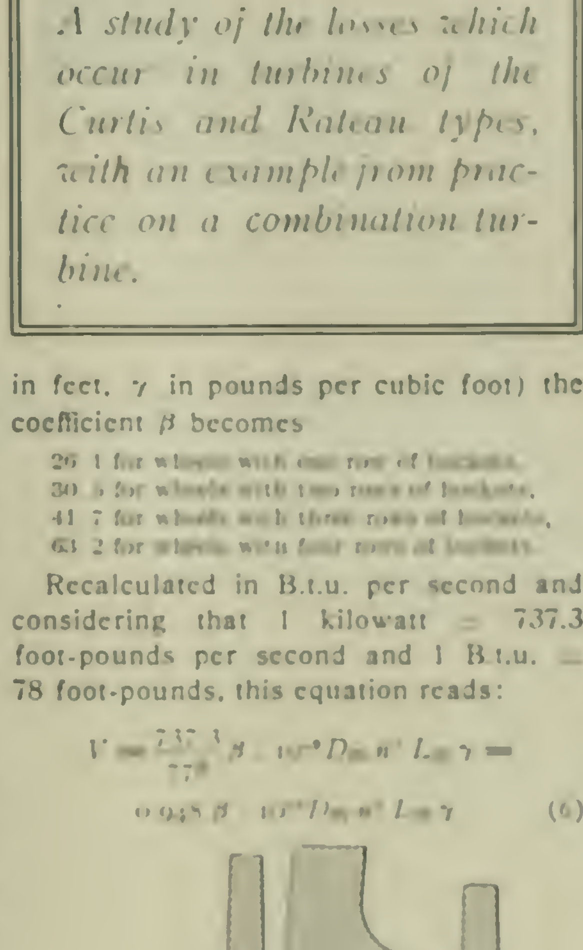

Fig. 11. Stuffing Box of a Rateau Stage

(3) *Losses through leakage at the wheel hubs.* Between the hubs of the wheel disks and the hubs of the rotating wheels there is, of course, a certain clearance through which steam can escape from one stage into the next without performing any useful work; see Fig. 11. If no resistance were opposed to the flow of steam through these clearances the actual passage velocity of the steam would be equal to the theoretical velocity c_{th}, which corresponds to the theoretical drop of heat. In order to get small losses one must take care, therefore, that this passage velocity remains as low as is practically possible, or, in other words, the resistance offered to the flow must be as high as possible. This is attained by a labyrinth packing, as shown in Fig. 11. This construction affords a reduction of the actual passage velocity down to 0.6 c_{th}. If $f = \pi d_s s$ is the cross-section of the orifice of loss and γ the specific weight of the steam leaving, the lost steam weight is:

$$g_s = 0.6 \pi d_s s c_{th} \gamma \qquad (7)$$

If further h_a equals the available energy in the stage in heat units per kilogram of steam, the loss through leakage may be expressed in heat units as follows:

$$s = g_s h_a \qquad (8)$$

In the first stage of an impulse turbine there is no leakage loss on account of the fact that there is no clearance through which steam could escape.

Energy to Be Regained

Part of the velocity of issue c_2 (Fig. 7, December 20), may be regained by catching the steam jet, emanating from the rotating wheel, in the following guide blades in such a manner that as little as possible of the inherent velocity of the steam is destroyed. It is customary to assume that with average quality of design and shop work, about 80 per cent. of the residual energy $\frac{c_2^2}{2g}$ of the steam is utilized in the following guide blades. Thus the energy regained per kilogram of steam passing through the blades is in heat units:

$$U = 0.8 \frac{c_2^2}{[illegible]} \qquad (9)$$

Combination of Losses

After having determined the various losses and the energy to be regained we combine the results in the following formulas: If g pounds is the weight of steam flowing through the turbine per second, we must bear in mind that not the whole of it passes through the guides and moving blades, but that the amount g_s passing through the clearance at the hubs must be subtracted, so that $g - g_s$ pounds per second pass through the blades rendering useful work. It must be further considered that the loss R

and the amount M of the regainable energy refer to the unit of steam weight which flows through the guiding and moving blades, while the calculated amount for windage V and for leakage losses U refers to the total steam weight flowing through the turbine. If we designate by L the sum of losses per pound of steam,

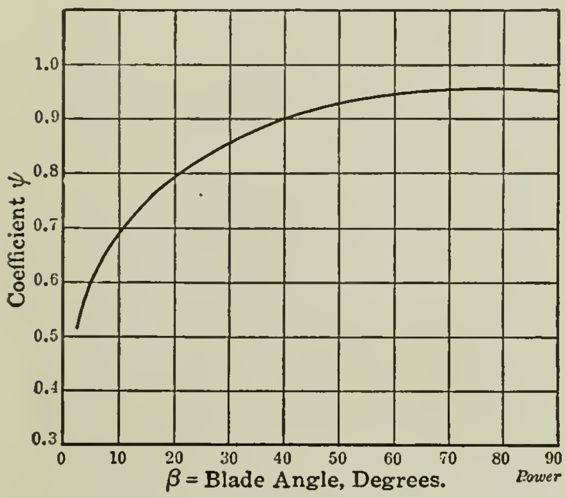

Fig. 12. Coefficient of Resistance of Rotating Blades

the total loss in the turbine is: $L \times g$, and we get the following equations:

$$L g = (g - g_o) R + U + V - (g - g_o) M = (g - g_o)(1 - \eta_i) h_o + g_o h_o + V - (g - g_o) M = g(1 - \eta_i) h_o + g_o h_o \eta_i + V - (g - g_o) M \qquad (10)$$

Hence the loss per pound of steam is found to be:

$$L = (1 - \eta_i) h_o + \frac{g_o}{g} \eta_i h_o + \frac{V}{g} - M \qquad (11)$$

of a turbine, where leakage losses do not occur, we get:

$$L_1 = (1 - \eta_i) h_o + \frac{V}{g} - M \qquad (12)$$

With Curtis wheels the residual exit velocity is, as a rule, not utilized for reasons of design and because it is very small. Hence, we have for Curtis wheels:

$$L_c = (1 - \eta_i) h_o + \frac{V}{g} \qquad (13)$$

researches, especially of Stodola. As to coefficients it is to be noted that the value depends essentially on the state of the surface of the nozzles or blades, which is to say, it depends preëminently on shop work. Further, it is to be noted that the nozzles and blades may vary the state of their surface even during operation, as a result of corrosion of the blades and of sediment of impurities of the steam. Hence, the coefficients of resistance of

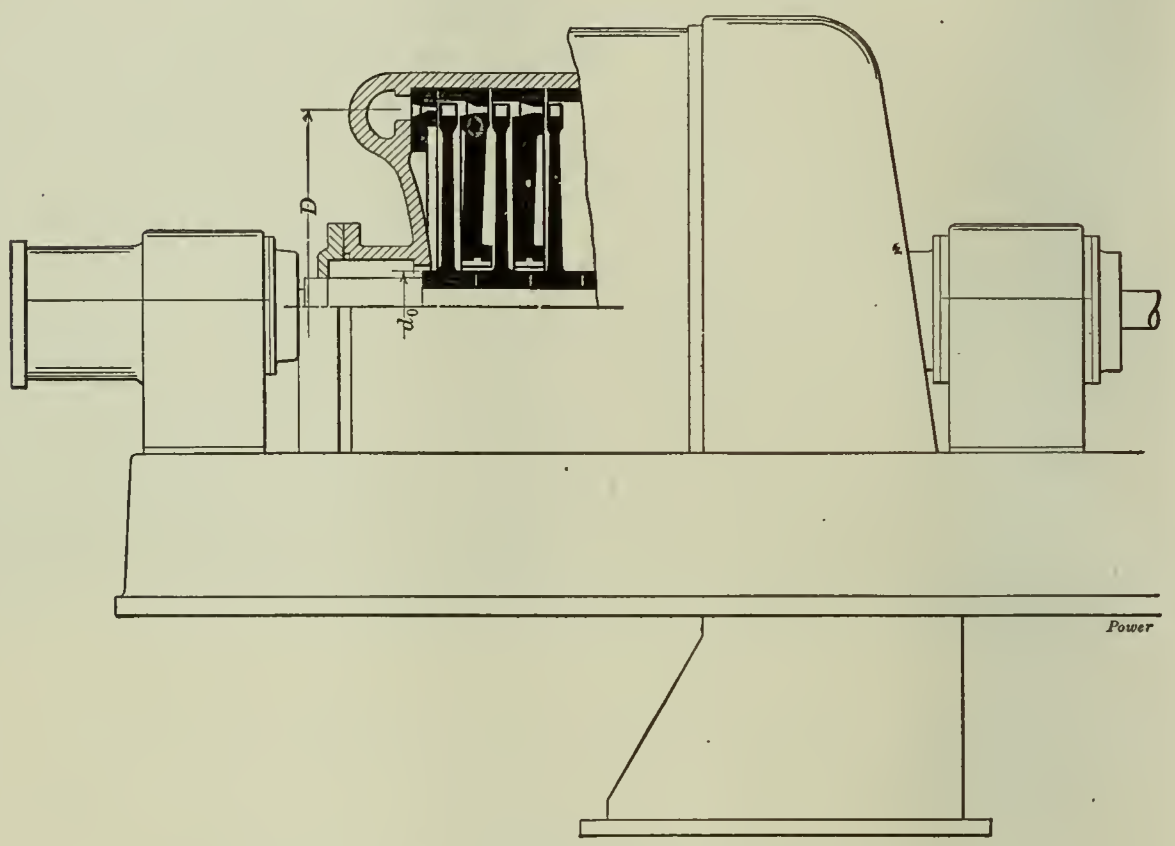

Fig. 14. Three Rateau Stages

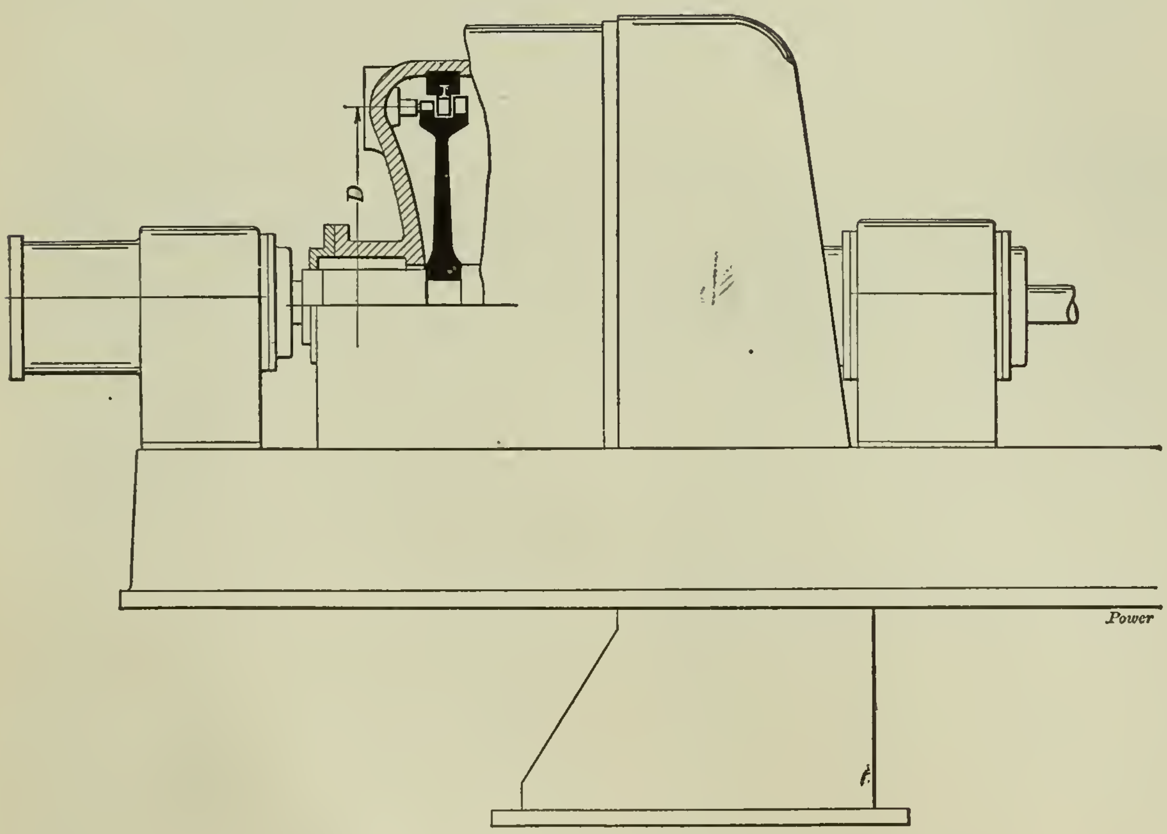

Fig. 13. Single-stage Curtis

In the above expression we have assumed the factor of M, $\frac{g - g_o}{g}$, to be equals 1 for the sake of simplicity, because the total amount of M is comparatively small and because g_o is a small amount compared to g. For the first stage

The Coefficients of Losses

Before attempting to carry through a calculation of an example on the basis of these reflections it appears necessary to determine the amount of the coefficients of loss, ϕ, ψ, ξ, wherefore we profit again by the latest experimental

one and the same turbine are far from constant.

The coefficient ϕ is usually assumed to be 0.95 for first-class shop work. As to the coefficient ψ the results of the experiments of various investigators differ essentially. Thus, for instance, Briling and Rateau found that the coefficient ψ increases with the relative velocity w_1, hence the loss of energy decreases, while Stodola and Huguenin found, in contradistinction, that ψ decreases with w_1. On the other hand, all experimenters have established the fact that ψ decreases with increasing curve of blade, that is to say, with decreasing blade angles. With this consideration in mind we assume according to Stodola that the coefficient of resistance is independent of the steam velocity w_1 and depends only upon the curve or angle of the blades, as shown in Fig. 12.

The number ξ in equation 4, representing the loss in the first row of blades, in percentage of the energy of issue $\frac{w_2^2}{2\,g}$, is assumed to be 25. This value was determined from an analysis of a Curtis turbine made by Stodola.

Example from Practice

In a turbine of 1000 kilowatts at 3000 revolutions per minute, consisting of eight simple-pressure stages (Zoelly system), the high-pressure part is to be replaced by one Curtis wheel. Figs. 13 and 14 show the two devices. In order to utilize by means of the original Rateau principle the same drop of energy as in one Curtis wheel we must assume at least three Rateau stages as its equivalent. Furthermore, the mean wheel diameter and therefore the circumferential velocity shall remain the same. In our example which is taken from actual practice the admission diameter is 1 meter = 3.28 feet. The operating conditions of the turbine are:

Admission pressure = 180 lb. per sq.in. absolute.
Steam temperature = 525 deg. F.
Superheating = 177 deg. F.
Vacuum = 94 per cent.
Steam consumption = 15 lb. per kilowatt-hour
Steam weight per sec. = 4.17 lb.

In the high-pressure part the steam expands down to 33.5 pounds per square inch. From the Mollier diagram is obtained a theoretical heat drop of 146 B.t.u. The clearly defined conditions of the comparison of the two systems are, therefore, one Curtis wheel as against three Rateau stages; equal circumferential velocity in both cases; equal heat drop to be utilized in both cases; coefficients of losses determined by same laws.

The theoretical exit velocity is $c_0 = 223.8\sqrt{146} = 2705$ feet per second.

The circumferential velocity is $u = \frac{3.28 \times \pi \times 3000}{60} = 515$ *feet.*

Curtis Wheel

Fig. 15 shows the Mollier diagram, Fig. 16 the velocity diagram. In the latter such angles have been used as obtain in practice.

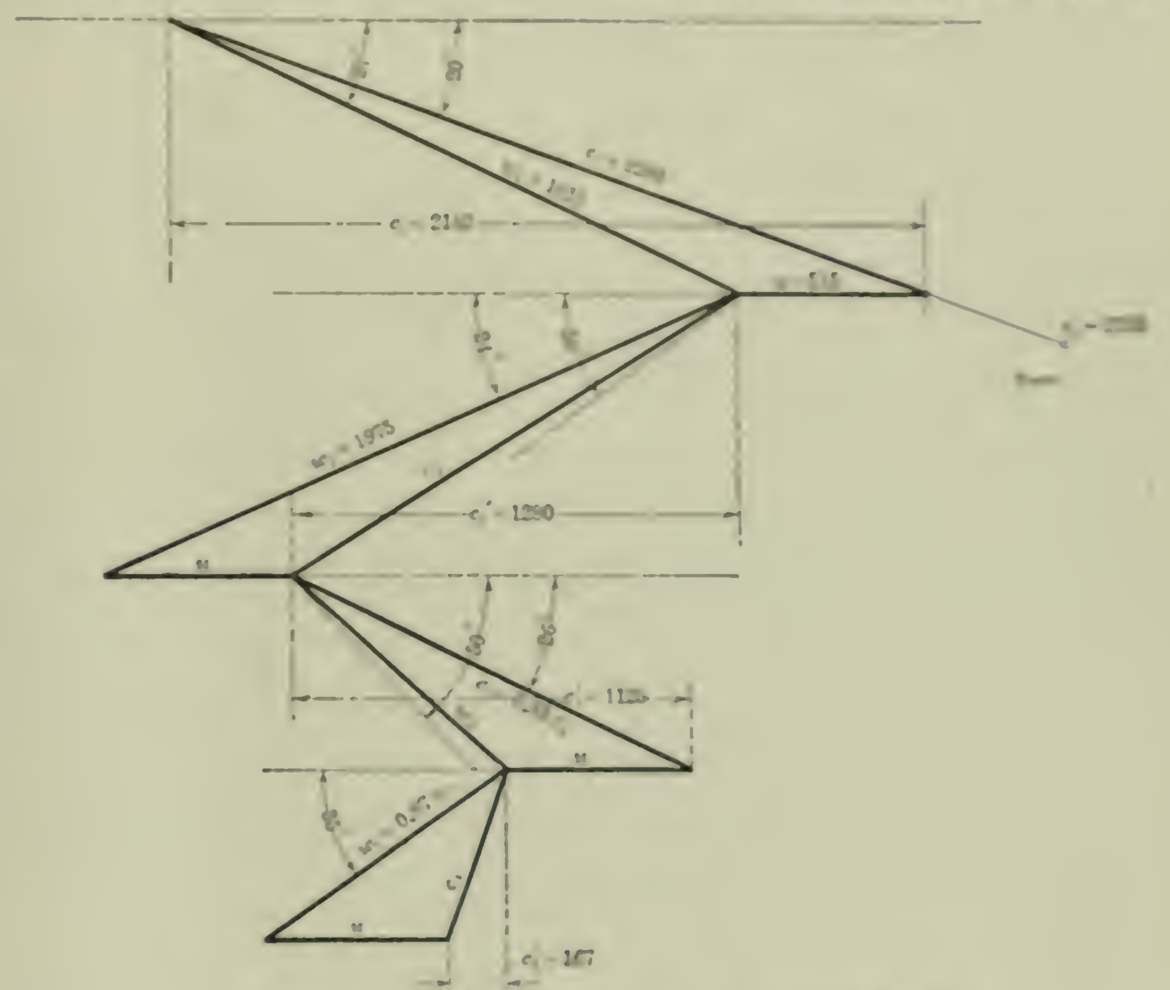

Fig. 16. Velocity Diagram of the Curtis Wheel

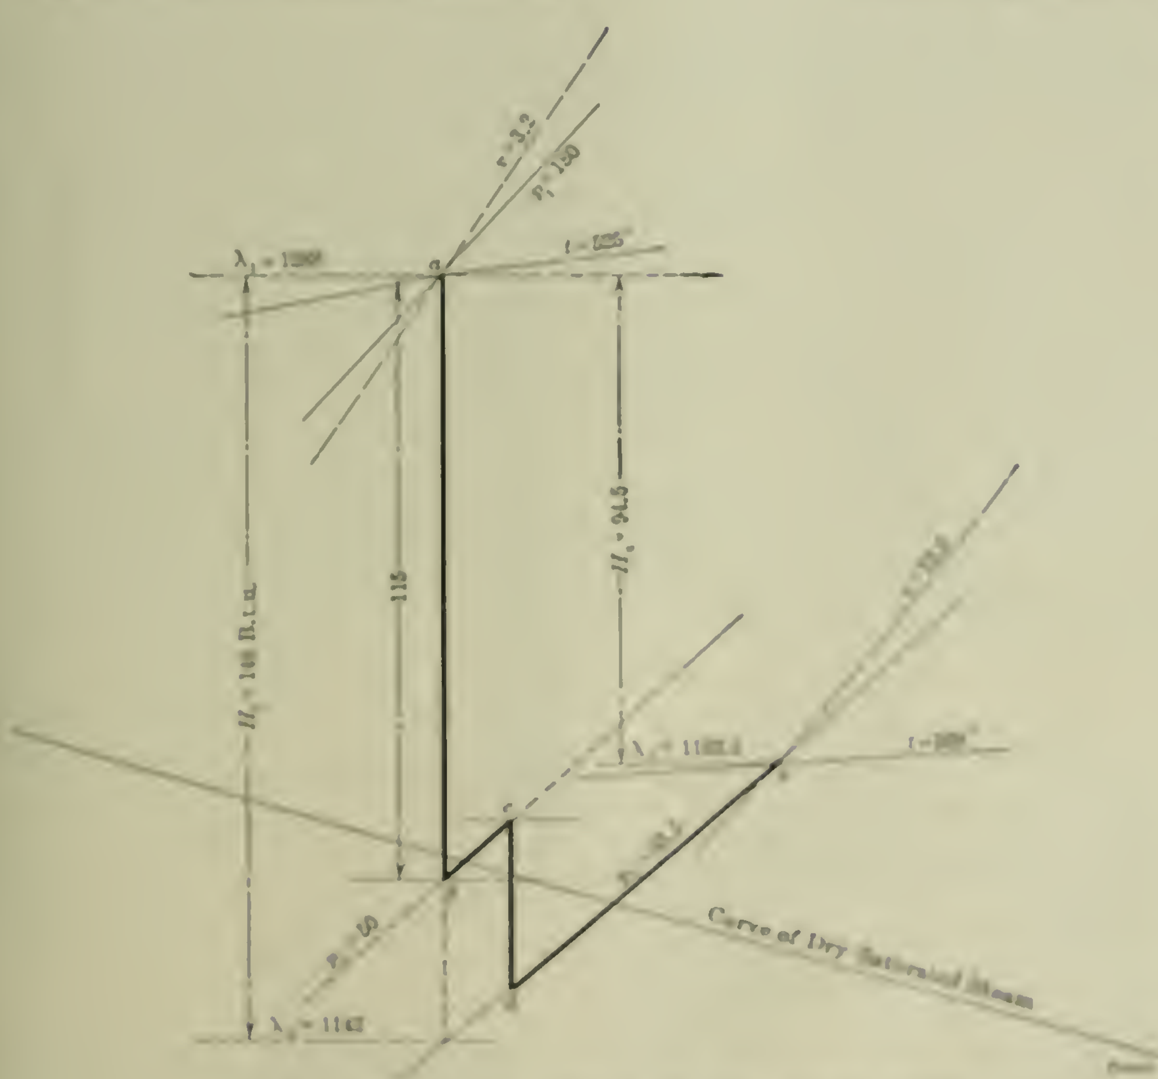

Fig. 15. Mollier Diagram of the Curtis Wheel

In accordance with the above we do not expand in the nozzle down to the counterpressure 33.5 pounds per square inch, but to the pressure 80 pounds per square inch. Then we find from the Mollier diagram that in the nozzle 115 B.t.u. are converted corresponding to a theoretical velocity of $223.8\sqrt{115} = 2400$ feet per second and an actual velocity of $0.95 \times 2400 = 2280$ *feet per second,* as shown in the diagram. In the nozzle we expand theoretically down to point *b*, but owing to the losses occurring the end point of the expansion is shifted to *a*. [Loss $115 (1 - 0.95^2) = 11.5$ B.t.u. per pound.]

In the first row of revolving blades we expand further down to *d*, realizing a drop of heat of $h_1 = 32$ B.t.u. From the velocity diagram is found $w_1' = 1810$ feet per second, and w_1 from equation 4 in the December 20 number

$$w_1 = \sqrt{\frac{w_1'^2 + 2g \times 778 h_1}{1 + \xi}} = \sqrt{\frac{1810^2 + 2 \times 32.2 \times 778 \times 32}{1 + 0.25}} = 1975$$

feet per second

Having w_1, we get from the velocity diagram c_1. This is the velocity with which the steam enters the deviating blades. For the latter we obtain for the smallest blade angle (20 degrees) the coefficient from Fig. 12, $\psi = 0.83$. And the velocity of the steam leaving the deviating blades, being equal to the entrance velocity of the steam into the second row of revolving blades, becomes $c_1' = 0.83\,c_1$.

The velocity conditions in the second row are normal and need not be further explained. It may be mentioned that as the smallest angle of the second row of revolving blades, 35 degrees, corresponds a coefficient $\psi = 0.87$. The respective projections of the absolute entrance and exit velocities upon the direction of travel are obtained directly from the velocity diagram.

The indicated efficiency, according to equation 4, is

$$\eta_i = \frac{2 \times 515 \times (2140 + 1280 + 1125 + 167)}{2705^2} = 0.663$$

Therefore the friction loss per pound of steam is

$$R = (1 - \eta_i)\, h_o = (1 - 0.663)\, 146 = 49.2 \text{ B.t.u.}$$

It remains to determine the windage from equation 6. The mean length of blades has been assumed as ⅝ inch = 0.052 feet. The mean diameter d = 3.28 feet, the specific weight from the Mollier diagram $\gamma = \frac{1}{13.6} = 0.0735$ pound per cubic foot, the coefficient $\beta = 30.5$. Thus we get the following formula:

$$V = 0.948 \times 30.5 \times 10^{-9} \times 3.28 \times 3000^2 \times 0.052 \times 0.0735 = 9.8 \text{ B.t.u.}$$

and per pound of steam per second $\frac{V}{g} = \frac{9.8}{4.17} = 2.3$ pounds of steam per second.

Hence the total loss according to equation 13:

$$L_c = 49.2 + 2.3 = 51.5 \text{ B.t.u. per lb. of steam}$$

and the interior efficiency of the Curtis wheel is:

$$\eta = \frac{146 - 51.5}{146} = 0.647$$

Uncle Pegleg's Philosophy

The old man explains the difference between force and work, shows how the resultant of two forces may be obtained, and incidentally works out some problems in proportion.

"I started in the other day to explain something to you and you led me off," said Uncle Pegleg, another day.

"So?" I said. "What was it?"

"When I asked you about the pull of that bag of gravel they were hoisting, we got off onto the pull on the rope. I wanted to get at the stress on the strut."

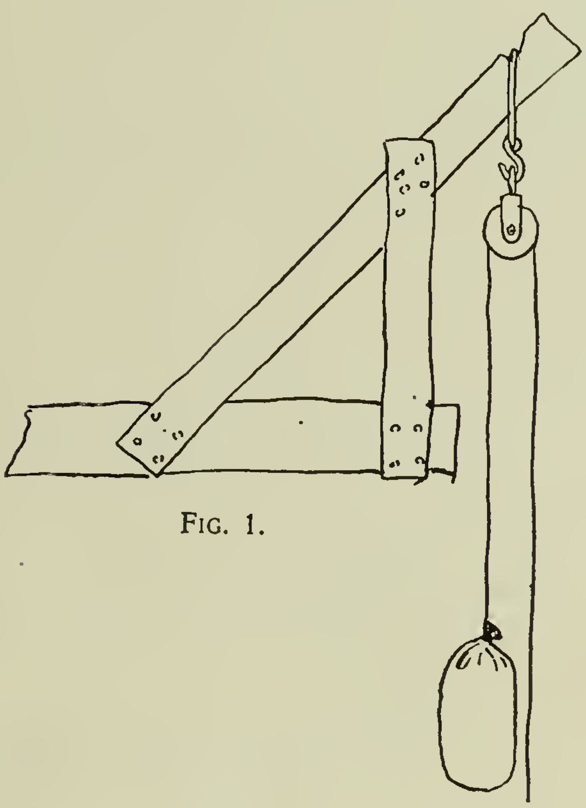

Fig. 1.

"What do you mean—the stress on the strut?"

"They had a board stuck up like this (Fig. 1) with a pulley on the end of it to hoist the gravel with. Well, I want to know what is the stress on that strut. How hard does it push on the nails that hold it? Take this case," and he drew Fig. 2. "Suppose the weight is 100 pounds. How would you go to work to find the force with which the boom was pushing down into the corner A?"

"Two hundred pounds, isn't it?" I said on a guess.

"No, because the pull in the part of the rope between B and C is 100 pounds, but it isn't pulling in the direction of the strut; and the pull on the piece of rope between C and D is 100 pounds, but that isn't pulling in the direction of the strut either. A pull that don't pull in the right direction may help some, but not its full amount."

"Well, what's the answer?"

"Suppose a boat was going across a river and the man in it rowed straight for the opposite bank all the time. If he went with a steady, uniform speed of 200 feet a minute, he would be here (indicating a in Fig. 3) at the end of the first minute, here (indicating b) at the end of the second minute, here (c) at the end of the third minute, etc."

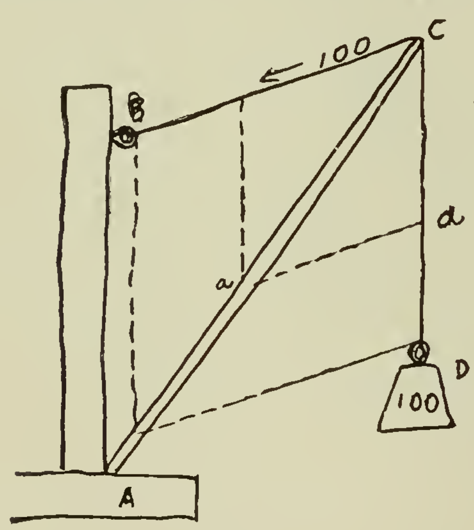

Fig. 2.

"If the current didn't carry him down," I said.

"Exactly. That's just what I was coming at. If the current carried him downward at the rate of 100 feet a minute, he would be at d instead of at a at the end of the first minute, just as though he had gone straight to a by reason of his rowing and then to d by reason of the current. At the end of the second minute he would be at e instead of at b and at the end of the third minute at f instead of at c; and always supposing that the velocities were uniform, the path that would have actually followed would be $o\,d\,e\,f$. Is that plain?"

I admitted that it was.

"Well, then, if $o\,a$ is proportional to his velocity in the direction $o\,a$, i.e., across the river, and $a\,d$ is proportional to his velocity in the direction $a\,d$, i.e., down the river, $o\,d$ must be proportional to his actual velocity, because he actually goes from o to d in the same time that the other velocities would have taken him from o to a or from a to d."

"What has that got to do with the force on the strut?" I asked.

"Everything. We will come to that. I am showing you now how, if you have two velocities and their direction, you can find the actual velocity and direction which they, acting together, will produce. The same thing applies to forces. Here (Fig. 2) you have two forces; one acting in the vertical direction $C\,D$ and the other acting in the direction $B\,C$. You want to find what their resultant in the direction $C\,A$ is. You do it the same way as with velocities. Now let us see what we do.

"Starting from the starting point o, lay off a line $o\,a$, Fig. 4, two inches long for the 200-foot velocity across the river, and from the same point a line $o\,g$, one inch long, for the velocity down the river. Complete the parallelogram of which these are two sides by drawing in the sides $g\,f$ and $a\,f$; then the diagonal $o\,f$, *drawn from the starting point o*, will be the actual or resultant direction and velocity."

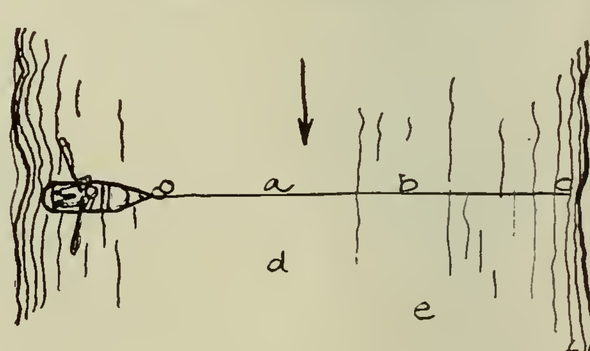

Fig. 3

"Wouldn't it be just the same if you took the diagonal $a\,g$?" I asked.

"No, because the corners may not be right angles. It only happened so in this case because the man was rowing at right angles to the current. Let's see what would happen if he started up the river at an angle of 30 degrees."

With the 30-degree angle of his drawing set he drew Fig. 5. The line *o a* points 30 degrees up stream. The line *o g*, one-half as long, because the velocity is one-half as great, points down stream, representing the direction in which the boat is carried by the current. Complete the parallelogram. Then the diagonal *o f* from the starting point is proportional in length and represents by its direction the actual velocity and direction which the boat would take. You can see that the other diagonal *a g* would be away off. Always start at the starting point to draw your diagonal. You could have done it just as well by drawing the line *o a* and then *a f* and connecting *o* to *f*, using only the triangle *o a f* instead of the parallelogram. They call this the triangle of forces or velocities, but if you ever get confused, go back to the starting point, put in both velocities or forces from that point, make your parallelogram and use the diagonal from the starting point and you will be all right.

"Now, then, let's see about the force. Here (Fig. 2) you have equal forces acting in the directions *C B* and *C D*. Lay off equal distances, since the forces are equal on these lines and complete the parallelogram drawing in the dotted lines. Then the force acting in the direction *A C* will be as much greater than 100 pounds as *C a* is longer than *C b*. If you make *C b* 1 inch long to equal 100 pounds and *C a* is 1.25 inches, then the force acting in the direction *C a* will be 125 pounds. If the force was any other number, 140 for instance, you would have to do it by proportion. Know how to do proportion?"

'I didn't.'

"Well, it's easy. The old rule of three. Come up to the house and I will give you an arithmetic. You can learn the whole section on proportions in an evening and they are always coming up. You know

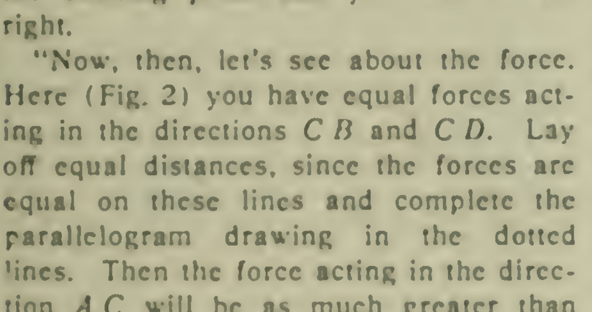

Fig. 4

three things and you want to know a fourth. For instance, in this case we know the length of the line *C b* and of the line *C a* and we know the force acting in the direction *C D*, say 140 pounds. We know that this force bears the same relation to the force acting in the direction *C A* that the length of the line *C d* does to the length of the line *C a*.

Set down the two similar terms that

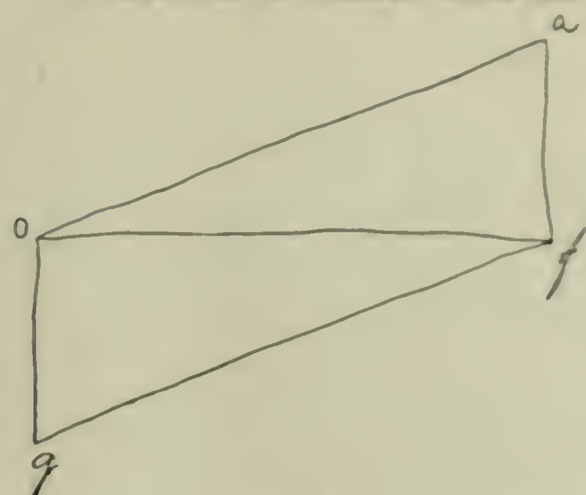

Fig. 5.

you know; in this case the two lengths of the lines, 1 inch and 1.25 inches, putting the one that agrees with the odd term that you know first

$$1 : 1.25 :: 140 : x$$

This reads, as one is to 1.25 so is 140 to the quantity you want to know.

"The thing to look out for is to get them so that the two quantities to the left of the double colon will bear the same relation to each other as those to the right and in the same order. Thus,

$$2 : 4 :: 3 : 6$$

You know that 2 is one-half of 4 and 3 is one-half of 6. If you get them in this order it will be true that the product of the two inside figures will be the same as that of the two outside. Try it."

I saw that $2 \times 6 = 12$ was the same as 4×3.

"If you have any three of them you can find the other," continued my instructor. "If one of the end ones is missing, multiply the two middle ones together and divide by the end one which you have. If one of the middle ones is missing, multiply the end ones together and divide by the inside one which you have. Simple enough, isn't it? In the case of the strut we have the two middle terms given, 1.25 and 1.40, and one end term, 1.

$$\frac{1.25 \times 140}{1} = 175 \text{ lb.}$$

"That proportion rule is one of the handiest things in the trade," continued the old man. "All you've got to do is to look out and get them set down right.

"If you put the smaller of the pair of known terms first, fix it so that the smaller of the pair of unknown terms will come inside, i.e., will come first on that side. For instance, you know that the horsepower of an engine is proportional to the piston speed. If it runs twice as fast, other things being equal it will develop twice as much horsepower. Well, suppose an engine develops 360 horsepower at 120 revolutions, how much will it develop at 125?

Here your pair of similar terms are the revolutions 120 and 125; if you put them down in that order, you must put the 360 first in the next pair because the 360 goes with the 120 of the first pair.

$$120 : 125 :: 360 : hp$$

$$\frac{125 \times 360}{120} = 375 \text{ hp}$$

"But sometimes it happens that a proportion is 'inverse' or backward. You know that the smaller pulley you put onto a driven shaft the faster it will run. The speeds of the shafts are inversely proportional to the diameters of the pulleys. A shaft running at 180 revolutions per minute carries a pulley 36 inches in diameter which is belted to a pulley 24 inches in diameter on another shaft. How fast will the other shaft run? Here your known pair are the diameters 24 and 36; the known term of the unknown pair is the 180 revolutions. Well, you put it down so

$$24 : 36 :: 180 : rev$$

or so

$$24 : 36 :: rev. : 180$$

You know that the revolutions will be greater than 180 with the 24-inch pulley, as much greater than 180 as 36 is greater than 24, so that you can see that the first way is right and that whereas with a direct proportion you put the known term of the incomplete pair first if its corresponding term was first in the other pair (120 revolutions for 300 horsepower both first in the other example). You now put them just the other way.

$$\begin{matrix} rev & rev & hp & hp \\ 120 & 125 & 360 & 375 \end{matrix}$$

$$\begin{matrix} diam & diam & rev & rev \\ 24 & 36 & 180 & 270 \end{matrix}$$

$$\frac{36 \times 180}{24} = 270 \text{ rev}$$

"How much do you suppose that crosshead bears on the guide," asked the old man, coming back to the main question, after this little lesson in arithmetic, "when the crank is at an angle of 45 degrees?"

It was too deep for me even with the explanation which I had heard, so I let him figure it.

"Let's lay it out," said he. "Give me that little drawing board and the tools."

I tacked a clean sheet of paper on his small board and he laid the T-square on it and drew the center line *A B*, Fig.

6. On this he drew a circle for the path of the crank pin, put in the crank *O C* at an angle of 45 degrees with the line of centers, and drew the connecting rod *C D*, twice the diameter of the crank-pin

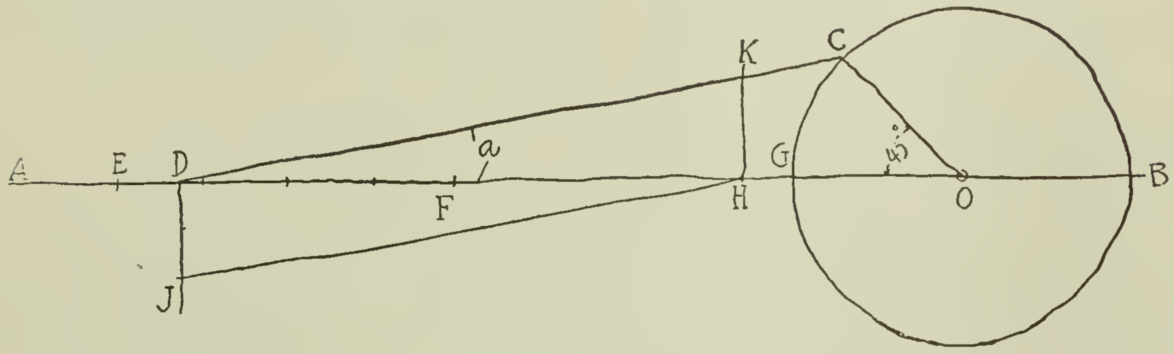

FIG. 6.

circle, for in our engine the connecting rod was twice the length of the stroke. Setting off the same distance from *G*, he determined the point *E* where the wristpin would be when the crank was at *G*, and from *B* the point *F* where the wristpin would be when the crank was on the farther center. He then showed me that the crosshead would travel from *E* to *F* and that it would be at *D* when the crank was at 45 degrees.

"There's another example in proportion for you," he said. "I've made the stroke here *E F* = 3 inches. The piston has traveled *E D* = about 9/16 inch. Our indicator takes a diagram 3¾ inches long. As the distance *E D* is to the distance *E F* so is the distance of the point on the diagram which represents the position of the piston at that point of the stroke to the length of the diagram.

$$ED : EF :: X : \text{length of diagram}$$

$$\tfrac{9}{16} : 3 :: X : 3\tfrac{3}{4}$$

Multiply the two outside terms together.

$$3\tfrac{3}{4} = \frac{15}{4}$$

$$\frac{15}{4} \times \frac{9}{16} = \frac{135}{64}$$

Now divide this by the inside term.

$$\frac{135}{64} \div 3 = \frac{45}{64}$$

"Good. Now measure out on one of your diagrams 45/64 of an inch and see how much pressure you have between the forward and back-pressure lines at that point."

I measured one of the diagrams and found about 72 pounds.

"That," went on the old man, "is the difference between the pressures on both sides of the piston when the crank is at *C*—on each square inch of it. How many square inches are there?"

It was an 18-inch cylinder and I found in the table of areas that it had 254 square inches. Multiplying this by 72 I found that the unbalanced push on the piston was

$$72 \times 254 = 18{,}288 \text{ lb.}$$

"Yes, over nine tons," said the old man. "Pretty good shove, eh? Now, this push acts on the wristpin *D* in the direction *D B*. Let's lay off *D H*, say 5 inches, to represent it. This force is split up into two forces, one that acts through the connecting rod in the direction *D C*, and one that pushes the crosshead down onto the guide in the direction *D J*. Now, if we draw *H J* and *H K* parallel to *D K* and *D J*, we shall have a parallelogram of forces of which *D H* = 18,288 pounds is the diagonal, and the downward force on the guides will be the same part of 18,288 pounds that *D J* is of *D H*, and the shove on the rod will be as much greater than 18,288 pounds as *D K* is greater than *D H*. You can scale it off. For instance, *D H* is 5 inches and represents 18,288 pounds. *D J* is about ⅞ of an inch.

$$DH : DJ :: 18{,}288 : X$$

$$5 : \tfrac{7}{8} :: 18{,}288 : X$$

$$\frac{\tfrac{7}{8} \times 18{,}288}{5} = \frac{7 \times \overset{2286}{\cancel{18{,}288}}}{8 \times 5} = 3200 \text{ lbs}$$

or over a ton and a half.

"If you want to get it more accurate than you can draw and scale it, you can calculate it."

"How?" I asked.

"You have a triangle *O C D* of which you know the length of two sides and one of the angles. A triangle has three sides and three angles. If you know any three of these six properties you can find the rest, but one of the known properties must be a side if you want to get actual lengths. You can get the proportions of the sides if you know only the three angles but not the actual lengths, for a triangle of the same shape may be so small you would need a microscope to see it or as big as all outdoors. Opposite each side of a triangle is an angle. The angle opposite the side *C O* is the angle at *D* which we don't know. The angle opposite the side *C D* is that at *O*, 45 degrees.

"The sides of triangles are proportionate to the sines of their opposite angles. Then, calling the unknown angle at the sharp point of the triangle *a*,

$$CD : \sin 45° :: CO : \sin a$$

Look up a table of sines in that handbook."

I passed him the book open to the table of sines and he showed me that the sine of 45 degrees is 0.70711.

"Now we know that the connecting rod *C D* is 4 times the length of the crank *C O*. Call *C D* 4 and *C O* 1; then

$$4 : 0.70711 :: 1 : \sin a$$

Multiply the two middle terms together and divide by the known end one.

$$\frac{0.70711 \times 1}{4} = 0.17678$$

This is the sine of the angle *a*. Hunt it up in the column of sines."

The nearest that I could find to it was 0.17794.

"That's all right. This table goes by quarter degrees or 15 minutes. That's near enough for our purpose. If we were working astronomy we should have to use finer tables. The sine value 0.17794 corresponds to 10 degrees and 15 minutes. See?"

That was as easy as looking up areas or circumferences.

"Now," continued the old man, "while your've got that angle there see what its tangent is."

I looked in the tangent column on the same line and found 0.18083.

"You don't know what a tangent is, do you?" he asked.

I had heard of things "going off at a tangent" and had a shady idea that it was a straight line hitched onto a circle.

The old man drew Fig. 7. "Here is a piece of a circle," he said, "drawn with a certain radius *O A*. Draw a line as *O B* from the same center and it will include a certain angle. Draw a line perpendicular to the end of the radius up to the line *O B*, bounding the angle, and it will

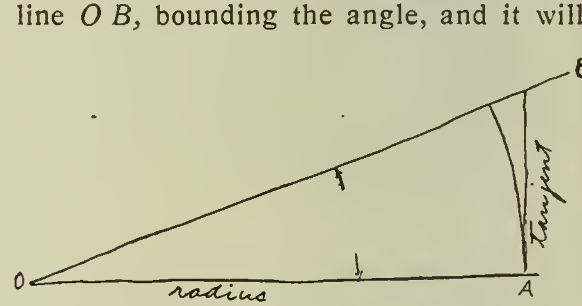

FIG. 7.

be the tangent of that angle. The table tells you what the length of the tangent would be if the length of the radius were unity or 1.

"Well, *H K* (Fig. 6) is the tangent of the angle *a* with a radius of *D H*; that is to say, for an angle of 10 degrees 15 minutes *K H* is 0.18083 of *D H*. Then, since *D H* represents 18,288 pounds, *K H* represents

$$18{,}288 \times 0.18083 = 3292 \text{ lbs.}$$

The Influence of the Cylinder Wall

By Prof. V. Dwelshauvers-Dery

> *In which it is demonstrated that the thermal influence of the cylinder walls depends very little upon the size of the machine and very much on the conditions of operation.*

The theory expounded by Professor Heck in the issue of September 13 last of POWER, under the title "Some Points Favoring Compression," is a complete abstraction of the disturbances brought about in the evolution of the steam by the thermal action of the metallic walls, which, during all the cycle, exchange heat with the steam. It seems that according to his idea this disturbing action will not be of importance except in small machines such as that with which I have operated at the laboratory of the University of Liège—diameter 12 inches, stroke 24 inches, 30 horsepower—but will be negligible for the larger machines, such as are met with in industrial use.

I do not know on what duly established facts he rests this hypothesis. I would like to believe that it is upon experiments made with the same precision as those made at the laboratory of Liège, and I should like to be assured upon this point. Meanwhile, I will try to demonstrate, contrary to his assertion, that the extent of the thermal influence of the cylinder walls depends very little upon the size of the machine and, on the contrary, very much on the conditions of operation. It is only the efficacy of the steam jackets which is reduced in large cylinders, but the evil or beneficial effects of the degree of admission of superheat and of high speed are as marked in the large as in the small machines.

It is this that I shall show, depending upon tests made with the greatest care, by different experimenters, and recorded in various periodicals, notably:

A. Bulletin de la Société Industrielle de Mulhouse Alsace. 1. 1876. Report of Hallauer on eight experiments made in 1873 and 1875 on the famous engine of Logelbach under the direction of G. A. Hirn, by Hallauer, Grosseteste and V. Dwelshauvers-Dery. 2. 1888. V. Dwelshauvers-Dery. New method for representing the exchanges of heat between the metal and steam. 3. 1889. V. Dwelshauvers-Dery. Exposition of the experimental theory of Hirn for single-cylinder machines.

B. Act of the International Congress of Applied Mechanics, held at Paris, September 16 to 21, 1889. 4. V. Dwelshauvers-Dery. Note on various methods of economizing steam in single-cylinder machines.

C. Excerpt from the minutes of the proceedings of the Institution of Civil Engineers, London, Volume XCVIII, Session 1888-1889. 5. Bryan Donkin and V. Dwelshauvers-Dery. Heat expenditure in steam engines.

Of the experiments with which these memoirs deal, seven have been made by Bryan Donkin on a small experimental machine of six indicated horsepower; diameter, 8.4 inches; stroke, 14 inches; revolutions per minute, 90; real degree of expansion, 0.684; clearance, 0.10 of the piston displacement. This engine was provided with a gas-flame jacket, and the object of the test was to compare the performance of the engine with and without the jacket. Of these seven tests we will retain in that which follows only the two carrying the numbers two and four respectively, made without jackets, the first condensing and the second noncondensing; the first on August 9, 1888; the second, July 26 of the same year.

Twelve have been made by Willans, the celebrated English engine builder, in order to determine the effects of differences in speed. They are classed in four series of three tests each: the first with the point of cutoff at 0.437, the second at 0.339, the third at 0.264 and the fourth at 0.216; and in each series the first test at about 400 turns per minute, the second at 200, the third at 100, all noncondensing. The engine is single acting; diameter, 13 inches; stroke, 6 inches; indicated horsepower varying between 35 and 6; clearance, 0.07 of the piston displacement. We will consider here only the three tests of the fourth series, Nos. X, XI and XII, for which the real degree of expansion was 0.28.

Eight tests were made by Hirn on the celebrated engine of Logelbach, operating ordinarily with superheated steam: two in 1873, one November 18 with superheated steam, the other November 28 with saturated steam; six in 1875, all with superheated steam and all condensing save one, that of October 28, which was noncondensing, with degrees of expansion varying between 0.102 and 0.457. Of these eight tests we will retain only three under the respective numbers II, V and VI: No. II, of November 28, 1873, condensing and with saturated steam with an actual degree of expansion of 0.227; No. V, of September 7, 1875, condensing, superheated steam, real degree of expansion 0.162; No. VI, September 9, 1875, condensing, saturated steam, real degree of expansion 0.162.

The dimensions are: Diameter, 24 inches; stroke, 70 inches; clearance, 0.01. The number of revolutions did not vary widely from 30 per minute, and the output was 150 horsepower. The object of the test was multiple. It bore principally on the effect of superheating, of condensation, of the ratio of expansion and the economy of the engine.

We hope that this last machine of 150 indicated horsepower will find grace in the eyes of Professor Heck and will not be, like the two others and that of the laboratory of Liège, considered as too small. In any case it differs sufficiently from those of Donkin and of Willans that one can deduce by experiment the certitude that the size of the machine has not a sensible effect on the disturbances brought about by the exchange of heat between the metal of the cylinder and the working vapor.

Since I have indicated my sources of information it is possible for the reader to verify the conclusions of the tests in question, and of which a table will be found at the end of this article. I have abstained from presenting the data of the tests and have given simply the calculated results, on the subject of which a little preliminary explanation is due.

Contrary to the ordinary theory of the steam engine, the only one which Professor Heck apparently sees, is what experiment has revealed on the action of the heat carried by the steam into the cylinders of our engines.

During admission a part of the inflowing steam condenses against the walls, chilled on the preceding stroke by communication with the condenser.

During the expansion a part of this water condensed on the surface of the walls during admission is revaporated usefully, contributing to increase the exterior work. But ordinarily the water is not entirely evaporated, and there remains at the end of the expansion and at the moment when communication with the condenser is established some still unevaporated.

During exhaust the rest of the water which was on the walls is evaporated simply to pass through the condenser, which constitutes a complete loss so far as work is concerned. For one readily sees that this water thus coming to the condenser has come in the form of steam from the boiler, has passed through the cylinder by the favor of the metal, and has entered the condenser anew under the form of vapor, without having in any fashion contributed to the work done.

We will not talk of the phase of compression in the clearance space in order not to unnecessarily complicate the argument, and in the same spirit, we will neglect the heads and exhaust leads, as well as the small quantity of steam which fills the clearance at the end of the exhaust.

Therefore, during the admission there comes from the boiler into the cylinder a weight M_a pounds of steam, which separates itself into two distinct parts: the one in the gaseous state occupying a volume V_o corresponding to the pressure p_o indicated upon the diagram, of which we will call m_o the weight; the other, in the liquid state, is spread over the surface of the walls, and its weight is $M - m_o$.

The difference $M_a - m_o$ has received the name of missing quantity at the end of admission, and for this reason: In order to estimate m_o, the weight of the saturated steam present in the cylinder at the end of admission, and occupying the volume V_o corresponding to the pressure p_o, one finds in the steam tables the weight d_o pounds per cubic foot of saturated steam, and the product $v_o\ d_o$ is equal to m_o. As to M_a, it is a quantity determined directly by experiment. The ratio

$$\frac{m_o}{M_a} = x_o$$

is called in French *"titre du mélange,"* and in English "quality of the steam."

It is this which it is necessary to know for the discussion of engine economy. This is also true of the ratio

$$\frac{M_a - m_o}{M_a} = 1 - x_o$$

It should not be concluded that the missing quantity is of small importance. In the tests recorded in the final table this quantity $1 - x_o$ varies between 20 and 44 per cent.

In the same way at the end of the expansion there remains in the cylinder a volume v_1 corresponding to saturated steam of the pressure p_1 of which the weight is $V_1\ d_1 = m_1$ pounds. Its quality is, therefore, $x_1 = \frac{m_1}{M_a}$ and the missing quantity equals

$$1 - x_1.$$

Generally during the expansion a part of the $(M_a - m_o)$ pounds of water is evaporated, with the result that one has

$$x_1 > x_o \text{ and } 1 - x_1 < 1 - x_o$$

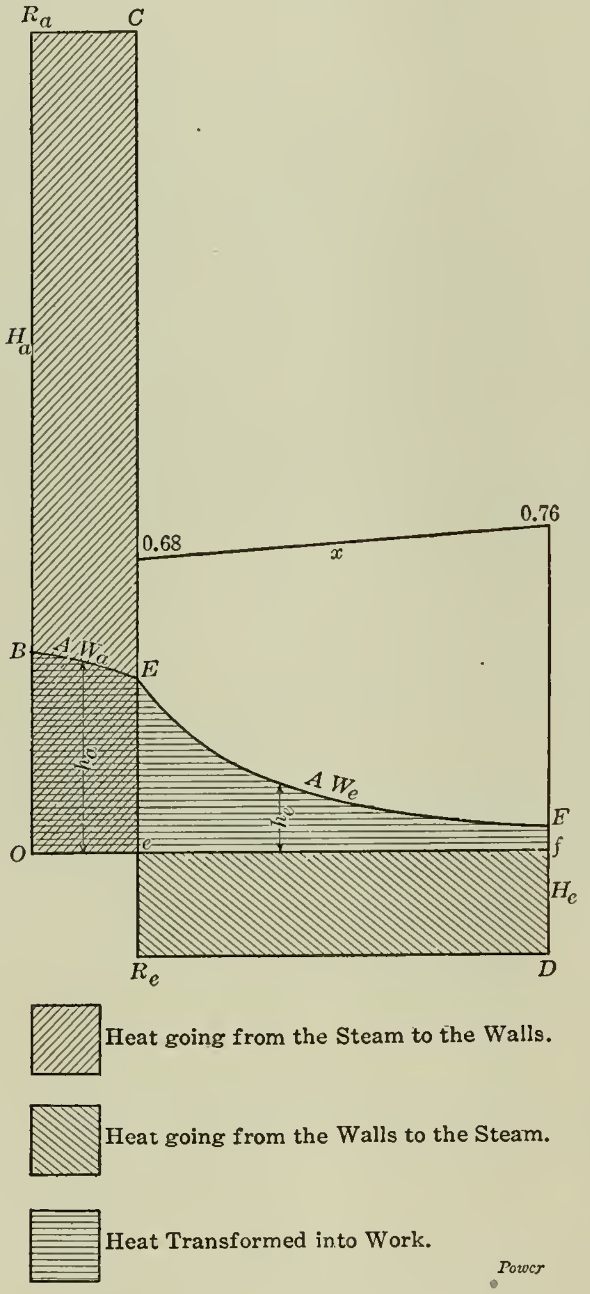
For the eight tests of engines recorded in the final table the values of $1 - x_o$ and of $1 - x_1$ are given. Let us now pass to the valuation of the quantities of heat in play.

The M_a pounds of steam coming into the cylinder for one stroke of the piston bring in Q thermal units, of which a part disappear to produce the work W_a foot-pounds. This part equals $\frac{W_a}{778}$ B.t.u., which we will call $A\ W_a$, representing the reciprocal of 778 by A. A second part, R_a thermal units, represents the heat given up to the metal of the cylinder walls. The rest

$$V_o = Q - A\ W_a - R_a$$

is present in the steam at the commencement of expansion. The experimental theory gives the means to calculate R_a by this equation, in furnishing experimentally the value of V_o, of Q and of $A\ W_a$.

During the expansion the steam which had V_o thermal units at first loses $A\ W_e$ thermal units to produce the work of expansion. It gains the heat R_e thermal units that the walls restore in vaporizing a part of the water which covers them and finishes by still containing U_1 thermal units from now on completely lost, so that



$$U_o - A\ W_e + R_e = U_1$$

Experiments giving the values of U, $A\ W_e$ and U_1 make it possible to deduce the value of R_e from this last equation.

To recapitulate, for the entire stroke of the piston, the heat utilized in work is

$$A\ W_a + A\ W_e = A\ W_f$$

The loss to the cylinder walls,

$$R_a - R_e = R_f$$

Loss by heat of exhaust steam, U_1.

The Diagram of Heat Exchange

Whatever the length of the stroke of the piston in the engine in question, that stroke is represented invariably upon the diagram by a length of two inches $= O\ f$ in the accompanying figure. The fraction of the stroke passed through during admission is represented by $O\ e$, and that during expansion by $e\ f$. The steam line $B\ E$ and the expansion line $E\ F$ of the indicator diagram are traced in upon a convenient scale. Then the area $O\ B\ E\ e\ O$ represents upon a certain scale the heat equivalent of the work performed by W pounds of steam during admission; that is to say, $\frac{W_a}{778}$ B.t.u., that we call $A\ W_a$ in making $A = \frac{1}{778}$.

In the same way and to the same scale the surface $e\ E\ F\ f\ e$ represents the heat equivalent of the work furnished by the steam during expansion. In order to distinguish these areas I have covered them with horizontal rulings.

We will call h_a and h_e respectively the hights of two rectangles, of which the bases will be $O\ e$ and $e\ f$, and of which the surfaces are $A\ W_a$ and $A\ W_e$.

Now, knowing by experiment the quantities of heat R_a furnished by the steam to the metal during admission, and R_e restored by the metal to the steam during expansion, these may be represented by surfaces on the same scale as those proportional to the work effected. In order to represent R_a thermal units a rectangle is drawn, of which the base is $O\ e$ and the hight H_a, calculated from the equation

$$O\ e \times H_a = R_a$$

that is, the rectangle $O\ B\ R_a\ C\ E\ e\ O$. In the same way we proceed to represent R_e, which gives a rectangle having $e\ f$ for the base and H_e for hight, calculated by the equation

$$e\ f \times H_e = R_e$$

The sign for R_a is, however, the contrary of the sign for R_e, the one representing the heat ceded by the steam to the metal, and the other by the metal to the steam. For this reason we place the first rectangle R_a above the axis $O\ f$ and the second below, distinguishing the surfaces besides by different inclinations of the cross-hatching.

The diagram of heat exchange is, therefore, $O\ B\ R_a\ C\ E\ e\ R_e\ D\ f\ O$. It is easy to trace it if one knows the ratio of R_a to $A\ W_a$ and that of R_e to $A\ W_e$, ratios equal to $\frac{x\ H_a}{h_a}$ and $\frac{H_e}{h_e}$ respectively.

We add to the figure a line of which the ordinates represent the quality x of the steam during the expansion, and of which the values are $x_o = 0.68$ at the commencement and $x_1 = 0.76$ at the end. We suppose, although this will not be exact, that the diagram of this quality will be a straight line. The diagram is drawn upon the scale of two inches equals unity. Under the conditions assumed, the heat R_a lost during admission is 4.47 times greater than the heat $A\ W_a$ utilized for the work, and it is greater than the heat R_e restored by the metal during exhaust, with the result that there is a positive loss equal to

$$R_a - R_e = R_f$$

which we will call the final loss R_f. It is important to consider also the ratio of the final loss R_f to the heat equivalent of the final work

$$A W_f = A W_a + A W_e$$

In the accompanying table we give these ratios

$$\frac{R_a}{A W_a}, \quad \frac{R_e}{A W_e}, \quad \frac{R_f}{A W_f}$$

which permit diagrams of the heat exchange for the eight tests of Donkins, Willans and Hirn to be traced. One who has not studied in actual operation the evolutions of steam in the cylinder will perhaps with difficulty believe that the quantity of heat ceded to the metal during the admission can amount to 4.47 times that which represents the work effected during the same period. He will believe without doubt that our diagram is exaggerated, but if he will cast his eyes over our table of experimental data he will see that the figure 4.47 was obtained in text X of the Willans engine at 400 revolutions per minute, and that at 138 the same ratio has increased to 9.20, that in the VI test of the Hirn engine of 150 horsepower this ratio amounted to 6.6, while in the two tests II and IV on the Donkin engine of six horsepower the ratios were 3.55 and 2.67 respectively. In fact, our diagram is very approximately that of test X of Willans as to degree of expansion, as to work diagram, diagrams of exchanges and to qualities x_0 and x_1. Our diagram makes very apparent the relative importance of the heat exchanges between the metal and the steam comparatively to the heat converted into work. It presents this advantage over the entropy diagram, which conceals rather than illustrates the real phenomena and which is plotted only with great difficulty and by graphic calculations impossible to control, while our diagram is based on figures obtained by arithmetical calculations. But let us return to the principal object of our discussion and commence by giving the table of tests chosen as enumerated above.

Is Professor Heck justified in believing that the disturbance brought about by the thermal action of the walls are sensible in small engines and negligible in the larger machines, such as one finds in practice? The accompanying table gives the results obtained on three machines, one large of 150 horsepower, another small of 6 horsepower, the third intermediate of 35 horsepower. It seems to me that the differences are sufficient to show themselves. Well, the examination of the table leads to the following conclusion. The loss by the walls during admission varies according to circumstances from 4.33 to 6.59 in the large machine, 2.67 to 3.55 in the small machine, 4.47 to 9.20 in the intermediate machine.

The restitution by the walls during expansion from 0.80 to 1.22 in the large engine, 1.90 to 2.50 in the small engine, 1.20 to 1.90 in the intermediate engine.

The positive loss by the walls from 0.97 to 1.94 in the large engine, 1.51 to 1.70 in the small engine, 1.08 to 2.30 in the intermediate engine.

The proportion of steam condensed during admission varies from 25 to 37 per cent. in the large engine, 20 to 23 per cent. in the small engine, 32 to 44 per cent. in the intermediate engine.

The proportion of water reëvaporated during expansion varies from 2 to 8 per cent. in the large engine, 3 to 4 per cent. in the small engine, 8 to 10 per cent. in the intermediate engine.

To sum up, the action of the cylinder walls does not vary with the size of the engine, but considerably with the conditions of operation. If this action is more intense in the intermediate machine, it is that this was single-acting, and its walls exposed for one-half of the time to free and cool air.

REJOINDER BY PROF. R. C. HECK

In so far as the foregoing is controversial in form, it is to a large degree based upon misconception, as has been already pointed out. Assumptions and "theories" are attributed without any real foundation in my article of September 13. It is regrettable that the tone of personality should be so strongly injected into a presentation of scientific information, and so much space wasted on the demolition of theories which are now held by no intelligent thinker.

The thesis still stands that in its combination of small size and low speed the engine in the laboratory at Liége is not representative of commercial practice, and that deductions from the results of experiments upon it cannot be directly applied to large or fast-running engines. The same actions exist in large engines, but their relative magnitude is less.

In the foregoing paper the discussion which follows the presentation of references and data, describing the general action of the cylinder walls in causing condensation and reëvaporation and in wasting heat on the exhaust steam, is all common knowledge; no one questions it or is ignorant of it. The scheme of graphical representation of thermal action is one of the recognized methods, although it is doubtful whether engineers in this country ever use it. For most purposes, and especially when considering such an involved and uncertain matter as the way in which the action of the cylinder walls varies in different engines and under different conditions, the mere percentages of steam initially condensed and then reëvaporated constitute a close enough measure of the wall effect.

The Hirn engine which is quoted certainly had a large cylinder, but was of slow speed. However, in the sense of output it was not a large engine; an engine, excluding pumping engines, only begins to be considered large at 500 horsepower. That the Donkin engine shows less condensation than the Hirn engine is accounted for by higher speed and late cutoff, which factors overbalance the smallness of the cylinder. The Willans engine has its marked peculiarities, and besides is no bigger (in piston displacement) than the Donkin engine; as a minor correction, the size is 14x6 inches, not 13x6 inches. Altogether, the data presented are too few and too discordant to give a clear idea of the influence which any of the controlling conditions exert upon cylinder action. These governing conditions are, speed in revolutions per minute (not piston speed), size (with which the type of cylinder design must be included), ratio of cutoff or of expansion, and range of pressure and steam temperature within the cylinder.

Reciprocating Engine and Low Pressure Turbine*

Some interesting figures in support of the low-pressure turbine as used in connection with the reciprocating engine were shown by the tests of the steam yacht "Vanadis." This vessel, which is of 1300 tons displacement and 279 feet length overall, was built in 1908 and fitted with three Parsons turbines, one high-pressure and two low-pressure. The builders guaranteed a coal consumption of 26 tons per 24 hours when cruising at 13 knots, but it was found that in actual service this figure was greatly exceeded, in fact, so much so that the steaming radius with the limited bunker capacity was cut unconveniently short.

To remedy this, it was decided to remove the high-pressure turbine and replace it by a triple-expansion reciprocating engine, leaving the low-pressure turbines connected to the outboard shafts. After the completion of these changes a set of standardization trials were made. First, the propellers were removed from the turbine shaft and the vessel run at 13 knots with the reciprocating engine alone, during which the steam consumption was approximately 17 pounds per indicated horsepower-hour. Next, the propellers were replaced and the reciprocating engine run in connection with the two turbines—a speed of 13 knots being maintained—in which case a water consumption of 14½ pounds per indicated horsepower-hour was attained, as against 20½ pounds before the change was made.

*Abstracted from a paper read by C. H. Crane before the Society of Naval Architects and Marine Engineers.

A Rule of Thumb for Horsepower

By F. R. Low

The horsepower of an engine is the product of the piston area, the piston speed and the mean effective pressure divided by 33,000.

The piston area is 0.7854 times the square of the diameter.

The complete formula then is;

$$H.P. = \frac{0.7854\ D^2 \times \textit{piston speed} \times M.E.P.}{33{,}000}$$

Dividing the 33,000 by the 0.7854 this becomes,

$$H.P. = D^2 \times \frac{\textit{piston speed} \times M.E.P.}{42{,}017}$$

The quantity by which the square of the diameter is to be multiplied will be for the usual case somewhere between 0.5 and unity. When it is unity, i.e., when the product of the piston speed and the mean effective pressure is 42,017, the formula becomes delightfully simple

$$H.P. = D^2.$$

This would be true of any of the combinations of piston speed and mean effective pressure given in the first double column of the accompanying table. A condensing engine might easily have a mean effective pressure of 52.5 pounds and run at 800 feet piston speed, and for such an engine this simple formula would give out of hand an excellent idea of its capacity.

The remaining double columns of the table give the combinations of piston speed and mean effective pressure which would justify the use of the single-place numbers 0.9, 0.8, 0.7, etc., at the heads of the column. The common assumption of 600 feet of piston speed and 40 pounds mean effective pressure would call for 0.57 to which a column is devoted, but 0.6 D^2 would give a close approximation to this condition.

The idea is that the horsepower will usually lie between

$$H.P. = D^2$$

and

$$H.P. = 0.5\ D^2\ or\ \frac{D^2}{2}$$

For simple condensing engines at high piston speeds the first and simpler formula will give a close approximation. With lower piston speeds and mean effective pressures the square of the diameter may have to be multiplied by a factor running down to 0.5 for the conditions given in the last column of the table.

$H.P. = D^2$ $P. \times S. = 42{,}017$		$H.P. = 0.9\ D^2$ $P. \times S. = 37{,}815$		$H.P. = 0.8\ D^2$ $P. \times S. = 33{,}614$		$H.P. = 0.7\ D^2$ $P. \times S. = 29{,}412$		$H.P. = 0.6\ D^2$ $P. \times S. = 25{,}210$		$H.P. = 0.57\ D \approx \frac{D^2}{1.75}$ $P. \times S. = 24{,}000$		$H.P. = 0.5\ D^2 = \frac{D^2}{2}$ $P. \times S. = 21{,}008$

On account of numerous cases of cholera, which it is thought may be traced to that source, the Minister of the Interior of Hungary has forbidden the cutting of ice from ponds and rivers. This would seem to open an unusual opportunity for builders of ice and refrigerating machinery in that country.

A good telltale that will show when a bucket trap is not working or is getting more water than it has capacity to handle can be made by connecting a brass-tube air valve to the top of the trap, which will blow whenever the trap is full of water.

Gas Power Department

Everything worth while in the gas engine and producer industry will be treated here in a way that can be of use to practical men

The Gas Cleansing Plant at the Lackawanna Steel Works*

By E. P. Coleman

At the Buffalo works of the Lackawanna Steel Company is located the first gas-engine power plant to be operated in this country with blast-furnace gas. As far as can be learned, the selection of the type of engine was made in 1900, based on extended observation by a committee of the working of blast-furnace gas-power plants in Europe. The types observed were the Cockerill, Otto, Oechelhaeuser and Koerting. The Oechelhaeuser engine was disregarded on account of the crank-shaft design and the four-stroke cycle engines were not favorably considered on account of exhaust-valve troubles which did not seem to have been mastered at that time. The engines were built by the De La Vergne Machine Company, New York, after designs by the firm of Koerting Brothers, Hanover, Germany.

At this plant 12,000 to 15,000 net horsepower is normally developed by gas engines operated with blast-furnace gas, the greater portion for blowing the furnaces. There are sixteen blowing engines, each rated at 2000 indicated horsepower, and eight electric power units, each consisting of a gas engine rated at 1000 indicated horsepower, direct connected to a 500-kilowatt generator. Four of the latter units generate direct current at 250 volts and the other four generate three-phase 25-cycle alternating currents at 440 volts. All of the engines are of the two-stroke cycle type, equipped with twin cylinders and cranks spaced 90 degrees apart.†

The general arrangement is shown in Fig. 2. There are six blast furnaces in a line extending approximately north and south. These furnaces are grouped in pairs, each pair forming a unit with reference to the arrangement of its stoves, ore bins, gas plant and various auxiliaries. The engines in blowing-engine house No. 2 furnish air for furnaces 3 and 4. Furnaces 5 and 6 are supplied with air by the engines in blowing-engine house No. 3. The air for furnaces 1 and 2 is usually supplied by steam engines located in the north end of blowing-engine house No. 2. The gas-driven electric generator units are located in the south end of power house No. 1.

The general process of preparing the gas for use in the engine cylinders is as follows: The gas leaving the furnace top passes through large downcomer pipes to the dust catcher, where the heavier portion of the dirt is deposited under the action of gravity. From the dust catcher, portions of the gas pass through pipe mains respectively to the hot stoves, the boilers and the gas engines. That portion used by the gas engines is cooled and partially cleaned by means of water sprays in the pipes and chambers through which the gas passes, after which it is further cleaned by passing through centrifugal fans into which water is also sprayed. From the fans the gas passes through separators which remove the entrained moisture and its entrained dirt, and thence under a few ounces of pressure (above atmospheric) to the engine houses.

The six blast furnaces under consideration produce about 2000 long tons of iron per 24 hours, or about 108 tons per hour. The gas amounts to about 150,000 cubic feet per ton of iron, or, say, about 16,000,000 cubic feet per hour or more from the six furnaces. Approximately 2,500,000 cubic feet per hour is used for the gas-engine plant, the remainder being burned in the hot-blast stoves and under the boilers.

All of the dust catchers are provided with a suspended partition or baffle wall of firebrick cutting off direct passage of gas from inlet to outlet; the gas having to pass under this wall and up to the outlet.

Piping

The general arrangement and main dimensions of the piping for washed gas are shown in Fig. 1. Each group of eight blowing engines is served with washed gas through a 60-inch overhead main of riveted steel plate delivering gas to a main header of 96 inches diameter alongside the wall of the engine house near the yard level. The eight 1000-horsepower engines at power house No. 1 are supplied with gas from furnaces 1 and 2 through a 30-inch underground pipe of cast iron. This pipe is cross-connected with the 96-inch header near the south end of blowing-engine house No. 2 by means of a 42-inch overhead pipe. Gas washers 3 and 4 are connected with gas washers 5 and 6 through a 36-inch equalizing pipe, as shown. Low points in the piping are provided with drains. The general arrangement of this piping deserves adverse criticism, as will be shown.

No gas holders are installed or required. The length of the 30-inch main supplying the power house is about 1190 feet. The 60-inch main supplying engine house No. 2 is about 525 feet long, and the 96-inch header at blowing-engine house No. 3 is supplied through about 415 feet of 60-inch pipe. In this main

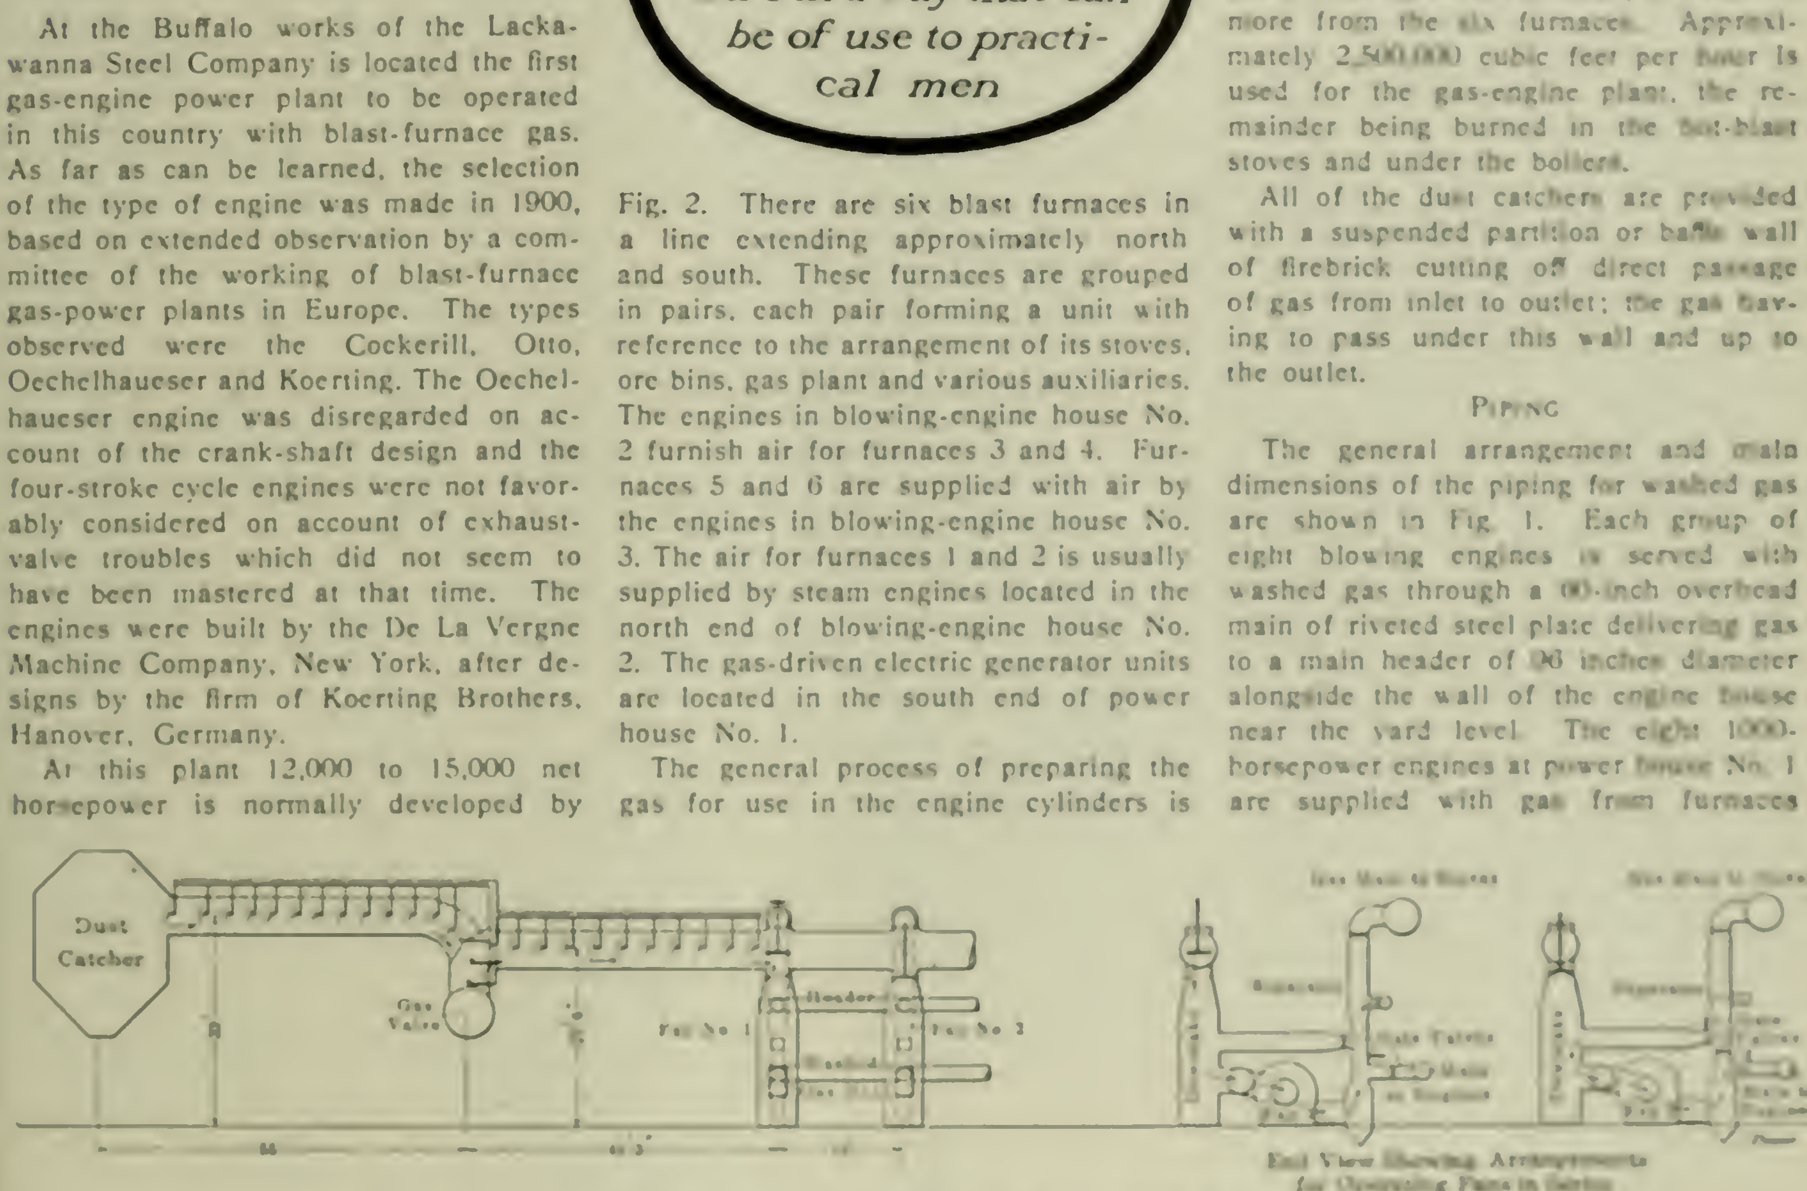

Fig. 1. Schematic Diagram of Gas-washing Plant for Furnaces 1 and 2

*Partial abstract of a paper read before the American Society of Mechanical Engineers, December, 1910.

†These engines were described in Power several years ago; hence a detailed description of them is omitted here.

at the south end of the engine house is a 60-inch venturi meter. The blowing-engine house header lies along the east side of the building. It is supported on the concrete work of the exhaust tunnel and is about 400 feet long. The 8-foot section is 255 feet long and is of riveted ⅜-inch plate. The plates of the 6-foot portion are 5/16 inch thick. A 24-inch connection is taken off for each engine on the side nearest the building. Water is drained from the header by means of an inverted siphon. The total length of piping from the washers to the engine houses is about 3800 feet.

Nos. 1 and 2 Gas Washers

There is a gas-cleaning plant at each pair of furnaces consisting of chambers equipped with water sprays for cooling the gas and washing out a portion of the dirt, centrifugal fans also provided with water sprays, separators for removing the entrained water, and the necessary valves and piping. Schematic diagrams, Figs. 1 and 3, show the general arrangement of the washing plants, the former illustrating the washery first installed at furnaces 1 and 2, and Fig. 3 the arrangement of apparatus at furnaces 3 and 4. The general arrangement of washers at furnaces 5 and 6 is similar to that at furnaces 3 and 4. In the plant represented in Fig. 1 the gas is taken from the dust catchers through horizontal pipes where it is given an initial cooling and washing by means of water sprays. The cool gas then passes to four fan washers located between the two furnaces. These fans are normally operated in pairs, each pair forming a unit consisting of the two fans operating in series with each other; the first fan draws cool gas from the main supply and discharges it to a first-washed main, and the second fan takes its gas from this main and discharges it to the second-washed main, from which the gas passes to the 30-inch gas line and to the power house.

The pipe leading from the dust catcher to the fans is 70 inches in diameter. At a point about midway between the fans and the dust catcher a water-seal valve is located, consisting of a horizontal steel tank 8 feet in diameter, through which the gas passes on its way to the fans. By filling with water it acts as a shut-off valve and by partly filling with water the gas flow may be reduced to any desired extent, these functions being useful when a furnace is working badly and giving a poor quality of gas. The 8-foot tank also serves as a receptacle to which the water is drained from the cooling sprays.

The 70-inch pipe connecting the dust catchers to the fans is about 236 feet long, the total travel of the gas from dust catcher to fan being about 123 feet. Located in this piping are 99 water sprays for cooling the gas on its way to the fan washers. These spray nozzles are located at the axis of the pipe, about 3 feet 6 inches apart, and discharge a cone-shaped spray into and against the stream of gas. The sprays are supplied from a 3-inch header through 1-inch pipe connections and each spray consumes about 8 gallons of water per minute. The water drains first into the 8-foot tanks and from thence through a seal into tank cars beneath, where the dirt is deposited and the water passes off from an overflow into the general drainage system.

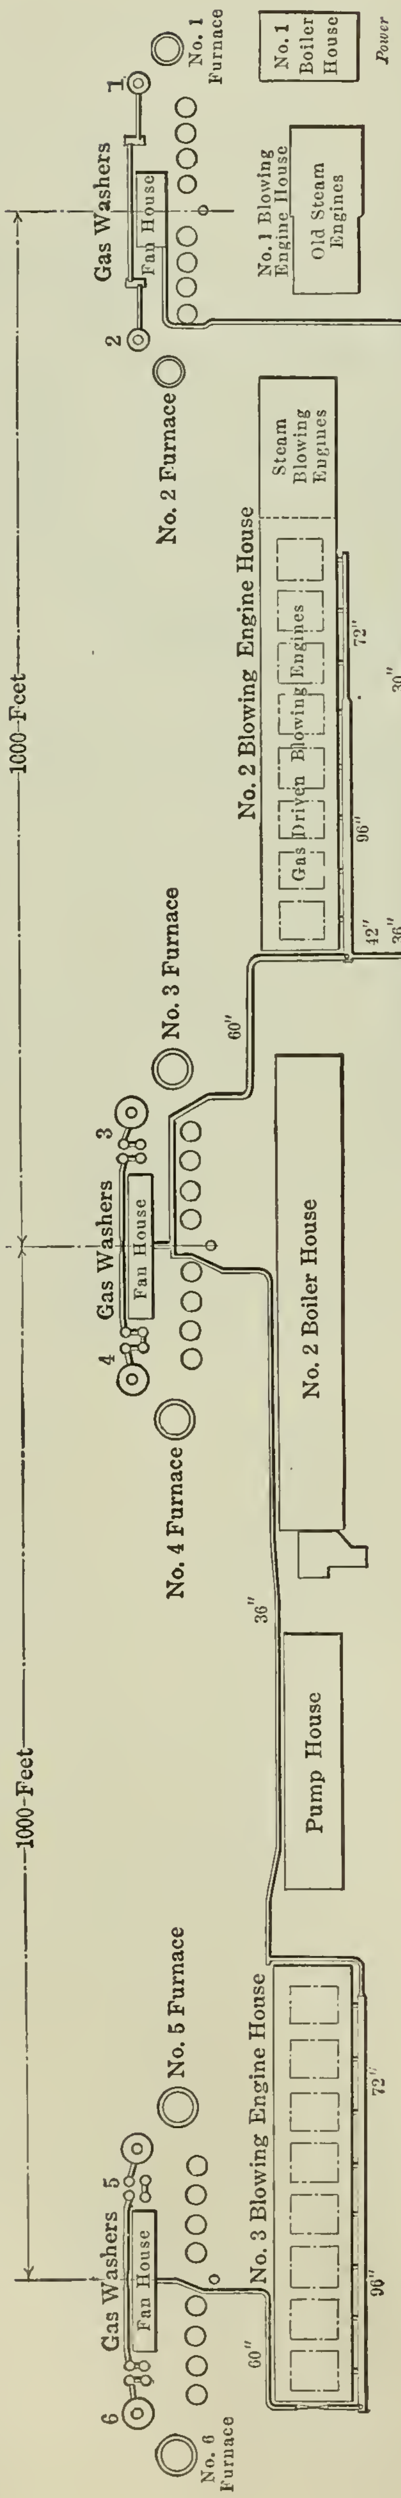

Fig. 2. Plan Diagram of Furnaces, Washers and Power Houses of Lackawanna Steel Works

The connections to the fans are taken from the bottom of the 70-inch main, the connection being 48 inches in diameter, enlarging to 70 inches diameter. Each connection can be shut off from the gas pipe by means of a disk valve operated by a chain drum and handwheel located on top of the gas pipe, and each connection is provided with a hopper bottom, valve and drain, forming a pocket for the mud and water brought down with the gas. The drain pipe extends downward into a well, forming a seal.

The fans are very similar in general features to ordinary centrifugal ventilating fans. The wheels are 6 feet 11 inches in diameter. There are 8 blades, each 15½ inches wide at the inner end and 13 inches wide at the tip, carried on tee-iron arms set in a cast-iron hub. The cast-iron suction connections are rectangular. The main is 20¼x52 inches. A branch 21x48 inches leads to each side of the fan, the opening to the fan casing being 36 inches in diameter. These connections are provided with cleaning holes to facilitate removal of mud. Water connections are provided for four nozzles on each side carried through the casing and discharging through the circular inlet to the fan. Waste water from the furnace tuyeres and bosh plates flows from the furnace troughs into a stand pipe equipped with an overflow located at the proper level, and a portion of the water in the stand pipe passes through pipes to the fans.

Each fan is driven by a 75-horsepower electric motor direct connected to the fan by means of a flexible coupling, and each one discharges horizontally at the bottom through a 21½x45-inch connection into a water separator. The separator is a steel box 4 feet square by 9 feet high, containing a set of baffles consisting of three rows of 3-inch steel channels, the flanges of the channel bars facing the stream. The openings between channels are about 1 inch wide, and the spacing is alternate or staggered, such that the streams of gas are broken and turned. The separated water and mud drop to the bottom of the separator and pass out through a seal. The gas leaves the separator at the top through a 24-inch pipe connection.

First-washed gas which has passed through one fan passes back into one of the 70-inch vertical connections on the cool gas main, and is isolated from it by means of the disk valve at the top, previously mentioned. The gas then flows through the second-wash fan to the second-washed gas main; and thence through the 30-inch line to the power house. The piping and valves are so arranged that any fan may be used for either first or second washing. The valves in the fan connections are 24-inch gates, with seats and disks of cast iron.

Nos. 3 and 4 Gas Washers

In the washing plant shown in Fig. 3, the gas passes from the dry-dust catcher through a 96-inch connection leading to a set of four cooling towers 12 feet in diameter and 72 feet high. The cooling water is sprayed into these towers through numerous nozzles set in the sides. The first-washed gas passes from the fans through a water separator into a 78-inch header called the first-wash main, from which it is passed back to the suction side of the fans working on second washing, these being shut off from the cooled-gas main. From these fans the gas passes through the separators and into the second-washed main of 60 inches diameter. The 60-inch main supplying the engines is connected to the middle point of this header.

The four cooling towers are carried on a structural platform which is located 18¼ feet above yard level to provide clearance for mud cars which receive the drainage from the bottom connections. The connections between the towers are 8 feet in diameter and the travel of the gas is up and down in alternate towers. Each tower is provided with a hopper bottom and pipe seal having connection with a common drain pipe which delivers the discharge of all four towers to the tank cars beneath. Towers *A* and *B* are further provided with emergency seal drains at a higher level. These emergency seals are normally idle, but should the bottom drain become clogged the tower will then drain through the emergency seal. Tower *A* is also provided with a steel plate baffle in front of the inlet opening. When the tower is filled with water to the required hight the water and baffle serve as a valve to shut off communication between the towers and the dry-dust catcher, a sealed overflow maintaining the proper water level when desired.

The first tower is equipped with about 30 sprays, the second has 35, and the third and fourth about 20 to 25 sprays each. The sprays are placed in five circular rows, 6 feet apart vertically; the lower row is about 20 feet from base of tower. The nozzles are of brass throughout, and made as shown in Fig. 4. The shell has a 2½-inch external pipe thread which screws into a flange riveted to the shell of the tower. The helical passage produces a whirling cone-shaped spray of about 90 degrees "spread" and 6 to 10 feet maximum diameter. The 1½-inch plug permits access to the spindle for cleaning. These sprays use about 7 gallons per minute at the average pressure carried.

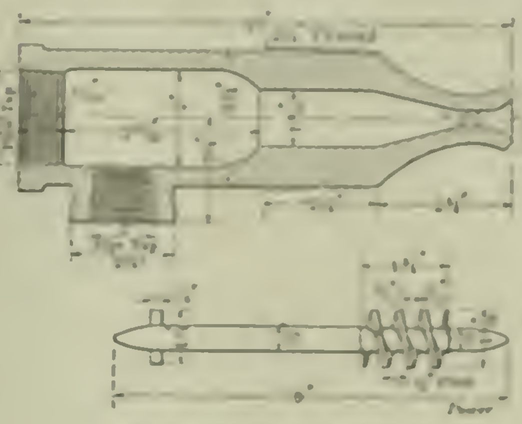

Fig. 4. Spray Nozzle

From the towers the gas passes through a 7-foot pipe to the fans. This pipe also is provided with nozzles which spray water into and against the stream of gas, the nozzles being located at the center of pipe. The gas leaves the cooled-gas main at the bottom and passes to the fans through vertical suction connections. The latter have hoppers and water-sealed drains at the lower end and may be shut off from the cooled-gas main by means of bell valves operated by a winch and handwheels located on top of the horizontal main. These valves seat in a water seal. The opening is of 45 inches diameter. At the midpoint of the cooled-gas main connecting the two sets of towers is located a shut-off valve consisting of an inverted siphon which may be partly or wholly filled with water to regulate the amount of gas coming from either furnace.

There are eight fan washers housed in a steel-frame building and set with their shaft centers 9 feet 8 inches above the yard level, this elevation being necessary for drainage. The wheels are of ¼-inch steel plate, 7 feet 1 inch in diameter, having eight blades each 29½ inches wide at the inner end, and 27½ inches wide at the tip. The central opening of wheel is 40 inches in diameter. The casing is of cast iron and of the double-suction type; each branch of the suction connection is rectangular, 20x50 inches, opening into the fan through a 36-inch diameter inlet. The bottom-discharge connection is 40x36 inches. The wheel shaft is direct connected through a flexible coupling to a 100-horsepower motor running at 480 revolutions per minute. Six of these motors utilize alternating current and two direct current. The two types are used so that should there be an accident to either circuit, the motors on the remaining circuit will continue to operate and keep a part of the engines running until the necessary corrections can be made.

Water is thrown into each fan through 16 spray nozzles. Eight of these discharge into the central inlet openings, four on each side; the other eight discharge into the fan through the upper half of its periphery. The sprays are fed by four 1½-inch lines connected to a 6-inch header extending the full length of the building, over the fans. Each spray connection is a ¾-inch pipe. The water for the fan sprays is taken from the waste of bosh-cooling water from the furnace, which overflows from a stand-pipe, a portion under the necessary head going to the fans.

From the fan washers the gas passes to water separators constructed as follows

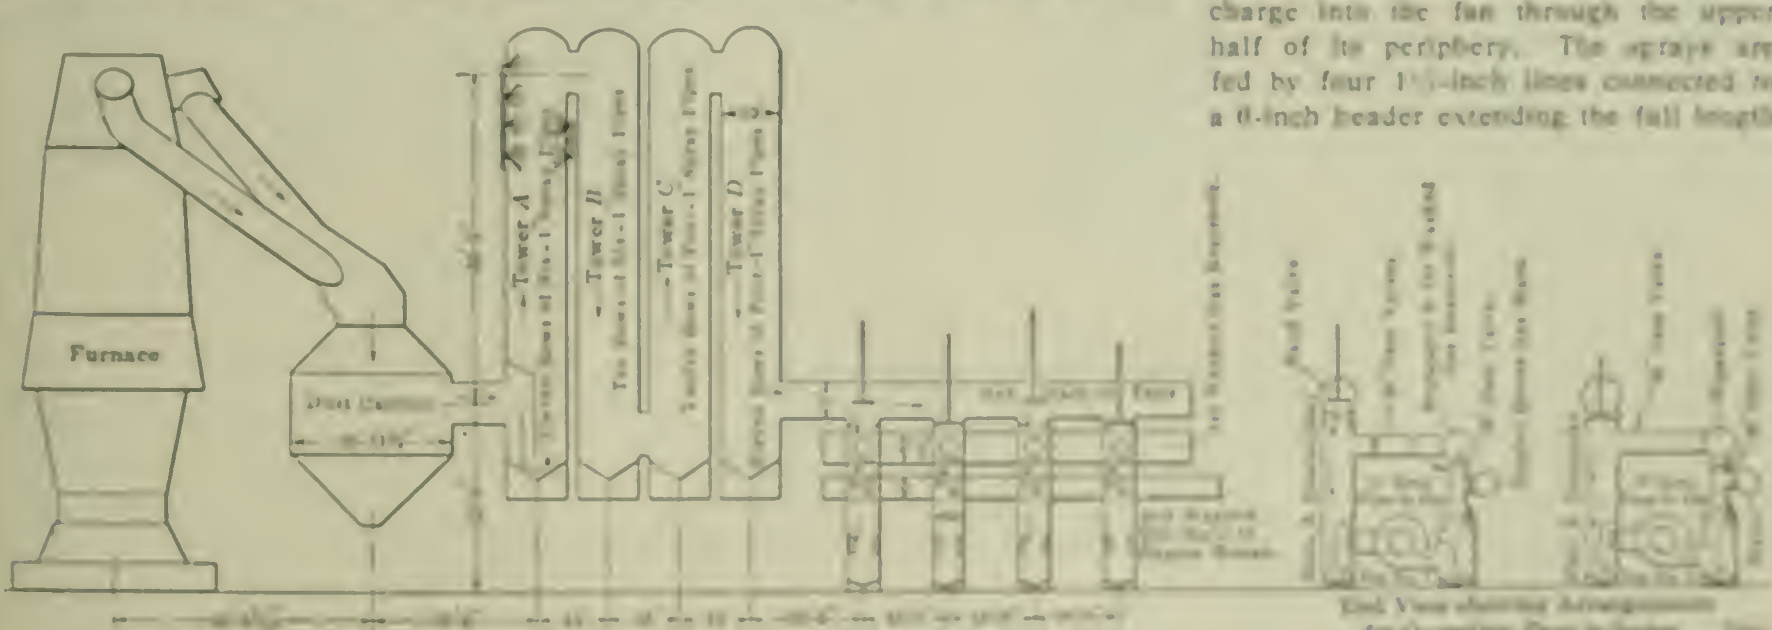

Fig. 3. Schematic Diagram of Gas-washing Plant for Furnaces 3 and 4

in Fig. 5. The gas passes first through a set of baffles consisting of four rows of 4-inch channels set vertically, the openings between the channels being 1½ inches wide, with staggered spacing so that the streams of gas are broken and turned. The separated water falls down the vertical channels, carrying with it the dirt, and passes out at the bottom through a seal to the drainage system. After passing through the channel baffle, the gas rises through annular disk baffles and passes from the separator through a 36-inch top connection.

Each separator is equipped at the top with a cast-iron tee providing outlets through 36-inch gate valves to the first-washed and second-washed mains. Fans working on first washing discharge their gas into the first-washed main. This gas is then taken by the fans working on second washing and by them discharged into the second-washed main. The diameters of the first- and second-washed mains are 78 inches and 60 inches. The first-washed main extends the full length of the fan house, and is connected to the vertical suction connection of each fan through a 42-inch gate valve. The valves and piping are so arranged that any fan may be operated on either first or second washing.

The gas-washing plant at furnaces 5 and 6 is substantially the same as that described for furnaces 3 and 4, but the water separators have a different style of baffling. One of these separators is shown in Fig. 6. The gas circulates through zigzag passages formed by narrow plates assembled as shown. The projecting edges of plates are formed to catch the water and lead it to the bottom of the chamber, where it passes out through a seal. There are two sets of baffles through which the gas passes in succession, one at the bottom and one at the top.

General

The delivery mains from the three gas-cleaning plants are interconnected by two pressure-equalizing pipes. These mains for hot gas, cooled gas and washed gas are locally interconnected in parallel relation at each pair of furnaces. It is therefore possible to control the amount of gas taken from each furnace and the gases from the two furnaces are thoroughly mixed by discharging into a common washed-gas delivery main. In order to promote in the best manner uniformity in the composition of the gas, the joint delivery from the several washeries should then discharge into a common distributing main or holder. The locations of the three delivery mains, however, and the relative locations of the two equalizing pipes are such that it is impossible for such mixing to occur even locally or approximately, as reference to Fig.1 will make clear.

A partial solution constituting a great improvement would consist in relocating the 30-inch delivery pipe from washers Nos. 1 and 2 along the west wall of blowing house No. 2, to form a junction at the southwest corner of that building with the 60-inch delivery main from washers Nos. 3 and 4. Also the 36-inch equalizing main should deliver gas into the 60-inch delivery main from washers Nos. 5 and 6, instead of into the north end of the 96-inch header at blowing house No. 3. Power house No. 1 and blowing house No. 2 would then receive the average of gas from four furnaces, whereas at present blowing house No. 2 receives gas only from furnaces 3 and 4, and at power house No. 1, the four north engines may receive gas from furnaces 1 and 2, and the four south engines from furnaces 3 and 4. Under these conditions of piping, the gas supply at any point is but an average of that from two furnaces, and at times the irregularity is considerable, the heat value occasionally varying between the limits of 105 and 80 B.t.u. per cubic foot, within a period of a few seconds.

Both the gas-cleaning apparatus and the gas engines were installed at an early stage in the history of the art and are necessarily imperfect when compared with modern examples to which have been applied those refinements that can be gained only through experience. The average dust content of the gas delivered to the second-washed main amounts to about 0.022 to 0.035 grain per cubic foot, which would rightly be considered bad practice in modern gas-cleaning plants.

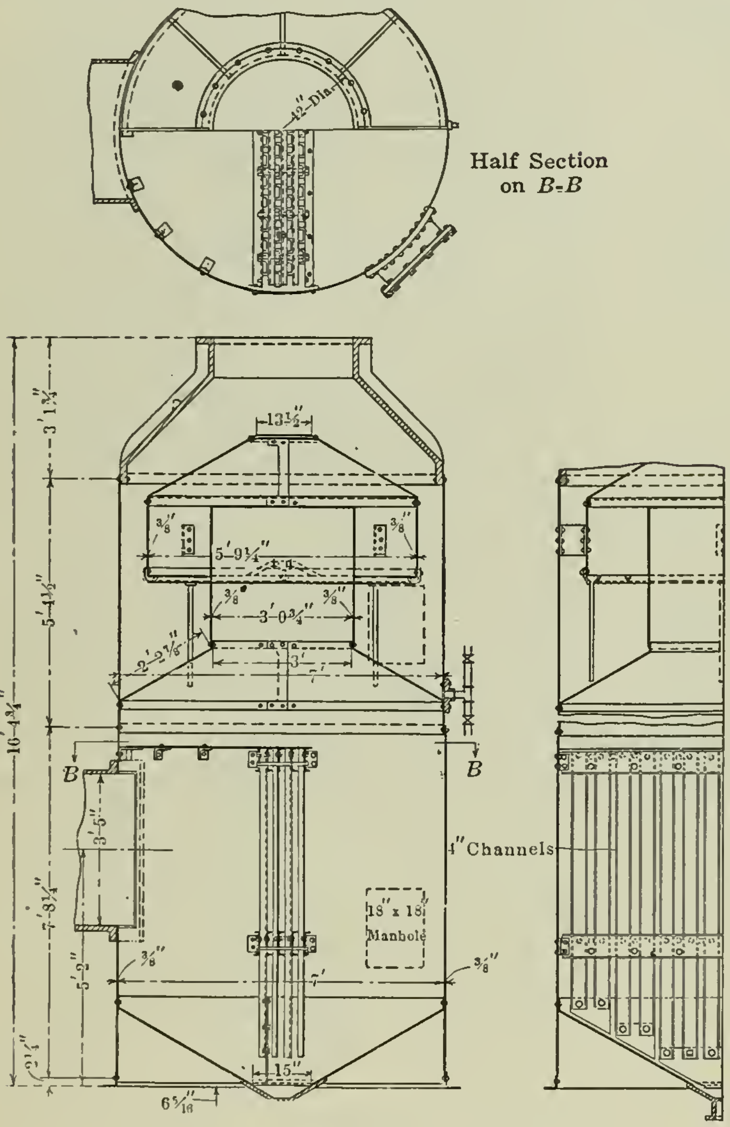

Fig. 5. Water Separator at Gas Washers of Furnaces 3 and 4

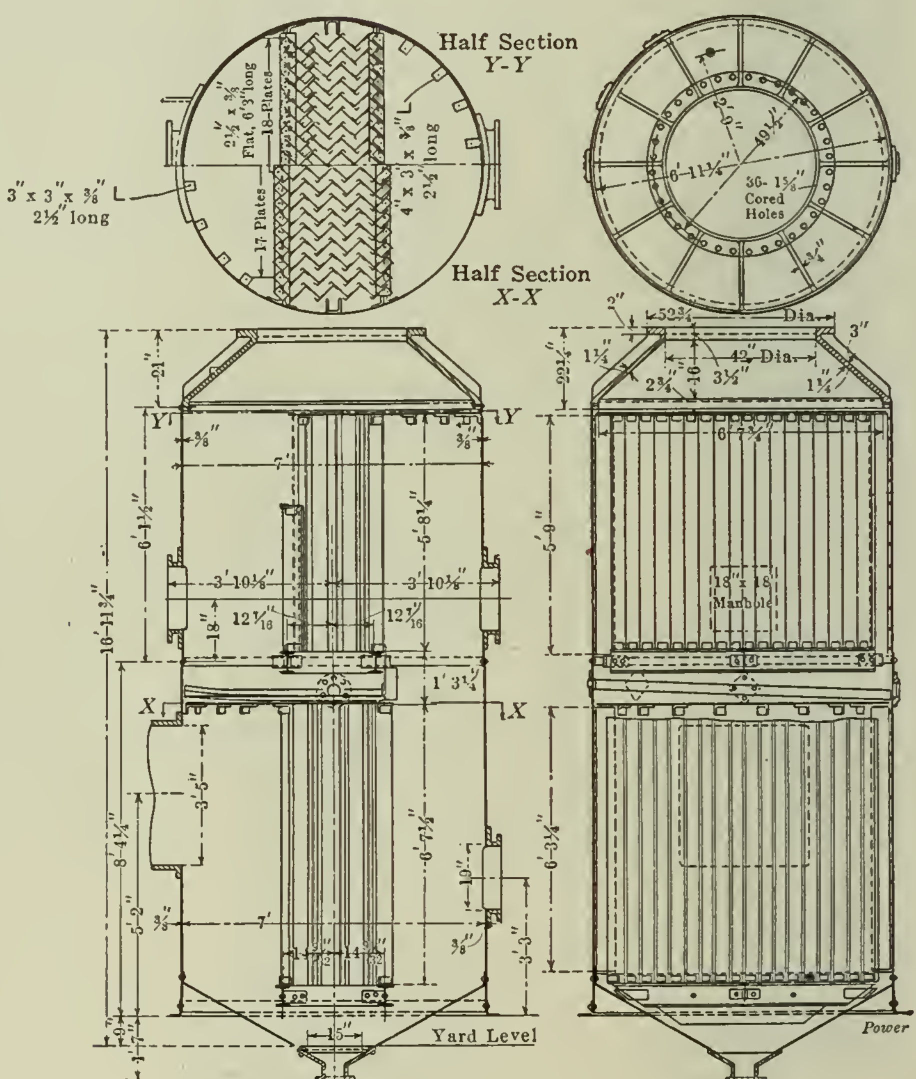

Fig. 6. Water Separator at Gas Washers of Furnaces 5 and 6

The cleaning of the gas at washers Nos. 1 and 2 is less complete than that at washers Nos. 3 to 6. At the two former the dust content in second-washed gas as delivered averages about 0.035 grain per cubic foot. At gas washers Nos. 3 and 4 the average dust content is about 0.328 grain per cubic foot of cooled gas, 0.061 grain in first-washed, and 0.022 grain per cubic foot in second-washed gas.

The gas supplied through the 30-inch main to power house No. 1, therefore, contains more dirt and moisture than that delivered from washers Nos. 3 to 6, in consequence of which there is more trouble with dirt at the power house than at the blowing-engine houses. Moreover, the long 8-foot gas headers at the blowing-engine houses are of probable value in taking moisture out of the gas.

Discussion

In the discussion of Mr. Coleman's paper, George D. Conlee paid tribute to the painstaking thoroughness with which the tests described in the paper had been made and brought out some interesting points regarding some indicator diagrams which were shown in an appendix to the paper.

Louis Doelling, vice-president of the De La Vergne Machine Company, said that the troubles that had been experienced with these engines were due partly to errors in design but largely to dirty gas. The dust in the gas now runs from 30 to 80 milligrams per cubic meter and four years ago it was often as high as 200, whereas good practice puts the limit at 20 milligrams. In the early days, too, the gas was unstable; there were sudden rises of hydrogen due to water getting into the furnaces, and these produced premature ignitions, causing excessive wear and repairs. With clean gas a cylinder ought to run five years before requiring reboring.

The high gas consumption (18,500 B.t.u. per blowing cylinder horsepower-hour) of the Lackawanna engines, Mr. Doelling explained, was due largely to the excessive power consumed by the gas and air pumps and the loss of gas during the final half of the scavenging period. In later engines the pump loss is much smaller by reason of the use of poppet valves and the reduction of the maximum pump pressure from 10 to 4 pounds per square inch. The later engines regulate much more closely also, due to the control of the air and gas taken in by the pumps instead of bypassing the pumps; this gives sufficiently close regulation even for cotton-mill work.

George A. Orrok explained that the Lackawanna power houses are situated unfortunately in that they are between a row of blast furnaces and a row of Bessemer converters, each row being about 60 feet from the power houses. The result is that coke and ore dust from the furnaces and steel dust from the converters are constantly blown into the engine rooms and settle all over the engines. He expressed wonder that the engines would run at all under the existing conditions.

Fan Dynamometer for Testing Stationary Engines

The fan dynamometer designed by Joseph Tracy, the well known automobile expert, for testing small gasolene engines* has been adapted by Mr. Tracy to the testing of stationary gas and oil engines of moderate output. The accompanying picture shows the machine as made for this purpose. It is equipped with a pulley of a diameter which is a submultiple of the diameter of the engine pulley and the fan arm and vanes are made so that the vanes can be adjusted toward and away from the shaft by small increments, according to the amount of power to be absorbed. The arm bears a scale for each fan vane, and the dial of the indicator is graduated

Tracy Fan Dynamometer

with a power scale corresponding to each position of the vanes on their scales. Consequently, the power absorbed at any setting of the vanes can be read directly from the indicator dial.

Because of the difference between the diameters of the engine and dynamometer pulleys, the engine speed cannot be read directly from the speed scale, but by using a convenient diameter ratio, such as 2, 3 or 4, the engine speed is, of course, calculated instantly from the dial indication.

It is evident that there must be a slight loss in both speed and power by reason of the belt slippage. For this reason Mr. Tracy does not recommend the dynamometer for making close efficiency tests or fuel-economy tests. It is intended for determining approximately the maximum ability of an engine and for supplying an artificial load while "running in" an engine or testing its endurance.

Gas Power Progress during the Past Decade*

By J. R. Bibbins

Since the beginning of the present century there has been considerable progress in the field of gas power. In size, engines have developed from single-acting units of 100 horsepower or so to double-acting tandem units of 4000 to 5000 horsepower designed for and operating under the same conditions as the steam engine. Producer units have developed from a diminutive 50-horsepower size up to 1000 horsepower or more and the problem of gasifying bituminous fuels is well along toward solution; the practice is tending in the direction of the induced-draft type for both large and small units with the self-contained vaporizer. Opinion is somewhat divided on the tar question but all efforts are directed toward the elimination of this undesirable byproduct by gasifying it.

In its varied applications the direct-combustion principle has indeed achieved success. The gas engine has made possible the submarine, the motor boat, the automobile and the aeroplane. The aeroplane motor affords an object lesson in the results of high relative speeds. The motor of the "Antoinette" weighs only 3½ pounds per horsepower and the "Gnome" aeroplane motor weighs still less.

The gas-electric motor car is another interesting development in railroad practice for service on extensions or suburban branches where steam locomotives are not warranted. The car is propelled by standard railway motors supplied from a generator driven by a compact 8-cylinder gasolene engine located in the cab. Sixty-seat coaches usually make a schedule speed of 25 miles an hour, including stops, and demonstration runs have shown a fuel economy of 0.30 to 0.48 gallon of gasolene per car-mile.

In the way of conservation, there is the utilization of blast-furnace gas, coke-oven gas and byproduct oil gas from refineries, as well as the use of low-grade fuels unsuitable for steam making. A power plant is now being built for utilizing waste cupola gas, which has a heat value of about 90 B.t.u. and requires about 200 pounds compression in the engine.

By reason of its high efficiency the gas-driven pump has been adopted for water-works service, sewage disposal, hydraulic excavation and long-distance gas transmission. The absence of standby losses makes it equally desirable in emergency service such as fire protection, auxiliary power supply and canal-lock operation.

*Abstract of preliminary address [illegible] Gas Power Section, A. S. M. E., at the annual meeting, December, 1910.

Gas-engine Details

The development of the heavy-duty double-acting gas engine has been accompanied by certain interesting features. The side-crank type has been generally preferred to the foreign center-crank construction. Dry metallic-rod packing has been substituted for the elaborately water-cooled kind. Valve mechanism has been simplified by using a single cam to open both the inlet and the exhaust valves. Mixing is now done only at the inlet valves, minimizing the results of a back-fire and contributing to uniform mixture quality at all valves by eliminating fluid-inertia effects.

The electromagnetic igniter has found much favor by reason of its simplicity and the feasibility of using several igniters in each combustion chamber without entailing complex mechanism.

The series system of water circulation has reduced water consumption and also the troubles from the sweating of rods working in high-sulphur gas. The foreign practice of cambering piston rods is not followed here. With light pistons the rod flexure is not greater than is desirable to keep the sectional packing free.

Desired Features

A serious handicap in industrial work is the inability of the gas engine to supply enough exhaust heat to warm a factory. Some progress has been made with the exhaust heater but the 5000 or 6000 B.t.u. per brake horsepower-hour available from an engine is not sufficient to do the work. Some system including an auxiliary gas-burning heater must be worked out.

More convenient and practical methods of measuring the volume and heat value of gases should be provided. Some large plants have adopted the venturi meter, but even this simple apparatus is sensitive to deposits in the throat. A continuously recording calorimeter is greatly needed, and some progress is being made in this direction.

There is a disposition to discount the demand for large engine and producer units. With steam-turbine units increasing rapidly in size the gas-power industry must respond in kind or have the gas engine remain an auxiliary for special conditions.

Education of the operator, the salesman and the manufacturer is essential. The great mistake is made in partial education—an incomplete understanding of the conditions, a make-shift equipment and a jealous guarding of knowledge of defects. The results are loss of confidence, dissatisfaction and failure.

Power from Crude Oil

Development of the oil engine has made great progress abroad since the expiration of the basic Diesel patents. Two of the principal builders have turned out 250,000 horsepower in engines, some of which rated as high as 1000 horsepower per cylinder. The smaller engines mostly work on the four-stroke cycle, but above 1000 horsepower the two-stroke cycle prevails.

In the various experiments with oil-gas producers the small progress has been discouraging. Two systems have been used, the retort and the partial combustion. In the former, difficulties with carbon deposition in the retorts are encountered; in the latter, excessive production of lamp black. Both are hopelessly low in efficiency as compared with the oil-burning steam plant. A large oil-gas plant in California, operating gas engines as water-power auxiliaries, endeavors to apply to power purposes mixed gas, consisting of part retort and part carbureted water gas, utilizing the carbon deposits of the former as briquets in the latter process. In this mixed gas, the hydrogen content is kept down to about 30 per cent., but in the oil gas it is very much higher, 40 to 60 per cent. For straight power purposes the combustion producer seems more promising both in simplicity and efficiency.

Peat

We have looked to Canada for important developments in the use of peat, but private experiments have failed so signally that the Government has started a peat-manufacturing and power plant to demonstrate the process on a commercial scale and reëstablish confidence in this industry. Director Haanel, of the Bureau of Mines, thus summarizes his investigations: Artifical drying processes have failed commercially and a machine process must be substituted for the manual labor. The department is, therefore, proceeding along European lines of established success. He states that Russia alone produced 4,000,000 tons of peat fuel in one year—1900. Peat containing not over 25 to 30 per cent. of water has been found an ideal fuel for gas-producer work, requiring no additional steam and being quite free from high temperature and clinker. The long series of fuel tests at Montreal have served to confirm the results of our Government tests on lignites in demonstrating the great possibilities of these lignite deposits, especially in the Canadian northwest.

Gas Engine Troubles

A remarkable array of facts on gas-engine troubles was presented by Charles Kratsch in a paper before the National Gas and Gasoline Engine Trades Association during its recent meeting at Racine. The information was collected from the trouble calls arising from one hundred engines ranging from one horsepower to 125 horsepower multiple-cylinder verticals for generating electric current; the makes included nearly all types from the old slide-valve Otto of thirty years ago up to the modern types which are on the market today.

Seven per cent. of the failures came under the classification of causes due to installation. Among these causes were "engines installed by the purchaser to save first cost; gas bag too far from the engine; no coil in the ignition circuit; cooling water reduced so that the engine overheated, and cam-shaft gears not in mesh properly."

Thirteen per cent. of the failures were classed as causes due to fuel. The principal one of these was the location of the supply tank too far from the engine to feed sufficient fuel at all times; faulty fuel supply due to carbureters or mixing valves; fuel-supply pumps, or clogged piping was another.

Ten per cent. of the failures were due to lack of proper instructions for operation, some of the results of which were too much or too little gas; no cylinder oil; too much or too little cooling water; weak or dead batteries; defective or improperly adjusted vibrator on spark coil; parts put together wrong after the Saturday night tinkering.

Five per cent. were classed as due to faulty construction, under which head came defective parts blamable to design, such as crank shafts of too small dimensions; insufficient valve area; valves opening late or for too short a time; not enough lift to valves for perfect mixture or clear exhaust; bad gasket faces, causing water leaks.

Seventeen per cent. came under the head of causes due to natural wear and accident, of which the following were cited: worn cylinders; shafts cut, sprung or crystallized; valves needing regrinding; governor fingers worn out; lost motion in bearing brasses; loose flywheel; gaskets blown out; crystallization of connecting-rod studs; general overhauling; engine totally wrecked.

Nineteen per cent. were classified as causes due to ignition troubles, as follows: parts inside the engine damaged by wear and neglect; movable electrodes worn out; igniter plugs requiring new bushings, new points, springs, etc.

Twenty-nine per cent. of the failures were due to equipment and accessories and nearly one-half of these were troubles that could have been anticipated and shutdowns eliminated if an extra igniter had been furnished. Eleven of the 29 per cent. in the "accessories" class were ignition troubles caused by poor wire, defective switches, bad installation of wiring, poorly connected terminals, wires short-circuited through poor insulation, burned-out coils, poor magnetos and cheap batteries. The remainder of this division were troubles due to igniter points being burned off by excessive ignition current, the current being supplied by small generators driven at too high speeds or from lighting circuits presumably of too high voltage.

Electrical Department

Especially conducted to be of interest and service to the men in charge of the electrical equipment

Electrical Barring Machine

The accompanying engraving shows a simple and compact motor-driven appliance devised by the American Ship

ELECTRIC BARRING MACHINE

Windlass Company, Providence, R. I. to do away with the difficulty attending the turning over of a large engine at the works of the Stanley Company, Bridgewater, Mass. The illustration shows the barring machine geared to the flywheel of a 32- and 36-inch by 60-inch engine, nominally rated at 2000 horsepower, and running at 75 revolutions per minute.

The machine consists merely of an electric motor worm-geared to the "barring" shaft, which carries on its outboard end a spur pinion meshing with an internal gear bolted to the inner rim of the 20-foot 75-ton flywheel. When the machine is not in use, the pinion is drawn out of mehs with the gear by means of a hand lever which slides the complete machine along rails on the bedplate. The motor is an 11-horsepower Westinghouse machine, which runs at 700 revolutions per minute on a 220-volt direct-current circuit. It turns the flywheel through one revolution in about a minute. It is especially wound for heavy starting torque and is provided with a reversing controller having five forward and five reverse positions.

An alarm bell is so connected with the outfit that it rings during the entire time that the pinion is in contact with the gear on the rim of the flywheel, thereby reminding the operator to throw the pinion and gear out of mesh before starting the engine.

The Electrical Equipment of a Large Department Store

By Norman G. Meade

The Gimbel building, located at the intersection of Broadway and Sixth avenue between Thirty-second and Thirty-third streets, New York, is the largest one in the country devoted to retail mercantile purposes. The electrical installation consists of approximately 25,000 incandescent lamps, 30 electric passenger elevators, 10 electric freight elevators and package conveyors, ventilating fans, pumps and the multitude of an auxiliary apparatus that is usually included in the equipment of a large building. The supply of electricity is obtained from the Waterside plant of the New York Edison Company.

Owing to the size and nature of the installation it was deemed expedient to install a regular substation in the building to receive current directly from the Waterside stations, which are about two miles distant. Consequently, three independent feeders were laid from the sta-

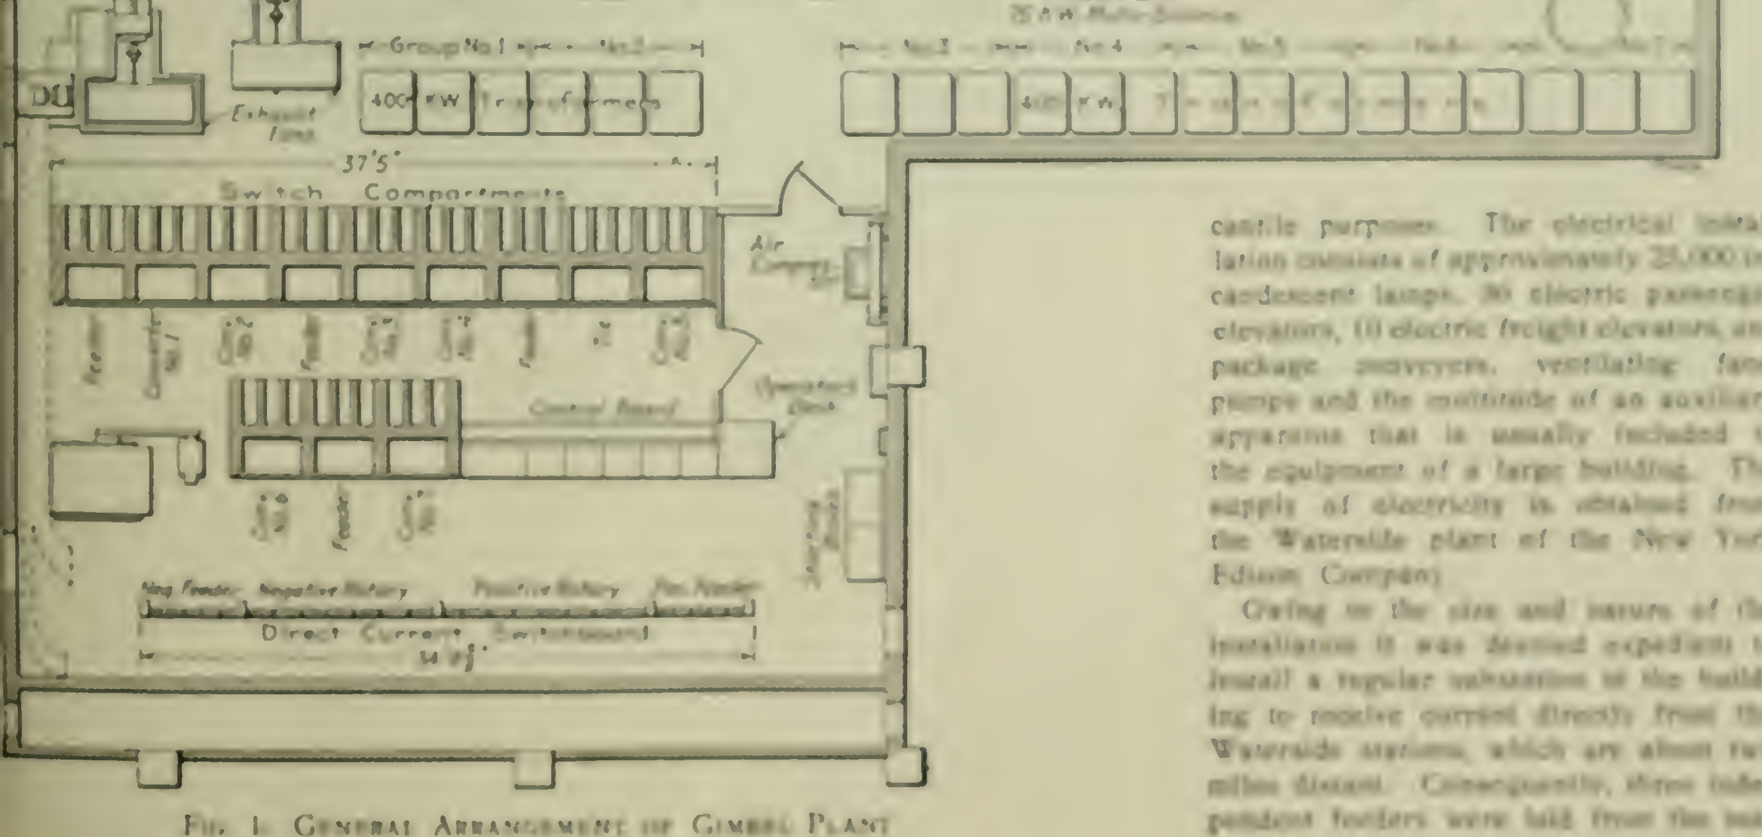

FIG. 1. GENERAL ARRANGEMENT OF GIMBEL PLANT

tions to the Gimbel building, carrying three-phase currents at 6600 volts and 25 cycles frequency. The equipment of the substation consists of six 1000-kilowatt Westinghouse six-phase rotary converters of the synchronous-regulator type, and

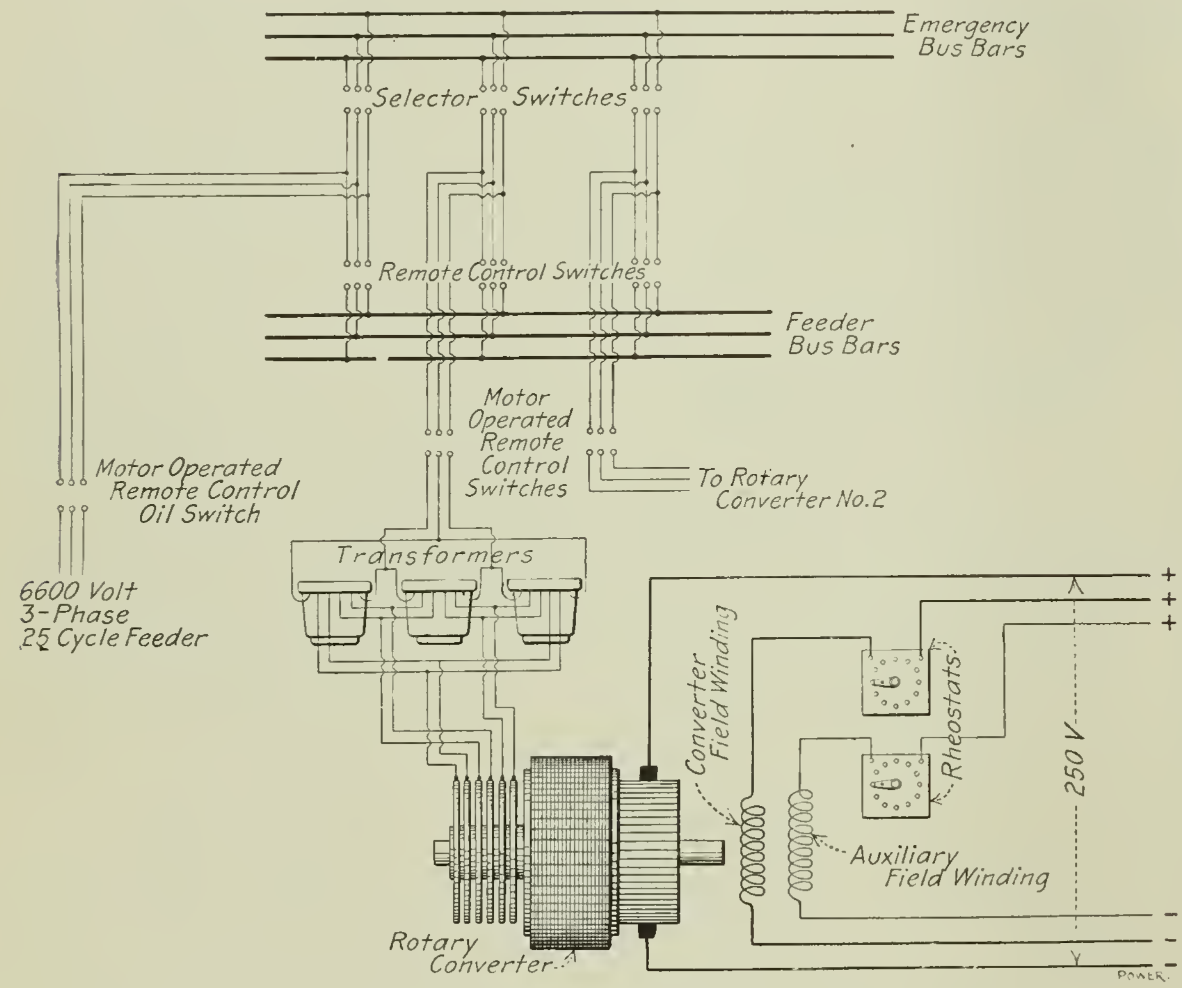

Fig. 2. Diagram of High-tension Alternating-current Wiring

one 1000-kilowatt General Electric six-phase rotary converter, controlled by an induction regulator. All of the converters deliver direct current at 250 volts. The high-tension alternating current is stepped down by twenty-one 400-kilowatt air-blast transformers, three to each converter, connected in delta at the primary terminals, and double delta at the secondary terminals to obtain six phases. In rotary converters of large capacity higher efficiency and more economical distribution of copper are obtained with

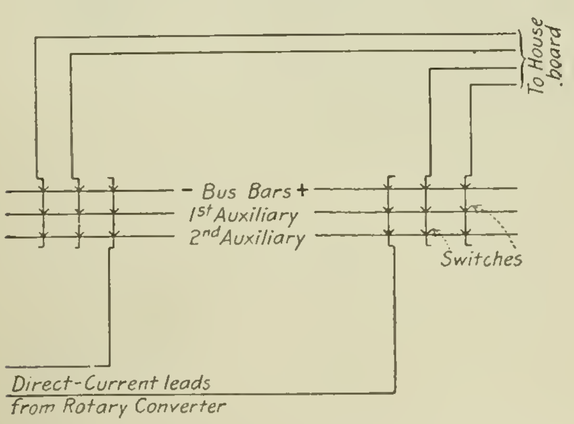

Fig. 3. Schematic Diagram of Direct-current Busbar Connections

the six-phase winding than with the three-phase winding.

The transformers are set in a single row across the room, over a large conduit or air duct. The air blast is furnished by two motor-driven blowers, one of which is held in reserve. The heated air leaving the transformer dampers is removed from the room by a motor-driven exhaust fan and discharged outside the building.

The high-tension switches are inclosed in masonry and are all of the remote control type, operated from the control switch board, as indicated in Fig. 1. The feeder and rotary converter switches

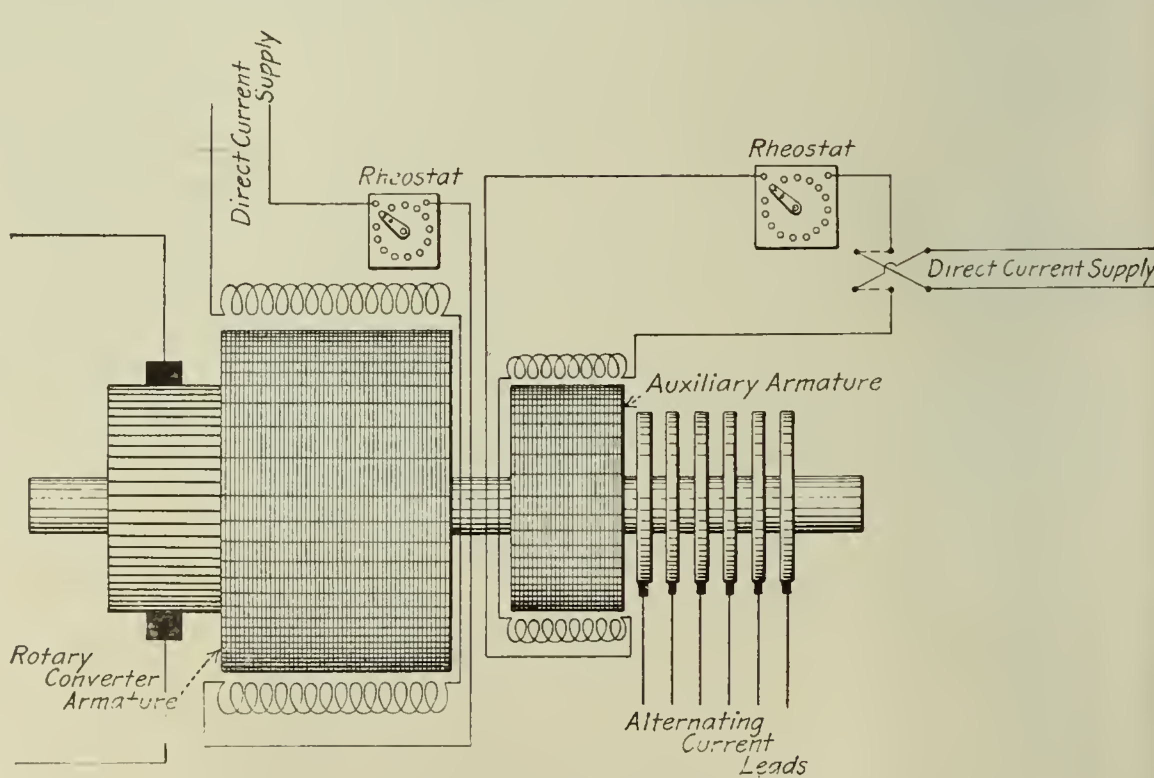

Fig. 5. Diagram of Synchronous Regulator Type of Rotary Converter

are motor operated and the selector switches are operated by solenoids.

The direct-current terminals of the rotary converters are connected to a direct-current switchboard provided with separate busbars for the rotary converters and the feeders. This board is connected to the house board controlling the building load and is also provided with a connection to the low-tension direct-current street mains of the Edison system.

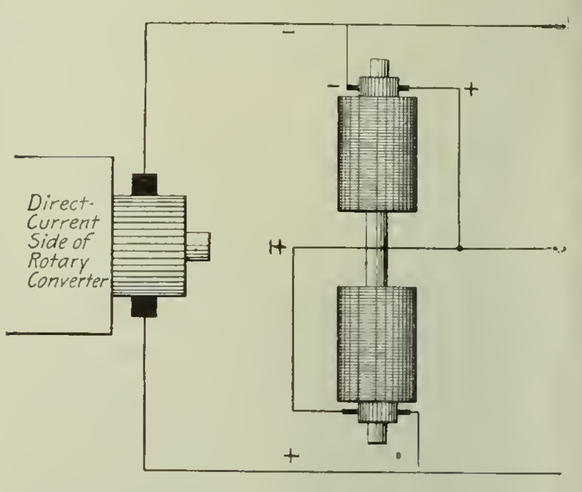

Fig. 4. Connections of Motor Balancer

Fig. 2 shows the elementary connections of the high-tension alternating-current wiring. The alternating-current switchboard is provided with two sets of busbars; the feeder busbars are divided into four sections but the emergency busbars extend the whole length of the board. Each feeder normally supplies two rotary converters. The seventh converter may be used in place of any of the other six, or may be used to assist other Edison substations by means of a tie-in feeder.

Each main feeder is connected to the alternating-current switchboard by a remote-control motor-operated high-tension oil switch, and in turn may be connected to the emergency or the feeder busbars by means of remote-control selector switches. Each converter is connected by means of a motor-operated remote-control switch and may be supplied with current from the emergency or the feeder busbars by closing the proper selector switch. This arrangement of connections is very flexible and makes it possible that in case of emergency one rotary converter can be substituted for another almost instantly. All of the converters are started from the direct-current side in a manner similar to the starting of a direct-current motor and when the synchronizing lamps indicate synchronism the high-tension converter switch and the proper selector switch are closed.

A schematic diagram of the main direct-current switchboard is shown in Fig. 3. It is provided with a main positive and two auxiliary positive busbars and one main and two auxiliary negative busbars. As will be seen from the diagram, which shows the direct-current leads from one converter only, any one of the three busbars on either the positive or the negative side may be used by throwing in the proper switches. Likewise the feeders to the house board or to the street network may be connected to the various busbars at the option of the attendant.

The building is wired throughout on the three-wire plan, and as the converters deliver the overall voltage (250) a motor balancer set is provided. This consists of two direct-current machines coupled mechanically and connected up just as they would be in a straight direct-current plant where the generators give the over-all voltage. Fig. 4 is an elementary diagram of the arrangement. The commutator of only one converter is shown, but the others are all connected in parallel with the one shown and do not affect the operation of the balancing set. The set is capable of taking care of 150 kilowatts of unbalanced load.

One of the most interesting features of this substation is the synchronous-regulator type of rotary converter, which differs considerably from the ordinary type of converter. The synchronous-regulator type of machine is provided, in addition to the usual component parts, with an alternating-current generator built integral with it and having the same number of poles as the main field magnet of the rotary converter. The armature of the alternator is mounted on the converter shaft and its winding is connected between the main armature winding and the collector rings. When the polarity of the field winding of the auxiliary alternator corresponds to that of the main converter field winding the voltage of the alternator armature is added to that of the rotary converter. Consequently, the ratio of alternating to direct voltages at the main terminals is increased and the direct-current voltage is lowered. If the polarity of the auxiliary field winding is reversed the electromotive force of the alternator or auxiliary armature opposes that of the rotary converter armature and the resultant alternating electromotive force is reduced correspondingly, with reference to the direct-current voltage; the latter is therefore increased, because the alternating voltage is fixed by the supply circuit and changing the converter ratio can change only its direct-current voltage. The degree to which the direct-current voltage is raised or lowered by the auxiliary armature is controlled by a simple rheostat in the auxiliary field circuit. This rheostat is operated by a motor which is controlled from the switchboard. The polarity of the auxiliary field magnet is changed by a reversing switch (shown diagrammatically in Fig. 5), also operated by remote-control from the switchboard.

Fig. 6. One of the Synchronous-regulator Converters

Electrical Accidents Due to Carelessness

By Howard S. Knowlton

No course of instruction in the university of hard knocks conveys a more lasting lesson than that of accidents and misfortunes. Year by year the study of casualties and their prevention leads to safer operating conditions in every branch of industry. Repeated reference to these matters is justified on the ground of economy in operation no less than that of preventing human suffering. New conditions are constantly arising and new men entering the field. The older men engaged in the operation and construction of engineering systems tend to overlook the sources of danger, while the fresh recruits frequently fail to realize the disasters which can result from small beginnings. This is peculiarly the case in the electrical industry. A review of the causes of a number of electrical fires and accidents which occurred within one year in a single municipality may well emphasize the importance of trouble prevention over a wider field. In the following paragraphs the essential features are given of troubles occurring almost entirely as a result of negligence, which in most cases were handled without serious financial loss, but which might easily occur anywhere and produce less fortunate results.

Some Electrical Fires

The careless leaving of an elevator motor connected to the supply main when the machine was stopped for the night roasted out the field winding and started an incipient fire, which fortunately was discovered before anything but the motor was injured. In another case, for lack of proper attention the brushes on a 1-horsepower motor became so badly worn that violent sparking occurred as the commutator and oil, dirt and sweepings, which had been allowed to collect, became ignited. In a third instance, a defective rheostat was in service in a basement, and when the operator of the plant started the motor-driven machinery serious overloading of the motor occurred; the protective equipment did not operate quickly enough to prevent a burnout, and the machine was badly injured. While the fire in none of these cases spread to cause any serious damage in the vicinity of the electrical equipment, it was due only to the prompt discovery of the situation through the smell of burning insulation and rapid accumulation of smoke that the fire loss was small.

Careless handling of wires during the installating of electrical apparatus is responsible for much trouble. A slight fire in a basement hallway was caused by linemen working outside on overhead wires, who permitted the circuits to sag sufficiently to make contact with a trolley wire and street lamp post at the same time, permitting current to pass from the wire to the post and thence by means of a gas main to the adjacent building, where a water pipe was in contact with a gas pipe running to a gas bracket on a side wall. Holes were melted in the gas pipe, the gas became ignited, and a small fire occurred. This occurrence illustrates the ease with which the improper handling of electric work may lead to troubles at some distance from the immediate locality where the negligence happens. In the same class of accidents are those where derrick guy wires and chains are unintentionally brought in contact with either the feed or trolley wires of an ordinary direct-current railway service, one side of which is grounded. The failure to screw the plugs of fuse cutouts tightly home is another efficient cause of trouble. The poor contact causes heating, which becomes intense through arcing or lowered conductivity, and if the fuse does not blow enough energy may be released in a small area to produce a disastrous blaze. One fire last year was caused by a porter leaving a coat and pair of overalls hanging over a cutout of the cartridge type. As a result of loose connections at the fuse clips, probably caused when the clothing was hung up, arcing and heating of the contact resulted, and the garments were set afire.

A small fire in a garage started on a table where several 6-volt ignition batteries were being charged. The batteries were left alone during the night and some had boiled over. Current leakage occurred between two of the jars, the liquid on the surface of the table having acted as a conductor. Here again the presence of heavy smoke warned the occupants of the building that something was amiss.

Two other representative fires were due to unrelated causes. One occurred through the burning out of the armature of a ¼-horsepower motor, which was due to the bearings becoming dry through inattention; the second was an out-of-door flare-up produced by the end of a wet rope coming in contact with one side of a series arc-lighting circuit. The rope had been used by the lineman of a signaling company to temporarily fasten a new cable in position, and the current was grounded on a rainy night.

Personal Injuries

In spite of the frequency with which workmen in power plants and on the structures of elevated railways are warned against making short circuits, severe personal acidents of this kind occur repeatedly each year, and almost always through carelessness in the use of tools. Where one side of the circuit is grounded the trouble generally reaches a more acute stage in point of arcing than where the circuit is metallic throughout. Among the accidents of this kind which occurred last year in the community in mind was one where two men, both regular employees of the company, received severe burns about the face and arms while at work in a power plant of the 600-volt railway type. Their injuries were due to a short-circuit through a wrench which they were using in the removal of an iron pipe coming in contact with the live metal of a fuse board at the time when one end touched the pipe.

In another case a lineman was soldering a very heavy cable used for railway service, when the metal ladle which he was using came in simultaneous contact with the joint of the live conductor upon which he was working and a grounded pipe carrying compressed air.

In a third case the workman accidentally brought a wrench in contact with a live third rail while engaged in loosening nuts on one of the running rails of the track. Heavy burns about the face, hands and arms resulted. Two other accidents arose from the careless use of tools in the vicinity of a third rail and feeder installation. The first was caused by a carpenter's saw engaged in cutting off the end of a tie coming in contact with the third rail and grounded elevated structure; the second by a hammer which was being used in a cable box coming into simultaneous contact with a bare live connection and a bolt which was in contact with the structure.

Bad facial burns were received by two wiremen as a result of a short-circuit due to their own carelessness. They were to remove an unused and dead wire from a conduit, it being necessary to cut the wire before its withdrawal; by mistake they attempted to cut the wrong wire, which was alive and a short-circuit was caused by the cutters making simultaneous contact with the live wire and the pipe. A similar accident occurred in a power station where a workman was inserting a copper filler between the plates of a busbar structure, simultaneous contact being made between the busbar and the grounded framework supporting it.

Low potential systems are capable of causing personal accidents no less than high voltage installations. Severe burns occurred on the hands of an experienced installer as a result of a short-circuit caused by a monkey wrench on the shunt connections of a low potential motor-generator set. The use of a jackknife in making temporary connections at a junction box also led to a short-circuit, which caused painful burns. Care is equally necessary to avoid trouble in the installation of insulating materials in the neighborhood of busbars. In one recent instance severe burns resulted from a heavy short-circuit which occurred when a workman was attempting to put a bolt through a piece of alberene stone and angle iron for the purpose of fastening the stone to the angle iron. The bolt end came in contact with a live storage-battery busbar, and the current grounded through the bolt and angle-iron hanger.

LETTERS

Identifying Alternating and Direct Current

Referring to H. Priestley's inquiry in the December 6 number for a method of finding out whether the current in a lamp socket is alternating or direct, I would suggest that this can be ascertained by holding one pole of a permanent magnet against one side of the globe of an incandescent lamp while the lamp is lighted. If the lamp is supplied with direct current the magnet will attract the filament to one side. If it is alternating current the lamp filament will vibrate, due to the alternations.

R. L. Mossman.

Tampa, Fla.

[Exactly the same suggestion has been received from E. F. Potter, Urbana, Ill., and Roy Stolp, of Chicago.—Editor.]

I believe that the liquid method is as simple and reliable as any. Take a glass of water and put a pinch of salt in it. Insert the two ends of the wires in the glass, which should be in series with the lamp on the circuit to be tested. With direct current the negative wire will give gas off freely in the form of bubbles, while with alternating current both wires will give off gas to some extent, but in equal amounts.

Louis J. Gorilla.

Ironwood, Mich.

New Engine Required Lining Up

A new 12x16-inch engine was installed in a sawmill and, naturally, the management expected things would run smoothly. But for some time that engine did some queer stunts. It ran under, and the under guide ran hot. The engine seemed to labor hard and did not develop its rated power.

I was called upon to see what could be done and I found that not only the bottom guide of the engine ran hot but that the engine heated in other places also, although there seemed to be enough loose play. The crank box could be shaken at some parts of the stroke, but at other parts would be tight.

I put a line through the cylinder and got a surprise. The engine had a self-contained base, the outboard bearing and frame in one piece, and I could hardly think that the shaft would be out of line on this new engine, but in getting my line true with the cylinder base, I was surprised to find that the line was up above the shaft center, and that the cylinder was out of line with the guides.

Then, ignoring the cylinder, I tried to line up the shaft with the guides, and found that they were larger at the cylinder end than at the crank end, and were also smaller at the center than at either end.

There was no boring bar within miles of the plant, but, on looking around, I ran across a shaft that was of the same diameter as the stuffing box of the piston rod.

A box was found to fit this shaft and it was clamped to the crank disk. The shaft was then run through the stuffing box and the box on the disk.

I next made some clamps of heavy, flat iron to hold the tool, and then threaded a bolt long enough to feed the bar through the guides. A heavy bar of iron was placed across the cylinder end and was secured by two of the stud bolts. This end bar had a threaded hole in the center for the feed screw.

A handle was clamped on the crank end of the boring bar and two men were set at work turning the bar. With a set collar on the bar to feed against, I bored out the guide, and made a pretty good job of it, considering the tools I had to work with.

Next, the cylinder was removed from the frame in order to find out what made it hang down out of line, and I found that the frame had been faced off out of true. I did not care to try to face it up with the boring bar I had improvised, nor did I like the idea of putting any kind of soft packing in such a place. Then I thought I would try a plastic cement, and some was put in the opening left between the frame and the cylinder, and after lining it up I had a first-class job.

It was necessary to rebabbitt the main bearing to get the main shaft in line, but after this was done the engine ran like a new machine should.

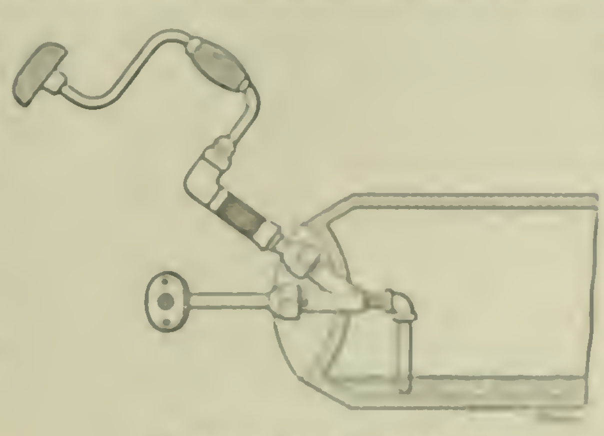
Bit Brace as a Wrench

The following method of using a common bit-brace, tightened firmly on the valve stem of an ammonia drum, as shown in the illustration, may be of some



OPENING THE VALVE

value. I have tried different styles of wrenches, but for quickness and sure control in opening the valve I have found nothing to equal the bit-brace.

Does It Pay to Waste Heat—Sometimes?

The writer had an interesting discussion a while ago with a prominent power-plant engineer in regard to a rather unique installation which has recently been completed for a large New England textile mill. Briefly, the plant consisted of three main turbine-driven units of 500 kilowatts each, with separate condensing units; four cooling towers with individual motor-driven fans; and the usual complement of auxiliaries of boiler-feed pumps, circulating and service pumps and a pump for the heating system.

Originally it was intended to utilize the condensed steam from the main units for heating the mill, there being no other use for which it could be utilized except heating the boiler-feed water. When this plan was presented to the owner he claimed that the "time factor" as regards heating had not been considered—that is, that the time he wanted the heating done was between 2 and 9 or 10 a.m., the greater part of which time the mill would not be running.

As a result it was decided not to utilize the exhaust steam for heating. Instead, jet condensers were installed for the main units, the boiler-feed suction being taken from the return line to the cooling towers. This is passed through a feed-water heater and was raised from about 90 degrees to 200 or 210 degrees by the exhausts from the various auxiliaries. The turbines operate at about 28 inches vacuum.

The mill heating system is of the hot-water, forced-circulation type, the water being heated by live steam except for the excess from the auxiliary exhausts which is utilized when the plant is running by passing it through a tubular heater through which the water for the heating system is pumped before going to the live-steam heater.

At first glance this layout may seem uneconomical in its utilization of heat units, but upon careful inspection it appears that, all factors being considered, the total cost of producing power may be less than in a plant where the effort is made to utilize every possible B.t.u. from the coal. There is a distinct economy in maintenance cost effected by the use of jet condensers and, furthermore, less circulating water is required. In this particular instance the water goes to the feed-water heater at about 90 degrees, whereas if it were taken from the condensed steam in a surface condenser it would reach the heater at perhaps 100 degrees with the turbines exhausting at a little less than 28 inches vacuum.

It seems very reasonable to expect that the cost of saving the heat represented by this 10 degrees might possibly be greater than the immediate loss due to throwing it away. As the plant is question has only been operating a comparatively short time, accurate figures are not yet available. The point brought out here may, however, be food for thought for both designing and operating engineers.

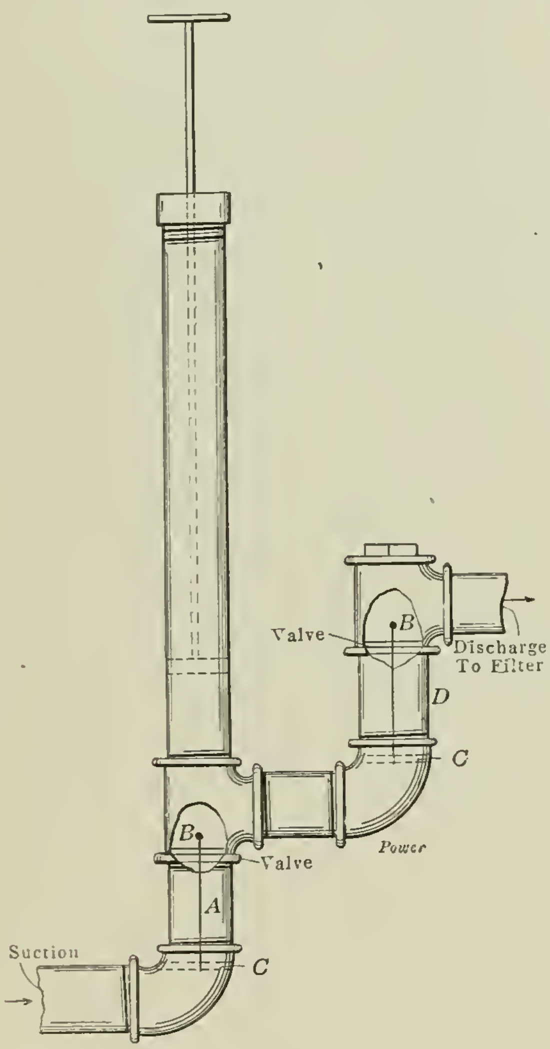
H. M. Wilcox.

Boston, Mass.

A Handy Oil Pump

When I took charge of a shift in a certain plant, I noticed that a compressor was fitted with a neat looking homemade waste-oil pump.

This compressor ran day and night



Details of Oil Pump

and, as it was of the vertical type, the waste oil drained into a receptacle in the base of the machine. Unfortunately the builders had neglected to provide means to remove the waste oil. Therefore, a hole was drilled through the side of the compressor wall and a pipe led through to the oil trays inside the base. The pump was then permanently attached to the machine, and the discharge pipe led to the oil filter. The cylinder of the pump was made of polished brass pipe and the other 1-inch fittings were given a coat of black japan.

The tops of the nipples *A* and *D* (see illustration), were filed flat and made excellent seats for the valves. Ordinary hard-rubber bibs were used as valves. A long nail extended through each valve and nipple and was riveted to a spider at *C*. This allowed the valve the proper amount of lift.

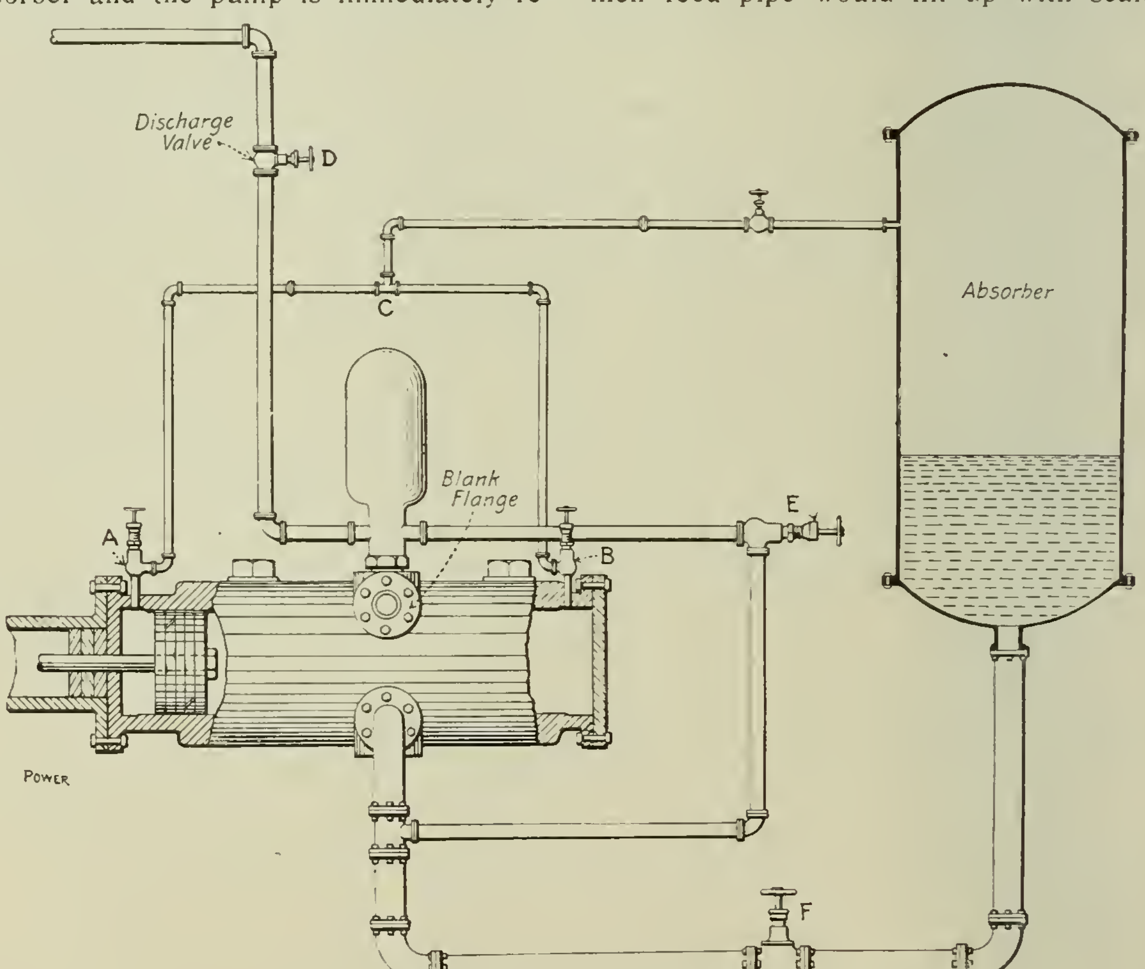
Lambton Mills, Canada.

Relieving an Aqua Ammonia Pump

Aqua-ammonia pumps are heir to the common ailment of becoming gas-bound, and when this happens, the engineer has no positive means of relieving the gas. Putting cold water on the pump and forcing the absorber pressure up does no good, as the pump will repeatedly become gas-bound when the pressure returns to normal. Sometimes it will take hours to get everything regulated so that the pump will work steadily, and during this time the temperature is rising.

The accompanying sketch shows a scheme that I applied to a pump with success. I drilled and tapped each end of the pump at the counterbore for a ½-inch connection and screwed in the valves *A B*. From these I ran two lines to the tee *C* and a line from *C* to the absorber.

When the pump plunger moves to the end of the cylinder, as shown, it compresses the gas and by opening the valve *A* a large portion of the gas will be driven into the absorber. When the plunger moves to the other end of the cylinder there is so little gas on the side of the plunger just relieved that the pressure will fall rapidly until it is below the pressure in the absorber. Then the liquor will be forced in from the absorber and the pump is immediately re-



Relief Pipes and Connections

lieved without interfering with the equilibrium of operation and without a loss of temperature.

The bypass from the discharge to the suction is very convenient when packing the pump. By closing the valve *D* and opening the valve *E*, after drawing a vacuum on the absorber, all of the ammonia is removed from the pump. Packing can then be carried on without being obliged to run from the ammonia fumes, but it will be necessary to close the valves *E* and *F* before starting to pack.

Why Did the Feed Pipes Clog?

In a power plant in Nevada where I was employed for eighteen months prior to dismantling the plant about a year ago, we had seven water-tube boilers of various sizes.

The water was very good and the condensed steam from the jet condenser passed over a cooling tower and back to the boilers.

A 4-inch header extended across the boilers and a 2-inch pipe ran from the header to each boiler; there were five turns in the 2-inch pipe and the entire piping was of wrought iron with some cast-iron fitting.

There was no scale in the 4-inch header to speak of and very little in the boilers; surface well water was used at a temperature of from 160 to 190 degrees Fahrenheit.

These boilers were kept practically free from scale; in a few months a 2-inch feed pipe would fill up with scale so that a ½-inch rod could not go through the pipe.

Will some reader explain why the feed pipes would clog up and yet no scale form in the boiler? A compound was used in the feed water.

Farmington, Utah.

Cooling Cold Storage Rooms

In laying out cold-storage rooms the engineer has several methods of cooling from which to select.

The best method for any particular case depends entirely on the kind of work. If it is necessary to eliminate moisture from the room, the plant should be laid out with a small room connecting with the main room. This room should be practically filled with brine or ammonia coils, with the exception of a small space at each end which should be utilized for the cold-air flue. The coils should reach the entire width of the room, and extend from the floor to the ceiling, thus making it necessary for the fan to draw the air from the main room through the coils.

A fan should be placed at one end of the room, and from this the cold-air flue should start. This flue should be made of galvanized iron, and fitted with small slides or openings about every ten feet.

The return flue should start at the other side of the small room and run on the opposite side of the main room. The floor plan is shown in the illustration.

Arrangement of Cold-storage Room Air Ducts

This system will enable one to keep the main room free from moisture, but it requires more refrigerating capacity owing to the indirect manner of cooling the room. It is also necessary to clean the frost from the coils occasionally, as in time it becomes so thick as to completely shut off the circulation of air. The quickest way to rid the pipes of snow is to close the air slides to the main room, and use a hose and hot water, afterward sweeping as much of the water out of the room as possible and absorbing the rest with sawdust. The brine or ammonia is shut off during this operation.

If a little moisture will do no damage to the contents of the room it can be cooled in a better and more direct way by the brine or ammonia coils being placed directly in the room. Of these two latter methods the ammonia coils are the most direct, as the ammonia is doing no work until it has passed through the expansion valve; therefore, the heat is absorbed directly in the room to be cooled; in the brine system the heat is absorbed in the cooler, thus cooling the brine, which is then pumped through the coils in the cold room.

Comparing these two methods, the direct expansion is far superior to the brine system for four reasons:

First. The expansion of the ammonia must take place either in the cooler or in the room direct. If the expansion takes place in the room, it is bringing the temperature of the room down; if in the cooler, it is bringing the temperature of the brine down, and as the brine must be brought to a low temperature before it will do any work on the room, it is not difficult to see that the room can be cooled much quicker with direct expansion, thus making the operating expense less.

Second. A brine pump is required with the brine system, which also adds to the operating expense.

Third. The brine loses considerable in temperature in traveling to and from the cold room.

Fourth. A larger coil is required for brine, in order to obtain the same results as from the ammonia.

The brine system has one very good point in its favor, in that the ice machine can be shut down for repairs between four and five hours, and if the brine pump is kept running the room can be held at the usual temperature.

Another very good system is a combination of the brine and direct expansion. A small pipe runs through a larger one, and brine is pumped through the larger pipe, while the gas is expanded through the smaller one from the opposite end of the coil. With this system it is not necessary to have a cooler or ammonia coil in the brine tank, which is used only to hold the surplus brine.

In some plants economy requires the installation of both brine and ammonia coils. In operation the room is brought to a low temperature by the direct expansion; then the machine is shut down, and the room held at this temperature for a considerable time by circulating the brine through the room.

Walter C. Ebot

Philadelphia, Penn.

Ethics of the Engine Room

There is such a thing as ethics in the engine room, and to this any live engineer will agree. Ethics is defined as the science of human duty.

The spirit with which any man enters into his work largely determines his success or failure. The man who can put his whole soul into his work and who believes his work is worthy of his best efforts, is pretty sure to succeed, even though he be a plodder. No man ever won success by working only when he felt like it.

The man whose habits of living are correct and conducive to the conservation of his physical and mental energy is able to overcome any obstacles that may arise.

No man rises above his ideals. Many a man makes the mistake of not keeping an eye on the job higher up and working and studying to fit himself for it. Then when the time comes to move up the line, he is ready.

The fire engine and the harness are ready, the men and horses are drilled and trained for action, ready to go when the alarm sounds. If this preparation were not made, what would be the result? Some day a man will be required for a job and if the man who should be promoted is not competent to fill the place, someone else will get it and the fellow who was "weighed in the balance and found wanting" will work away at his old job in a disappointed and half-hearted manner that spells doom to him, so far as advancement is concerned, unless he takes "a brace," gets the vision and pursues it with a determination to win.

A farmer fills his wagon box with potatoes and starts to market, and as the wagon bumps along over the country road the largest potatoes work toward the top. So it is with the man who really desires something better and is willing to fit himself for advancement. It is this desire coupled with determination that makes him a "large potato" capable of rising toward the top as he bumps along over the rugged pathway of life.

It is not what one might do, however, if he had so-and-so's ability and education; but it is the use that is made of the brains and energy we have that marks for success or failure. Strive for advancement, for, by the very effort, you will have bettered his condition, even though his aims are not fully realized.

Many complaints are heard with reference to certain men having a "pull," as though they needed only to have a "friend" or in some way to "stand in" with the "boss." This is a matter that usually adjusts itself; for, though a "pull" may get a job, it will not help to "make good."

A wise man is continually learning. He looks after his employer's interests with the same painstaking care that he would expect should he be employing men in a business of his own. Some may say, "The boss does not appreciate my efforts and I am not going to exert myself to look after his interest." If the "boss" does not appreciate your efforts, someone else will. The man who fools the "boss" fools himself more. It is better for a man to outgrow his job than to let the job do all the growing.

There are certain relations that should exist between employer and employee. Not only should the employee come to his work with the right spirit, but the employer should greet his employee as a man and a coworker, show him that his efforts are appreciated and give him enough insight into the business so that he can see his own relation to the business and to his fellow employees. In doing this a man's efficiency will be greatly increased because he realizes the importance of his own particular part in the business and is filled with a desire to make the best possible showing. The employer who does this and who gives his employees fair treatment in all matters is building up a business that will be both pleasant and profitable for all concerned.

What is true in a general way in the industrial world is also true in the power plant and the engine room. This same spirit, if maintained, will make the tasks easier to perform.

The man who does not develop manhood along with his work is missing the best part of life. The practice of keeping the engine room neat, clean and orderly; the practice of economy in the use of materials and supplies; the reading of magazines and books pertaining to the engineering profession, the posting of suitable mottoes in conspicuous places, all help to make him a better man.

Some time in life every man bumps into his "stone wall." The real man lands on the other side—Think it over. Be not overcome by difficulties, but overcome difficulties with an effort born of determination to win.

I have seen men go home from their work in the power plant wearing dirty, greasy overclothes and with hands and face unwashed. I have gone into the plant where these same men worked and found the appearance of things there untidy also. Unfortunately—for these men and for the profession—engineering magazines, with their helpful suggestions, valuable information and inspiring influence, do not often find their way into such engine rooms. If they did, conditions would soon be changed. A neat appearance will go far toward making a man think better of himself and of his work.

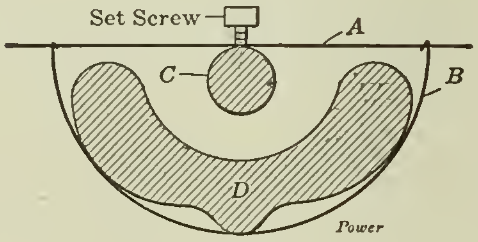
Fairport Harbor, O.

Piston Rod Clamp

The piston rod of some types of pump is often ruined by using a pipe wrench to hold the rod when removing the jam nuts in the water cylinder when about to pack the plunger. After the piston rod becomes badly marked it is next to impossible to keep the stuffing boxes tight.

A device that will save the piston rod a great deal is shown in the illustration. The piece *A* is made of soft steel, 16 inches long, 1 inch wide and ½ inch thick. *B* is a piece of soft steel of ½ inch diameter and about 2 feet 4 inches long, bent so as to fit around the body piece *D* of the pump. *C* is the piston rod. The ends of *B* hook over the ends of *A*, which is slotted. To prevent the piston rod from turning, it is only necessary to tighten the set screw.



PISTON-ROD CLAMP

ALFRED WOOLCOCK.

Evelette, Minn.

Manholes in Boilers

Although boilers have been manufactured and used for years, there are many still made and installed where little attention is given to the very important feature of accessibility, and this applies both to the setting and the boiler proper.

It is safe to say that a number of disastrous boiler explosions can be partly or wholly traceable to the fact that the design of the boiler and setting prevented proper cleaning and inspection.

But a few years ago it was the custom of some manufacturers to put handholes in the bottom of the front and rear heads of horizontal return-tubular boilers, and these have undoubtedly been the indirect cause of many a bag, blister, fracture and burned blowoff pipe.

The handhole in the back head is usually a constant source of trouble. Of late years the majority of boilermakers are putting a manhole in the bottom of the front head and no hole at all in the bottom of the rear head. This is an improvement over the handholes, as it permits of proper cleaning and inspecting. Usually the manhole in the bottom of the front head is 10x14 inches and, while it is possible for a good-sized man to get through a hole of this size, it would be much easier if it were 11x15 inches, and in most boilers the larger size could be put in with no additional cost and without weakening the boiler head. Boilers made by a certain firm have crow-feet braces, so arranged that it is necessary for a person to make a quarter turn of the body, after getting through the manhole, so that he can drop down between the braces to the top of the tubes.

In nearly all uptodate water-tube boilers, the openings are ample, but in one type the rear drum is so obstructed by a large mud pan that it is almost impossible to get into it, or to do any cleaning.

The openings in the settings of water-tube and horizontal tubular boilers are of all shapes and sizes, but in most of the former type they are ample for the purpose. One manufacturer, however, furnishes castings with 14-inch round holes, which are about the worst thing that could be installed. The brick is laid in the wall to conform with the casting and the result is an opening that is very difficult to get through, or to hoe out ashes and dirt. Square holes about 14x18 inches would insure better care and inspection of this type of boiler.

Every prospective buyer of a boiler should insist that the manholes be made 11x15 inches, that the through and crow-foot braces be arranged to permit easy access, that the openings to the combustion chamber be at least 15 inches wide by 24 inches high, or larger, and so placed that ashes can be readily removed.

THOMAS J. HANNA.

Cincinnati, O.

Making a Low Pressure Trap

The engineers in a certain plant were kept busy running around blowing the bypass on the high-pressure traps in order to keep the pipes drained.

This trouble was due to the traps being worked at too high a pressure, causing the pot in each to hang up to its seat. Some of these traps were remedied by putting in pressure-reducing valves where the high pressure was not needed. The remaining traps were made suitable for high pressure by plugging the seats and drilling a hole through the plug one-half the diameter of the original opening, thus reducing the area of the seat against which the valve was held by the steam pressure. An automatic air valve was put on the cover of the traps and the engineers then forgot all about them.

W. T. MEINZER.

Brooklyn, N. Y.

Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

Driving Keys

With reference to Mr. Taylor's letter on the above subject, which appeared in the issue of November 22, I believe that a few friendly criticisms will be beneficial.

Where is the necessity of marking or measuring the key at all, preparatory to driving it? The object to be attained is to take up whatever lost motion there happens to be between the pin and the brasses regardless of how far the key must be driven. He says that in driving a key the first time, in order to determine the proper degree of tightness, the connections should be moved sidewise or, if this is impossible, to drive the key solid and then back out the required amount. This is correct and the only safe method of performing that operation at any time; therefore, marking the key is of no benefit whatever unless when backing out after being driven solid. I fail to understand how anyone can determine accurately, as he says, just how far a key should be driven each time, as that is equivalent to knowing the exact amount of wear that has taken place, which is out of the question.

Again, he says that the wear is continually making the connecting rod shorter and putting in liners carries it back. From what he states about inserting liners on both sides of the pin he would have us believe by the insertion of liners on the key side we could rectify the length of the rod. A liner thus inserted, with the key remaining the same, would have the same effect as driving the key, thus making matters worse. If the key is on the side of the crank pin next to the cylinder the wear and consequent keying up will diminish the clearance in the head end of the cylinder. The same effect will be produced with reference to the crosshead pin if it be keyed on the side nearest the connecting rod.

In order to equalize the clearance, liners must be inserted behind the brasses on the side of the pins opposite the keys, or all may be put behind either one of them. This is assuming the piston rod to be keyed in the crosshead. If it be screwed in, the liners are unnecessary unless the keys have been driven clear up.

When the crank-pin key is driven the connecting rod moves while the crank pin remains stationary and in driving the crosshead key the connecting rod remains stationary and the pin moves.

The connecting rod may be assumed to be a long box. If we first key the crank-pin brasses to take up the lost motion, the connecting rod moves toward the head end, carrying everything with it except the crank pin and its inner brass. Then if the crosshead key is driven the pin will move still further toward the head end, forcing the piston along with it.

An engine with the crank-pin key or adjusting wedge on the opposite side of the pin from the connecting rod, and the crosshead key next to the rod, has a tendency to keep the clearance equal as the wear on one pin and set of brasses will offset that on the other. A great many engines are so built but the wear is rarely the same on both.

JOSEPH STEWART.

Hamilton, O.

Boiler Tube Failures

In the issue of November 29 there is an editorial, headed "Boiler Tubes," referring to some remarks made by Charles S. Blake, of the Hartford Steam Boiler Inspection and Insurance Company, regarding tube failures in recent times and citing one instance in particular, which is illustrated and described on page 2131 of the same issue.

It is hardly necessary to make any comment on Mr. Blake's contention that the thicknesses used today are identical with those used 25 years ago, whereas the pressure is now 80 to 100 pounds greater, for it is possible to obtain any gage required simply by specifying. Moreover, in those days charcoal iron was the only material used. Now we have hot- and cold-drawn seamless and lap-welded steel tubes, which, for the same gage, are nearly twice as strong as the charcoal iron under internal pressure, so that under the same conditions, by the use of a tube made of soft steel, twice the factor of safety may be obtained.

In the case of failure cited, it is clear that the low factor of safety was largely responsible for the trouble. The tube is reported as being of charcoal iron, No. 10 gage, which had been thinned down by wear to 1/32 of an inch at the point of initial rupture. Besides being nearly twice as strong for the same thickness, as well as more ductile, steel wears better and will not thin down so quickly as charcoal iron. Referring to failures of this kind the editorial states, "There is something wrong with the making of a tube which fails in that way." If charcoal iron is preferred for boiler tubes which are to be used under modern conditions, would it not be only reasonable, in order to maintain the same factor of safety as was provided for under former conditions, to increase the thickness proportionately?

F. N. SPELLER.

Pittsburg, Penn.

With Consulting Engineer Assisting

Mr. Weaver, in the November 29 issue, says, "operating engineers frequently say 'the engineer in charge is best qualified to pass on contemplated improvements.'" Well, it is my opinion that he *should* be, but it depends largely on the man whether he *is* or not. Every operating engineer should keep himself so well posted on the best modern practice that he could take intelligently in hand the rebuilding of his plant, or any part of it, at any time that it might be desirable.

How can he best do this? By carefully studying the advertisements that appear from week to week in such periodicals as POWER, and noting any item that would be of benefit in his plant, then writing to the makers for printed matter concerning these articles, carefully studying the literature thus obtained and filing it for use when needed. Then, when the time comes to make alterations and improvements, he is the man who should have the last word. A splendid source of valuable information in regard to any particular department will be found in the catalogs of the manufacturers of goods used in that department.

I have many times been saved from making errors, and have received information of much benefit to myself and my employers, by sitting down and talking with an intelligent salesman, and one rarely leaves me without first giving me some practical information to add to my store of knowledge.

However, the consulting engineer, from his broad experience in many plants, is not to be despised as an assistant to the operating engineer, and as such can be of great value, but the man that must operate the plant, perhaps 365 days in the year, should have the matter entirely in his hands from beginning to end, and his word should be final.

E. H. Roberts.

Norwalk, Conn.

What Causes the Engine to Run?

Referring to Mr. Teer's letter in the November 1 issue under the above caption, the following may answer his question:

Indirect, balance slide-valve engines take steam at the center of the valve instead of at the ends as in the direct, balance slide-valve types. When the bleeder valve on Mr. Teer's engine is opened, the steam passes through the bleeder pipe and enters the cylinder at both ends through the cylinder cocks. Ordinarily, the same pressure acts at both ends of the cylinder. But, if the engine is in the starting position, the steam that enters the head end through the cylinder cock cannot escape because the exhaust port is closed. Therefore, there is enough greater pressure in the head end to start the engine to turning over while the steam that enters the crank end through the cylinder cock escapes through the exhaust port until the engine has turned far enough to close this port for compression. Then, the momentum of the flywheel will carry the piston past the crank-end center when the exhaust port on the head end opens and lets the pressure drop. The crank-end exhaust port now being closed the steam cannot escape; therefore, there is enough pressure in this end to keep the engine turning over, and the momentum of the flywheel carries the engine over the center each time. Thus, the engine will continue to run as long as it gets steam in this manner.

Robert H. Dunlap.

Syracuse, N. Y.

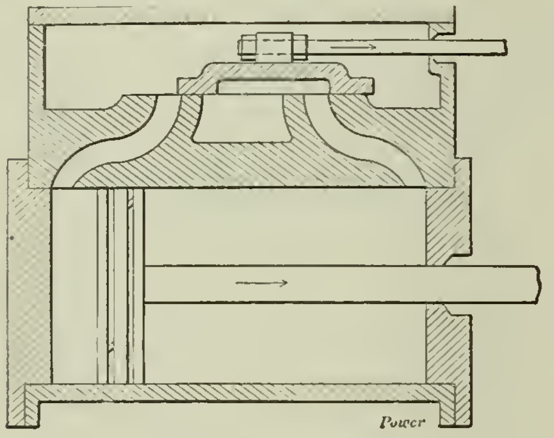
In the issue of November 1, E. R. Teer has a letter under the above title.

Referring to Mr. Teer's sketch it will be seen that with valve *A* open the steam is admitted to both ends of the cylinder through the drain cocks at either end of the cylinder as well as to the exhaust pipe. The reason that the engine will run is as follows:

The steam enters at both sides of the piston, but the pressure of the steam is not the same on both sides, as will be seen by a study of the accompanying figure.

The steam which passes up into the cylinder at the head end cannot get out but simply fills the steam chest, while at the crank end the steam passes up into the cylinder as before, but as the valve has moved almost to the end of its stroke to the right, thus opening the port to the exhaust cavity, the steam escapes through the exhaust pipe.

It is well known that there can be no flow unless there is a drop in pressure. Thus, there is a drop in pressure as the steam escapes through the exhaust port and through to the exhaust cavity at the crank end, while at the head end there is no flow and consequently no decrease in pressure. In this way a greater pressure is brought to bear on the head end, and if it is sufficient it will run the engine.



Section through Cylinder and Valve Chest

If, however, there is too much friction, there will not be sufficient pressure to run the engine.

E. S. Libby.

Chicago, Ill.

Power Plant Design and the Operating Engineer

In the November 29 issue I read Mr. Weaver's contribution under the above heading and, while the consulting engineer is appreciated if he is a good one, we must take Mr. Weaver's attack on the operating engineer as rather unwarranted. He said, in part, that every day one sees mistakes in the layout of power plants, owing to the designer being thick headed. The natural question is, who sees these mistakes? The answer is the operating engineer. Why? Because if he is an engineer of practical experience and technical knowledge, as every operating engineer should be, he has operated other plants and knows how he would have designed this particular plant to obviate the mistakes. Mr. Weaver further says that he believes that in the majority of cases blunders in power-plant design are due more to self inflation than to any other cause. I am glad that I can concur with him in this statement. As a rule this self-inflation is found in the inexperienced rather than in the mature and experienced engineers.

Mr. Weaver tells us that the consulting engineer laughs up his sleeve over mistakes made by the operating engineer due solely to ignorance of the laws of philosophy, simple laws which everyone should know. Perhaps Mr. Weaver has in mind starters-and-stoppers or oilers. The operating engineer can buy and read any engineering work published, providing he has the price. The engineering magazines keep him up to date. He may not be as good a draftsman or as conversant with the higher mathematics as the graduate of the school of technology, but he certainly has every means and method of obtaining engineering data that anyone has. And it is owing to this knowledge combined with practical experience that makes the operating engineer able to bring some semblance of order out of the chaos left him by some designing engineers.

Again, how can the engineer in charge secure uninterrupted and satisfactory service while watching the hundred and one things around a power plant, continually looking for places where improvements can be made and at the same time be a designing engineer? To begin with, if the engineer in charge could have the designing of his plant, he would not have a hundred and one places about his plant where improvements are needed and a smaller per cent. of his time would be needed to secure uninterrupted and satisfactory service. If he has had charge of a plant for some time and does not know where the improvements are needed he is a very ignorant or lazy man and should be replaced at once by an *engineer.* Will Mr. Weaver tell us how a man can properly design a steam plant who has not had a wide operating experience? Would he take swimming lessons of a man who had never been in the water above his knees? Would he employ a doctor of medicine who was just graduated and had no hospital or other experience? I think not. And no man should call himself a consulting engineer, no matter what his educational advantages may be, until he has had at least ten years experience operating steam plants. This is the kind of consulting engineer that is needed; men who are not blinded by preconceived ideas. Talk about the mistakes of the operating engineer, an issue of Power could be filled several times with details of the mistakes made by designing engineers. The operating engineer does not laugh up his sleeve or in any other way; he has to get busy and reconstruct and correct as far as possible their mistakes.

Mr. Weaver, like many other writers, uses the term *operating* engineer or chief *operating* engineer. In Webster's dictionary we find that an operative is a laboring man, a laborer, artisan or workman in a manufactory. The engineering papers and the men in charge of steam plants have been trying to make steam engineering a profession. No wonder Mr. Weaver thinks that we are on too low a social plane to associate with the self-styled consulting engineer of brains and achievements. In the Massachussetts engineer's and fireman's license laws, section 80, we find that the words, "have charge" or "in charge" shall designate the person under whose supervision a steam plant is operated. The person operating shall be understood to mean any and all persons who are actually engaged in generating steam in a power boiler. Perhaps Mr. Weaver was thinking of the fireman when he wrote the article under discussion, for no man who could not layout and install a steam plant would be a competent man to "have charge" of it after it was installed.

Does the Crosshead Stop?

We do not know that the editor of Power who answered the above question on page 1790 of the issue of October 4 needs any defense, but we cannot refrain from arguing the question with H. T. Fryant, whose letter appeared on page 2078 of the issue of November 22.

In Fig. 1, which is a copy of Mr. Fryant's figure, we point out that at the instant that the crosshead reaches the dead point H, the circle of motion of the crank-pin center is tangent to the circle described about H_1 as a center. Therefore, at the instant of dead center the crank-pin center is moving along the outer circle as well as the inner circle. Using, then, the argument obtained from Stevens' "Mechanical Catechism" that,

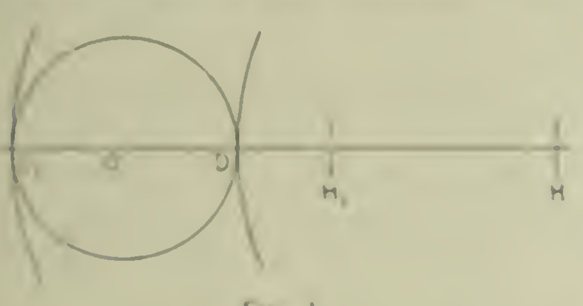

Fig. 1.

"The crosshead center could stand still only if the crank pin moved around it as the center," we have proved that the crosshead center does stand still at one instant. A similar argument shows this to be true also for the point H.

We submit, further, the following proofs, which may be more rigorous. In Fig. 2 let V represent the absolute velocity of the crank-pin center at any instant, being drawn to the point shown for the sake of clearness only. Resolving this velocity into its components perpendicular to and parallel to the motion of the crosshead-pin center we represent the velocity parallel to the motion of the crosshead by V_x and perpendicular to it by V_y. Let θ be the angle between V and V_x. Then

$$V_x = V \cos\theta$$

at any instant. V_x equals zero when θ equals 90 degrees. At the instant that the crank-pin center crosses the line of motion of the crosshead-pin center, θ equals 90 degrees and cos θ equals zero. Therefore, V_x equals zero and the motion of the crosshead-pin center is zero. An exactly analogous argument is used for either point H or H_1.

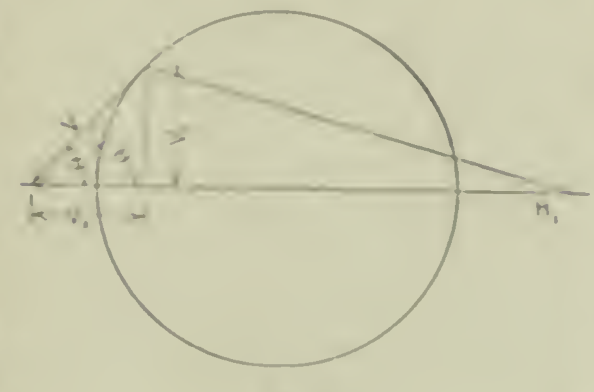

Fig. 2

In Fig. 3 is presented a third proof which we consider equally good with that connected with Fig. 2. Let ds be the infinitesimal distance traveled in a time dt. Then $\frac{ds}{dt}$ equals the velocity; that is,

$$\frac{Space}{Time} = Velocity$$

This distance ds may be traveled along the path dp perpendicular to the axis of the connecting rod, and then along dm parallel to the rod. The quantities $\frac{dp}{dt}$ and $\frac{dm}{dt}$ are, then, the respective components of the velocity $\frac{ds}{dt}$. Let φ be the angle between the axis of the connecting rod and the line of motion of the crosshead-pin center. The angle between ds and dp is a function of φ, say φ', by the geometry of the figure. Then, dm equals ds sin φ'. When φ becomes zero at the point H_1 or H, sin φ equals zero, and then dm equals zero, or the crank-pin center has no motion parallel to the axis of the connecting rod; then, since the crosshead pin center has no motion perpendicular to its line of action and since it can have at that instant no parallel motion, it must stop.

We do not doubt but that there is no

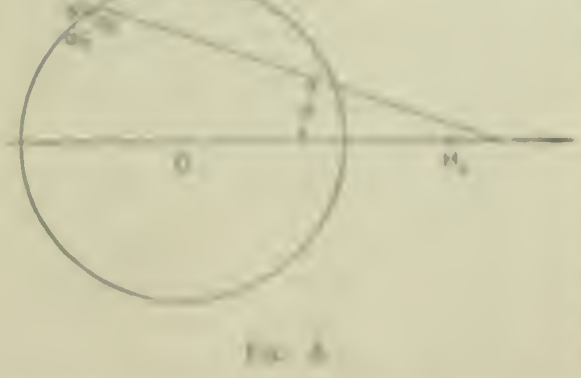

Fig. 3

interval "between the ending of one day, or month or year and the beginning of the next," but this has no bearing on the motion of a crosshead or on the pendulum motion of a clock. The clock merely serves as an indicator of the passage of time, and as such is necessarily subject to mechanical limitations which time is not. The pendulum of a clock does stop at either end of its arc, for at these points the kinetic energy of the pendulum mass, or its energy of motion, is all converted into potential energy or energy of position, which must then mean that the pendulum stops.

We have shown that the crosshead does stop, and that being the case, it does stand still, no matter how brief that time may be. The crosshead does not change direction without stopping. After the instant of stopping, say at the point H_1, the angles θ for Fig. 2 or φ for Fig. 3 become opposite in sign and there is an increase in the velocity component parallel to the axis of motion for the crosshead-pin center for Fig. 2 or parallel to the axis of the connecting rod in Fig. 3. The mathematics of this need not be discussed.

If there is anyone who still fails to see that the crosshead stops, we would like to have him show that a railroad train does not stop before it backs up.

The Economy of Vigilance in Small Matters

A correspondent in the issue of December 13 refers to losses due to small leaks. While this matter has been commented upon quite often, it should be kept continually before the eyes and drilled into the mind of every engineer.

There are several hundred valves and compression cocks, a large laundry, etc., in the building where I am at present employed. When I started to work here, some years ago, many of these valves and cocks were leaking and water was being wasted in other ways. By repairing all of the valves, and by continually requesting employees not to needlessly waste the water, the consumption was reduced by between fifteen and twenty thousand gallons every 24 hours. As much of the water which was being wasted was hot, and as many of the other leaks were steam, this saving meant also a saving in fuel.

As the men who deliver the coal to the boiler rooms and other parts of the building have an abundance of spare time, I got them to sift all of the ashes. During the first year that this was tried the fuel consumption was reduced by about 100 tons. This reduction has been kept up year after year. If extra help had been required to do the sifting, it would not have been a paying scheme, for one man's wages would have been more than enough to eat up the amount of money saved in the coal bill.

During eight years the only extra cost charged to this particular item has been $30 for repairs to the ash sifter.

James E. Noble.

Leakage through a Piston Valve

I was extremely interested in the publication in a recent number of results of tests made by George Mitchell, in the testing laboratory of the University of Pennsylvania, on the leakage of piston valves under actual operative conditions. I have made a great many visual tests myself on various forms of valves to determine the presence of leakage, but not to determine the actual amount. In these tests the method of showing this leakage was to set the valve in the center of travel, where it covered both ports; the exhaust valve under the engine in the exhaust line and cylinder drips were closed, the indicator plugs at both crank and head end of the engine were removed, and the throttle valve opened. In not one of over fifty of these tests for leakage of piston valves and flat pressure-plate valves was it practicable to open the throttle full for the reason that the leakage as shown by the steam escaping from the openings caused by the removal of the indicator plugs was so excessive that the room was immediately filled with steam.

Such a test naturally had to be made while the engine was in a state of rest.

The argument was often made that these tests were not fair ones, so far as the engine was concerned, inasmuch as a film of water between the valve and the bushing in a piston valve, and between the valve and the pressure plate in the pressure-plate valve, effectually eliminated the major portion of the leakage that was shown by these tests when the engine was not in operation.

The test, therefore, by Mr. Mitchell conclusively proves that the argument of water filling these spaces is a fallacy, as in his test the engine was operated under normal conditions.

The argument will probably be made that inasmuch as this valve was not equipped with packing rings, the leakage was greater than it would have been on a valve so equipped, but from the tests I have made I cannot notice any difference in the amount of steam escaping through valves equipped or not equipped with rings.

We have all heard the argument that the rings in a piston do not show excessive leakage, therefore why should the rings in a piston valve show any more leakage? The answer to this argument is simple:

If an engineer discovers a flaw or blow hole in the barrel of his cylinder, he would condemn the cylinder, for the reason that the piston rings traveling across this flaw would soon be cut and cause leakage. The rings in a piston do not travel across any ports, but merely up to the counterbore, whereas the rings in a piston valve must travel across the ports, and the ports are usually designed with bridges to prevent the rings from falling into them. The spaces between these bridges accomplish the same result, only to a much greater extent, as the small flaw in the cylinder would, for the reason that the bridges do not have as much bearing surface as the full bore of the valve seat and consequently wear faster. This greater wear at this point causes the rings to move in and out of the valve when crossing the ports, causing excessive wear on the rings, both on their circumference and on the side fit in the grooves.

I believe a test was made at Cornell University several years ago on a piston valve equipped with rings which could be tightened by hand, and I understand from one of those present that it was found that in three and a half hours after starting, the leakage was so great that the engine had to be shut down and the rings reëxpanded by hand.

I note a letter published in Power for November 8, by A. L. Ide & Sons, in which they give the results of several interesting tests to determine the increase in steam consumption with piston valves made 0.01 inch smaller than what they term "commercial fit." With 150 pounds steam pressure they got a consumption ranging from 26 to 27 pounds with valves with commercial fit. They then tested two valves that were made 0.01 inch under size and found that the steam consumption was increased in one case to 32.7 pounds. Taking an average of the results obtained with valves of commercial fit at 26½ pounds, it will be seen from these tests that a valve 0.01 inch smaller increased the steam consumption 22.3 per cent., which confirms Mr. Mitchell's findings of 22 per cent.

I think that any engineer will find on measurement that a piston valve, if it has been operating at least a year, will be even more than 0.01 inch smaller than the bore; in fact, I recently made a test of a piston-valve engine, the steam consumption of which was 54 pounds per brake horsepower per hour. I measured the valve and found it to be over 0.03 inch, or to be exact, 0.033 inch smaller in diameter than the bore.

Taking the calculations given by A. L. Ide & Sons, that each 0.01-inch wear increased the steam consumption 22.3 per cent., and assuming that the steam consumption of the engine I tested was 30 pounds per horsepower per hour when new, the leakage through the valve on this engine would be at least 3.3 times 22.3 per cent., causing an increase in steam consumption of 73.6 per cent. Therefore, if this engine with a tight valve would develop a horsepower-hour on 30 pounds of steam, 73.6 per cent. increase would result in a total steam consumption of 52 pounds, which is a trifle less than that indicated by the careful test which I made on the piston-valve engine.

I do not agree with the statement of A. L. Ide & Sons that a valve 0.002 to 0.003 of an inch under size is plainly a poor fit. The sliding fit for a hub on a shaft is from 0.002 to 0.003 inch for ordinary diameters, when the parts are cold, and I maintain that any piston valve must be at least 0.002 to 0.003 of an inch smaller than the bore to be free to slide.

From the visual tests I have made, the leakage on all flat-valve engines equipped with a pressure plate has been greater than on the piston valve. I say greater, for the reason that a greater amount of steam is always seen escaping through the openings left by the removal of the indicator plugs.

I have surprised a great many engineers by making this statement and the result has been that quite a number of these tests have been made, all of which confirmed my claims. Other confirmation may be had from the tests made by Messrs. Dean & Wood, the results of which were presented in a paper to the American Society of Mechanical Engineers at the meeting in Detroit, in 1908, an abstract of which, I believe, was published in Power. These tests also showed the flat pressure-plate valve to be a very leaky device.

I happen to know of a very fair test that was made on a pressure-plate valve engine in New York City recently, the results showing a steam consumption as high as 59 pounds per indicated horsepower per hour. All of which helps to prove the point that I am trying to make, viz., that a balanced pressure-plate valve shows greater leakage after a certain period of operation than the piston valve. This is probably due to the fact that the pressure-plate valve when absolutely new leaves the builder's factory with 0.003 to 0.004 of an inch clearance between seat and pressure plate. This clearance has been found necessary in order to provide freedom of action under all conditions, and this clearance becomes greater with use. Mr. Mitchell's test was made on a valve that was new, and had not been running for any considerable length of time, and I know from experience that this leakage would be much greater after the valve had been in operation for several weeks. According to the Dean & Wood report, valves can, and are, being made that are self-expanding to compensate for wear, and thereby eliminate leakage.

I wish Mr. Mitchell would make another leakage test on this valve after it had been run for four weeks' time, and also make a leakage test on a flat pressure-plate valve, when new and also after it has been in operation for a short time. These are just the tests that the engineering fraternity has been wanting for years, and Mr. Mitchell is to be complimented on his manner of making these tests, which method disposes effectually of any arguments that have been brought forth that both types of valves above mentioned do not leak steam under operative conditions.

Buffalo, N. Y.

Selection and Use of Packing

Engineers have but few subjects to consider that are capable of greater diversity of opinion than that of the results obtained from the various piston-rod packings now in general use. However good or however worthless they may be when considered separately, the results that are obtained are so conflicting that what is considered satisfactory by one is as honestly condemned by another. The great variety of conditions under which packings are used is, and always will be, understood as unavoidable. How to meet these different requirements could be answered by a hundred engineers, in a hundred different ways, according, of course, to the various experiences of each one, those experiences being due, of course, to the different conditions met with in each case, such as speed of piston, pressure, material, etc.

There are, however, faults attributable in many cases not only to the engineers, but also to the manufacturers and inventors of these articles of everyday use. It would be an injustice to assert that every engineer does not use intelligence in the matter of using an article. Yet it is often found that a well made article is condemned and thrown aside, owing to a want of knowledge as to its proper use or to carelessness in application. At the present time there is an abundance of varieties of packing, each one, of course, claiming a certain superiority over the rest. It is, nevertheless, true that in many cases quality has been sacrificed to price, notwithstanding the fact that manufacturers stoutly deny any difference in the quality of their product. Is it reasonable to suppose that such an assertion is true when one can buy at the present time for 50 cents an article similar in appearance to what formerly cost three times as much? I think not. This reduction in quality is often done in such an expert manner, however, that none but experts in fibers can detect it from outward appearance, and thus in numerous cases the poor results are attributed to some accident or carelessness in using.

This condition of affairs can only be remedied by the men who use the packing, and who should insist upon obtaining an article of high quality suitable to their own particular case, whatever the cost may be. The compensation will be obtained in the saving of wear and tear, fuel, power and in repairs. Packings having a flat surface against the rod allow the most perfect bearing and produce the least friction as the pressure is more uniformly distributed. Avoid those packings which produce a hard or rigid bearing beyond what is necessary to prevent leaking, which should be provided for by natural expansion. Of course, I assume that the rod is perfectly level and in line; trying to hold a rod steady by screwing up the packing hard when everything is out of line usually results in a miserable failure. If metallic packings are used the conditions must be more perfect to insure success than is generally the case with fibrous packings. However metallic packings are now being used with good success when applied intelligently and, when they are proof from the efforts of the monkey-wrench engineer, are giving excellent satisfaction. I have observed cases where metal packing was in use where when the least little moisture occurred around the rod, due to its not being exactly in line, or to a poor adjustment of the crosshead, the engineer screwed up on the nuts of the stuffing box until fire appeared. Men of this class will ruin any kind of packing, but it is a pleasure to say that they are very much in the minority. I do not presume to enumerate either the ordinary or the desirable makes of these goods, believing that these few hints may serve to arouse interest in the packing problem and thereby be instructive to engineers in general.

CHARLES H. TAYLOR.

Hotel Power Costs

In the issue of POWER for November 8, under the head "Hotel Power Costs," I saw the figures given by J. H. Morrow, chief engineer of the Great Northern hotel, Chicago. Mr. Morrow gave definite figures as to the power costs for a year before and after installing an isolated plant. I would be very glad to hear from other engineers of hotel and office buildings along this same line. Also, I should like to secure some data as to the cost of an installation per kilowatt.

Which would be the more economical for a small plant, a steam turbine or a reciprocating engine driving a generator where the exhaust is to be used in a heating system?

O. L. SHERMAN.

Duluth, Minn.

Introducing Solvents into Boilers

The article by C. H. Taylor in the December 6 issue on this subject will help quite a number of engineers who, like myself, have looked vainly through the advertising pages of POWER for a thoroughly reliable compound feeder. In several plants that I have visited there is some homemade affair that is doing the work with more or less success. Some time ago I went so far as to write a large manufacturing concern whose business was among other things, the making of force-feed lubricators, asking if they did not believe they could put something on the market that would "fill the bill," constructed on the lines of a force-feed lubricator which could be attached to the boiler-feed pump. Some compounds may have a sediment, thicken up, or contain acid which might attack the metal of the pump or valves. If any of the readers are using an ordinary force-feed pump with success, I would be glad to know it. There are quite a few little difficulties which crop up in connection with compound feeding.

Leakage at the gland would be particularly objectionable; hence a well designed stuffing box is essential. The tank or vessel from which the pump takes its supply should be elevated and have a graduated gage glass. The quantity pumped should be easily adjusted. An apparatus of this kind ought to command a ready sale. The amount of compound introduced would have a direct relation to the quantity of feed water put into the boiler, and this is a desirable condition. I have an apparatus that is working in a fairly satisfactory manner and which I partly made from scrap. The homemade product, however, is usually very crude, clumsy and quite frequently more costly than the originator would care to admit. There is so much of this homemade stuff to be found, so many ingenious, temporary repairs, etc., which, in the long run, are apt to prove extremely costly that anything of this nature ought to receive very careful consideration before adoption.

New Haven, Conn.

The Problem of Smoke Abatement

Some time ago POWER published a paper by Mr. Randall, on the suppression of smoke. Mr. Randall's paper was very interesting and readable, but he gave no real solution to the smoke problem.

As things stand at present, particularly as regards the payment of the firemen, no device made is really satisfactory in the suppression of smoke. This is no fault of the device in many cases; it is simply lack of knowledge on the fireman's part as to the method of utilizing the device to do away with the smoke. Steam jets, special arches, special grates and special furnaces and all characters require expert handling in order to obtain results, and they rarely get it. An expert fireman can get an almost smokeless furnace, unless it is being forced to the limit, with almost any of the coal sold in New England. If, however, an inexpert fireman takes the shovel, the results are radically different, and no matter how good the furnace is, smoke will be given off in large quantities.

The majority of manufacturers look on the fireman as merely a device for feeding coal under the boilers. Brute strength is the main consideration, and brains receive but scant acknowledgment. This seems rather extraordinary when one considers that one of the heaviest expenses in the power plant is the coal pile. A manufacturer will employ a first-rate engineer and pay him a good salary, for the express purpose of keeping his engine and shafting in good condition. He will purchase and install a high-grade engine and condensing outfit, if possible, in order to economize in steam consumption, but when it comes to the man who is largely responsible for the amount of coal burned on the grate, he is always looking for the strongest man at the lowest price. At this very point there is a tremendous opportunity for saving. A good fireman is worth money, and he will more than save the difference in his wages through the use of his brains. Less coal will be required and less smoke will be made. Less coal will be required, because he will see that the amount of air admitted to the furnace is graded to the amount of coal he puts on the fire, so far as the construction of the furnace will allow, and, therefore, he will burn up the volatile matter in the coal to a very large extent, which under the firing of a poor man, goes up the stack in smoke.

There is, of course, vast room for improvement in the construction of the furnace at present used for bituminous coal. In the first place, the hight of the boiler above the grate is far too small. There is not a sufficient opportunity for varying the amount of air which enters above the grate. The ashpit door is not large enough to give a thoroughly good admission of air under the grates, and the greater part of the air goes up through the grates at the back of the furnace, instead of at the front. All engineers know the material abatement in the smoke nuisance that can be secured through the use of the dutch oven and the very long fire box. This is due mainly to the thorough mixing of the air and volatile gases and the opportunity offered for them to ignite before they go over the bridgewall. In order to burn these gases, it is necessary that they be mixed with a proper amount of air and brought to a sufficient temperature to be ignited when they pass over the rear part of the fire. If they are not ignited before they go over the bridgewall, there is little or no prospect for their being ignited at all. Special arches in many cases will improve the combustion to the suppression of smoke, and increase the efficiency of the combustion.

My solution of the smoke problem is, then, pay the fireman enough to make it worth while his staying on the job, and then train him. Adjust the furnace so that air can be admitted both above and below the grate and thoroughly mixed with the combustible gases before these gases go over the hottest part of the fire. Train the fireman to coke the coal at the front of the fire, so as to drive off the volatile matter from the front end of the furnace. Push this coal back as the fire burns out at the rear, and shovel again in the front. It might be said that the automatic stokers do away to a considerable extent with the skill required by fireman. This, however, is by no means true. The automatic stoker requires adjustment of the air just as much as does hand firing; and a poor fireman cannot do as well with an automatic stoker as a good one.

Boston, Mass. HENRY D. JACKSON.

Air Bleeder for Boilers

In the December 13 number, Mr. Mistele has a letter on the subject of water hammer, in which he speaks of the trouble he experienced with air in the boilers when raising steam and the remedy he applied.

I regard it as a wise plan to have all boilers tapped at their highest point with a 1-inch bleeder connection. In raising steam this should always be left open until the gage shows some pressure. It should be given a good, strong blow before opening the stop valve to the line; particularly is this the case where condensing engines are being run, as a boiler which contains very much air will frequently cause a condenser to go down unless it is thoroughly drained of air before being cut in.

Another desirable feature of such a bleeder is that it allows a much more rapid cooling of the boiler when a hurry-up job of washing out is in order, as is so frequently the case in small plants where but a few hours can be had in which to cool down and wash a boiler.

O. B. CRITCHLOW.

Woodlawn, Penn.

Faulty Design

Under the above caption, Mr. Rayburn, in the November 22 issue of POWER, describes a condition of engineering which is not engineering; an exception is taken to his ruling of the term "engineer." The manifold errors cited in the installation of this particular steam plant tend to prove that an engineer, a real engineer, was not in evidence—degradation should not be cast upon the engineering profession at large to style those who were engaged as "engineers." As in all walks of life, in the engineering business today there are engineers, and there are engineers—there is a wide distinction. The "catalog" engineer, the inexperienced engineer, the inefficient engineer, the engineer who could not fill a drafting position, who follows the calling haphazard, and subsists on the earnings derived from the enterprise promoter not familiar with such design, who accepts a fee from his client and an additional fee from some particular manufacturer whose product he specifies and insists upon, these are not engineers, nor are their efforts engineering—it cannot be classed in that category.

The real engineer, the man who knows his business, does not necessarily have "to smoke black cigars and carry a slide rule," knowledge is not contained in these two elements, and I am under the impression that some engineers use neither. The real engineer is not given to words or boasting; as a rule, he is open to reasonable argument, and his actions and methods show results.

The selection of a consulting engineer for a certain work shouid be made only after investigation as to ability and past performances; the real engineer is alive to the best interests of his client, he expects future business from him, he expects his recommendation to others. The competent engineer always proves to be the cheapest in the long run.

L. R. W. ALLISON.

Los Angeles, Cal.

Water Gage Connections

In the December 13 issue of POWER, Mr. McGahey has a letter relating to the placing of valves in water-column connections. The pros and cons of this matter have been discussed in the columns of the mechanical papers and outside of them many times, but I do not remember ever having seen stated what I regard as strong justification for their use; namely, their great value when the water connection becomes clogged. With a valve in the steam connection which can be closed, full boiler pressure can then be brought to bear to blow out any obstruction in the pipe, whereas, with no valve in the steam pipe, the opening of the blowoff valve on the column but imperfectly cleans the water connection between the column and the boiler, due to the fact that the pressure in the column is, to a great extent, balanced. The same principle applies here as in the case when we close the lower valve first when a gage glass breaks, allowing the steam valve to blow and thus hold back the hot water. I was once saved from the necessity of a shutdown at a critical time by having these valves to use, and later when a Hartford inspector recommended their removal, I was able to convince him that it was better to leave them in.

O. B. CRITCHLOW.

Woodlawn, Penn.

Steam Turbines and Generators

By E. D. Dickinson and L. T. Robinson

A paper presented at the December meeting of the American Institute of Electrical Engineers, taking up the subject of testing turbo-generators from the point of over-all efficiency under conditions which are as near as possible to those under which the machine is to operate.

In manufacturing steam turbines a great amount of testing is necessary to determine the effect of changes in design or to verify theories which cannot be established by calculation; much of this is of a laboratory nature. There is also a large amount of testing done to establish the over-all economy of the complete unit, which is all that is of commercial value to those operating steam turbines.

The one positive method of testing a turbo-generator is to measure the steam that goes in through the throttle, and the electrical energy delivered at the terminals of the generator. The surest way of determining how much steam enters the turbine is to collect and weigh all the steam after it has been condensed. This necessitates the use of a surface condenser. In making such a test two things are essential: first, that all the steam used on the turbine be condensed and measured; second, that no steam or water not used in the turbine be allowed to enter the condenser. The condenser should have the leakage checked, before and after each test. This is accomplished by shutting all steam off the turbine and running the condenser for some time with full vacuum, the discharge from the hot-well pump being accurately measured. Split tubes sometimes cause leakage which is difficult to locate as they open only when the condenser is heated by large flows of steam.

When the condensed steam cannot be measured, as is the case when the turbine is operating noncondensing, or when the condenser is of the jet type, the steam consumption is found by weighing the water fed to the boilers. In making such tests, the liability to error is very great, and every precaution must be taken in order that the results may be reliable within a certain degree of accuracy.

The steam piping connecting the boilers and turbine must be disconnected from all other piping, and all openings must be blanked off; valves must not be relied on. All blowoff and drain valves must have their outlets visible, and all piping between the boiler feed pumps and the boilers must be exposed and have no branches. Leakage of the boiler itself is difficult to locate, as all water or steam escaping is vaporized and carried up the stack. The boiler leakage should be checked before and after each test by closing the throttle to the turbine, or if necessary, blanking the pipes at the turbine and running a test measuring the amount of water required with full steam pressure on the boilers and piping. The feed water used should be weighed and not measured by meters.

Tests which have come under my observation have shown a boiler leakage of 10 to 12 per cent., and one particular case showed a leakage of over 20 per cent.

The comparison of efficiencies of different machines is the most satisfactory way of considering their relative merits. To determine the available energy in one pound of steam it is necessary to know the pressure in pounds per square inch, the quality and the temperature of the entering steam; also the pressure at the turbine exhaust. To measure the vacuum a full-length mercury gage should be used. If the steam be superheated, since there is some difference of opinion concerning the specific heat of superheated steam, the figure assumed must be given. In testing turbines consisting of several stages, the pressures in the different stages should be measured, as this affords a check and should show any abnormal conditions which otherwise might not be observed. The kilowatt output should be net, that is, the kilowatts for excitation should be subtracted from the generator output.

All instruments, including meters, gages, thermometers and scales, must be very accurately calibrated before and after the test.

Whenever possible, turbines should be tested under the conditions for which they were built to operate, as corrections for different conditions are liable to cast doubt upon the accuracy of the test. In general, the corrections for steam pressure, moisture or superheat are less liable to be misleading than that for a varying vacuum, as comparatively large changes in any one of the first three will but slightly affect the results, but a slight change in the vacuum makes an enormous change in the available energy.

Electrical Output

First consider the measurement of direct-current output. Usually, station instruments in connection with the generator switchboard have been provided, but unless temperature conditions can be very accurately controlled and the instruments can be checked under operating conditions they should not be used. The station voltmeters may sometimes be satisfactory, but it is the usual practice to supply direct-current station ammeters to operate from shunts of approximately 60 millivolt drop, which requires that the indicating part of the ammeter be largely a copper circuit; therefore, the whole combination is subject to considerable error due to variations in room temperature, and with some shunt arrangements, to variations in the current to be measured. For the precise measurement of direct-current output, portable indicating ammeters should be used having 200-millivolt-drop shunts, and permitting the use of indicating millivoltmeters whose circuit consists largely of resistance material having practically no temperature coefficient.

When using either switchboard or portable instruments the influence of any stray fields should be investigated. Also, care should be taken to correct the observed indications of the millivoltmeter for any electromotive forces that may appear in the shunt or leads due to thermo-electric effects. The amount of error due to this cause may be observed by reading the millivoltmeter at the close of the test with no current flowing in the main circuit. Referring again to the station type of shunts, unless the ammeter is checked with the shunt connected into the busbars, care should be taken to see that the distribution of current flow through the shunt is the same when the ammeter is used as when it was tested. It is quite possible to have large errors due to this cause.

Next it is necessary to consider the proper use of the instrument transformers which usually provide the only means of enlarging the capacity of the instruments to meet ordinary requirements.

In using instrument transformers it is necessary to observe the precaution to have the secondary connected load the same as that which is on the transformers when they were tested for the certificate. It is also necessary if the test is to be made under conditions that will give a low power factor on circuits, to know that the phase displacements in the instrument transformers are not large enough to appreciably affect the results. It is also well not to use instrument transformers with interconnected secondaries except for the common ground which should be employed as a safety precaution.

If possible, a test should be made on noninductive load, in which case, if all the test arrangements have been satisfactorily attended to, the apparent power as shown by the volts and amperes should agree within 1 per cent. with the wattmeter indications and the watts indicated should be taken as the true output. If the test cannot be made at unity power factor, the voltmeters and ammeters should be included so that the general conditions of distribution of load, etc., may be known throughout the test. For this purpose the station instruments would be satisfactory.

Watt-hour meters should never be used unless checked in place at the frequency, voltage, etc., which are to be used in testing. If it is not possible to run a complete test at a fairly steady load it is usually possible to make a few runs on the watt-hour meter under load conditions and to use this check as a basis for determining the output by means of the meters during the test run on an unsteady load. It is still advisable to read the indicating instruments at short intervals so that their indications may be made use of in computing the final result.

Single-phase indicating instruments for polyphase service are to be preferred for precision work to polyphase instruments, for the reason that indications of a polyphase instrument are made up by the two elements in such a way that it is not possible to apply corrections to either element to get the true total result unless the division of load is known by single-phase instruments; and if the single-phase instruments are required for this purpose they may as well be of the precision class and used for the actual determinations, and the polyphase instrument omitted.

Discussion

After the presentation of the paper the discussion was opened and consisted, in part, as follows:

Mr. Dunn: The paper deals principally with over-all efficiency tests, but before these tests become necessary there must be an enormous amount of detail and special testing both of the generator and the turbine. One of the important things to know in regard to both these pieces of apparatus is the proportion of losses chargeable to each.

It is found, for instance, when retardation tests are made on turbo-generators, that vibration, windage, etc., occupy a different proportion of the total losses than on the ordinary classes of apparatus; and the proportion of these losses is not determined by prior conclusions. Empirical methods, only, will bring these out. Consider the mechanical balance of turbo-generators. It is well known that below the first critical speed, if the generator is run in flexible bearings and the chalk held against that part of the revolving surface which seems to be highest, it will hit the heavy part of the revolving member. But when the speed has increased to the point where the apparatus gyrates around its center of gravity then the chalk mark will be moved theoretically 180 degrees from its first position. It may appear easy to calculate these critical speeds but even when the best knowledge on the subjects of vibrations, inertias and gyrations are applied, the result will not agree with that found in practice.

Again, regarding ordinary efficiencies, where the company builds both the generator and the turbine, its responsibility is founded on the amount of steam consumed and the electrical energy developed; but where they are made by separate companies the individual performances are more important.

Mr. Emmet: Individual study of the generator and the turbine is very desirable, but is extremely difficult. This is because the generator is a high-speed piece of apparatus requiring a large amount of power and cannot well be run by anything but the turbine itself. However, there is one method of investigating the generator alone which has considerable value; this is the "deceleration" method. It consists in bringing the generator up to a speed, by motor or otherwise, in excess of that at which it is to be operated and then allowing it to decelerate, noting the rates of deceleration and from these rates, with a carefully calculated moment of inertia, determine the amount of power exerted in deceleration at any particular instant.

A matter of much interest but one which is only slightly alluded to in this paper is that of the steam meter. We have been using steam meters in all of our turbine tests for a long time and at the same time have been weighing the water. The results have checked within 2 per cent. in practically every case.

Mr. Dreyfus: An important characteristic of the steam turbine is that the inlet pressure varies almost directly with the load, provided the same steam pressure, superheat and vacuum are maintained. This affords a means for graphically checking the performance of a turbine.

Clearance in Ammonia Compressors

At the recent meeting of the American Society of Refrigerating Engineers, Thomas Shipley, of the York Manufacturing Company, presented a paper dealing with the effects of clearance in vertical single-acting compressors of the false-head type and horizontal double-acting compressors of the spherical-head type.

The compressors were [illegible] same diameter and stroke and were driven by the same engine, that is, when one compressor was in operation the other was disconnected. The runs were made at suction pressures of 5, 15.67 and 25 pounds gage, and the condensing pressure was 185 pounds gage. The speed was 70 revolutions per minute and during the runs all conditions were kept as nearly constant as possible.

In the single-acting compressor the clearance was controlled by screwing the piston rod into the crosshead and in the double-acting compressor by placing metal rings between the cylinder flanges and the heads.

Table 1 shows the relative effect of clearance on the horsepower per ton, and Table 2 shows the effect on the capacities. It will be noted that the losses due to clearance in the double-acting compressor are much larger than those in the single-acting compressor, and that the losses increase inversely with the suction pressure.

POWER

Condemn the Old Boiler

It is not often that the public exercises much concern as to the condition of steam boilers used in power plants, unless one of them explodes and kills somebody. Then censure is handed out right and left, and the less that is known about boiler practice the more harsh the criticism.

In the instance of a municipally operated electric-light plant those in charge decided that the lap-joint boilers were not fit for further service and new butt-joint boilers were accordingly installed in their place.

Before the old boilers were discarded, however, the taxpayers rose up in their might and loudly denounced the wastefulness of the town fathers for throwing out good boilers and wasting public money in purchasing new ones. In justification of their stand against this *needless* waste, a neighboring manufacturing plant was cited, where several boilers were in operation every working day of the year, and none of these boilers had been in service less than twenty years.

From a layman's standpoint these town folk were right in their views, and they were somewhat justified in taking the stand that if a set of boilers over twenty years old were good enough to serve a prosperous manufacturing company, their boilers, which were no older, were good enough to operate in the town lighting plant.

These town people were not aware of the fact that from the time a boiler is installed it begins to deteriorate, and that there comes a time when it is no longer safe to operate at the pressure originally allowed. Just when this time arrives is a matter of judgment on the part of those to whose care the boiler is intrusted.

Notwithstanding the opposition, the old boilers were thrown out and after the new boilers were installed and put to work the matter was dropped, except for muttered grumbling on the part of a few taxpayers.

Two years passed, and one day the air was rent with a mighty explosion; two men were killed and the boiler house of the manufacturing plant was completely wrecked. The old boilers that the town people had held up as safe and sound were lying in a heap of bricks and debris and one—the one that exploded—was a bent and twisted wreck.

Not one of the town folk can be found today who will intimate, let alone charge, that the town officials were wasteful of public money, or that they did not use the best of judgment when they threw out the old boilers.

There are but two reasons why an old boiler is allowed to remain in service: Either the firm owning it does not care to spend the necessary money for a new one, or the old boiler is made to do service while the new one is being installed, and it sometimes happens that the old boiler explodes in the meantime.

This matter of discarding old boilers will doubtless be allowed to rest with the judgment and conscience of the owner, in the future as in the past, a few States and cities excepted, until the death list becomes so great as to frighten owners into replacing their old boilers with new ones and, perhaps, convince the State legislature that every lap-seam boiler over ten years old is in reality a hidden mine, liable to explode sooner or later and add its toll of dead and wounded to the annual massacre.

Strength of Wheel Rims

Twelve or fourteen years ago, Prof. C. H. Benjamin presented papers on the "Bursting of Small Cast-iron Wheels" before the American Society of Mechanical Engineers which were remarkable in two ways: First, because he brought out complete and authoritative evidence on the subject, and, second, because of the small attention paid to them by engine builders. Some manufacturers today continue to place the flange between the spokes, just as they used to do, and they tell you with one breath that the strain in the rims of their wheels never exceeds one thousand pounds per square inch, and with the next breath that the efficiency of the flange joint is one hundred per cent. The professor stated in his paper that one would not think of putting a joint in the middle of a girder. This we can understand, but why do not these engine builders understand it? It is not that they do not understand that it is poor design to put a joint in the middle of a girder which is carrying a transverse load, but rather that they do not believe the girder is loaded in that manner; that instead of the rim of a pulley between two arms being loaded like a girder, it is in tension, and, therefore, if the flange has enough metal in it, and the bolts are as strong as the flange, the efficiency of the joint would be one hundred per cent.

In this discussion, we will confine ourselves to pulley wheels, by which we mean wheels with thin rims used to transmit or receive power by belting or ropes. Regular flywheels, having rims of heavy rectangular cross-section, give little opportunity for bending between the arms and, besides, in such wheels the rim is sufficiently deep to permit the use of links for fastening the sections together.

The assumption that the rim of a pulley wheel is in tension only, due to the centrifugal force, is wrong, unless the rim is not attached to the spokes—is free to expand under the influence of the centrifugal force and assume a truly circular form. There are a few such wheels, in which the arms fit into a socket in the rim, and as the wheel revolves the rim can increase in diameter. Such a wheel is said to have a "free" rim, and such a rim is in tension only. It is clear that if in such a rim is put a flange having no weight, the section of which is designed to withstand the tension due to centrifugal force, such a flange can have an efficiency of one hundred per cent. But the flange must have weight; and so, even with a wheel with a "free" rim, the efficiency must be less than one hundred per cent.

If, now, we assume a pulley wheel in which the rim is attached to arms which are absolutely rigid and will not stretch, the rim, when rotating, will tend to bow out between the arms and will act like a girder loaded with a uniformly distributed load.

So, we have two theoretical cases: one in which the rim is free to expand and take a truly circular form, in which case the rim is in pure tension and is not subjected to bending. In the other case, the rim is attached to rigid arms that will not stretch, in which case the strain is due wholly to the bending moment.

In practice, however, the pulley wheel is between these two extremes. The rim expands some and pulls out the arms, and though the arms stretch some, yet they pull in the rim, so it is not correct to consider the rim in tension only, or as a girder carrying a uniformly distributed load only, and, to complicate the matter further, we have a strain induced by the flange itself.

To determine the strength of an actual wheel, recourse must be had to the results of experiments, and for these we are indebted to Professor Benjamin. These experiments show that a wheel with a well designed flanged joint, which is placed between the arms, will rupture at about one-half the speed of a similar wheel with a solid rim. As the strain varies as the square of the speed, this means that the flange joint is only one-quarter as strong as the solid rim, or that its efficiency is only about twenty-five per cent.

The wheels upon which the experiments were made were only twenty-four inches in diameter, and some may say that these results would not apply to a wheel, say, sixteen feet in diameter; but there is no reason for such an opinion, because the efficiency is a ratio and not an absolute quantity, while the flanges were carefully made to scale from a larger flange in a larger wheel in actual use. If there is any difference, it would be in favor of the small wheel, on ancount of the thinner sections, and, therefore, the better casting.

Do not confuse the measurement of the efficiency of such a flange joint with the measurement of the efficiency of the joint in, say, a boiler shell. If we say, in referring to the latter, that the efficiency of a certain joint is seventy per cent., the rivet strength being high, we mean that thirty per cent. of the metal has been cut away and that only seventy per cent. remains, and it follows that the greater the pitch of the rivets (making up their area by increasing the number of their rows) the greater will be the efficiency. There are joints in boilers that have an efficiency as high as ninety-eight per cent., but a similar procedure cannot be followed with flange joints in a pulley wheel, where, as the joint is strengthened by the addition of metal, the centrifugal force of that same metal increases in the same ratio the strain it is called upon to bear. So, when we refer to the efficiency of a rim joint as twenty-five per cent., we do not mean that it contains only one-fourth the amount of metal in the rim, or that if put in a testing machine and pulled it would break at one-quarter of the load on the solid rim, but, rather, that the strain in it is four times as much as the strain in the rim. Take a wheel sixteen feet in diameter, running at one hundred revolutions per minute, which is equivalent to a rim speed of five thousand twenty-six feet per minute. If the rim is "free" and has no joint, the tension in the rim due to centrifugal force is seven hundred pounds per square inch. If, however, the rim is fastened to the arms, and there is a flange joint between the arms, whose efficiency is only twenty-five per cent., then the strain in the rim is twenty-eight hundred pounds per square inch, and that the factor of safety is low in such wheels is shown time and again by the short interval of time which elapses between the derangement of the governing mechanism and the moment the wheel goes to pieces. Wheels of reputable make have been known to stand only a few seconds of racing.

Talk to an engine builder who persists in the use of the interarm joint about the efficiency of the flanges in the pulley wheel which he builds and he will at once begin to talk about the importance of good design, good workmanship and careful foundry work. We have no desire to appear to slight these very important matters, but the point that we wish to make is that of two similar wheels, one with a solid rim fastened to the arms, and the other with the rim joined by flanges placed between the arms, the latter wheel may be but one-quarter as strong as the former.

Generating Power for the Navy

A recently issued report of H. I. Cone, engineer-in-chief of the United States Navy, says that designs have been prepared for battleships with water-tube boilers, fitted for the use of oil fuel and coal, the oil fuel to be used in conjunction with coal or independently, and designs for destroyers for water-tube boilers with oil fuel only.

A high-speed marine steam turbine with reduction gear is being installed in the collier "Neptune," now building at the works of the Maryland Steel Company, Sparrows Point, Md. She is to be a twin-screw vessel, displacing 19,360 tons with a speed of fourteen knots. Steam at a pressure of two hundred pounds will be supplied by three double-ended Scotch boilers to a Westinghouse-Parsons turbine on each shaft, each turbine developing about four thousand shaft horsepower at one thousand five hundred revolutions at full power. Between each turbine and its propeller shaft is to be interposed a Melville-McAlpine gear, reducing the propeller speed to 136 revolutions per minute.

Tests have been completed during the year at the Norfolk navy yard of nineteen representative types of internal-combustion engines for launches. Of this number nine proved to be fit for naval service.

Considerable progress has been made on shore in the development of bituminous producer-gas power plants. Owing to a lack of funds the Bureau has been unable to do its part in the development of the internal-combustion engine for large naval vessels. As stated in the Bureau's last annual report, we cannot afford to delay this development and the recommendation is renewed for authority to expend as much as $250,000 for the purchase and installation of an internal-combustion engine plant and an able collier or other suitable hull in the event that it is thought wise to experiment along this line.

The generally accepted belief in the safety of water-tube boilers seems to have received a severe jolt by the recent explosion in Brooklyn. The authors of text-books upon boilers will have to get out revised editions.

The tendency is in the direction of getting more service out of a given amount of boiler-heating surface than has been thought practicable. Shall it be by putting in more grate surface or by burning more coal per square foot of grate?

Inquiries of General Interest

Engineer's First Duty

What is the first duty of an engineer on taking charge of a new plant?

E. F. D.

He should learn the condition and arrangement of the plant, what it will do and what is required of it.

Pressure Due to Heat

From a tank on the roof two pipes lead to the cellar. One is quarter-inch and the other two inches in diameter. Will a pressure gage read the same on the bottom end of each pipe?

P. D. H.

Yes, the pressure per unit of area for the same hight of water will be the same regardless of the diameter of the pipe.

Volume before and after Compression

How far will the piston move in compressing air to a pressure of 100 pounds in the cylinder with no rise in temperature?

B. A. C.

As the volume of air compressed in the cylinder will be inversely as its pressure, the volume of the compressed air will be

$$14.7 \div 114.7 = 0.128$$

of the original volume and the piston will, neglecting clearance, leakage and the heating of the air, move

$$1 - 0.128 = 0.872$$

of the stroke in compressing air to 100 pounds gage pressure.

Exhaust and Inside Lead

What is the difference between exhaust lead and inside lead and how much exhaust lead should a valve have?

E. I. L.

Inside lead is the opening which the exhaust port has when the valve is in the middle of its travel. Exhaust lead is the opening which the exhaust port has when the piston is at the end of the stroke, and should be sufficient to allow full port opening early in the return stroke so that there will be no excess in the back pressure. It is sometimes customary to make the exhaust lead twice the steam lead.

Load on Braces

How can I know that each brace in a boiler carries its full load?

L. O. B.

By being sure that none are loose when the boiler is empty but that all are equally or nearly equally tight, as may be proved by sounding with a hammer.

Questions are not answered unless accompanied by the name and address of the inquirer. This page is for you when stuck—use it

Air Compressor Capacities

How may I find the required lift for a 2½-inch gas-compressor valve? Give a rule to find how many cubic feet a gas compressor, 32x60 inches, with five pounds pressure above the atmosphere in the suction pipe and seventy-five pounds discharge, will deliver at one stroke?

A. C. C.

A lift of one-fourth the diameter of the valve will give a discharge area equal to the area of the valve but it has been found that 75 to 80 per cent. of this lift is sufficient. The volume of gas compressed may be determined by the formula

$$\frac{14.7 + 5}{14.7} \times \textit{Piston displacement} = \textit{Volume compressed}$$

and the volume after compression and subsequent cooling to the original temperature will be the above quantity multiplied by $\frac{14.7}{75 + 14.7}$. The actual amount will probably not exceed 85 to 90 per cent. of the theoretical depending on the volumetric efficiency of the compressor.

Steam Engine Dimensions

In making a small engine, how shall I proportion the different parts to make it look right? I mean such parts as the shaft, piston rod, valve stem, crank pin, connecting rod, etc.

S. E. D.

Make the main bearing one-half the diameter of the cylinder and two diameters long, the crank pin one-half the diameter of the shaft and one and one-quarter diameters long, the piston rod one-fifth the diameter of the cylinder and the connecting-rod length three times the length of the stroke and the diameter of the necks equal to the diameter of the piston rod.

Air Compressor Operation

We have lately installed a cross-compound two-stage air compressor. The governor is set to stop the compressor at an air pressure of 95 pounds and the engine invariably stops on the center on the high-pressure side, and before the air pressure falls sufficiently for the low-pressure side to start the engine again the steam in the receiver condenses and the pressure falls so low that the engine will not start until live steam is bypassed to the receiver.

We thought of placing a pressure-reducing valve in the bypass pipe leading to the receiver, and set it at 30 pounds, the pressure carried in the receiver, and keeping the valve in the bypass open so that the receiver pressure could not drop below the regular amount carried; would this interfere with the proper working of the engine in any way?

W. W. W.

The governor should be so set that the engine will not stop when the desired pressure is reached but will "creep" past the center. If a reducing valve is placed in the bypass it should be set to maintain a pressure in the receiver which will be just sufficient to move the engine off the center when the air pressure falls below the desired pressure.

Uptake Temperature

If the pressure carried in the boiler is 100 pounds, what should be the temperature of the escaping gases?

B. F. T.

From 450 to 500 degrees Fahrenheit.

Air Pressure for Lifting Water

In an air lift with 200 feet submergence, what pressure of air will be required to raise water 50 feet?

A. L. W.

The pressure required to start the water will be

$$\text{Submersion} \div 100 \times 0.434 + 5 = \text{pressure}$$

Once started the air pressure will depend on the quantity of water delivered but will never be less than is required to support a column of water of a hight equal to the lift.

Pressure in Radiators

Is a steam-heating system, is the pressure in the radiators farthest from the boiler the same as in those which are nearest?

P. I. R.

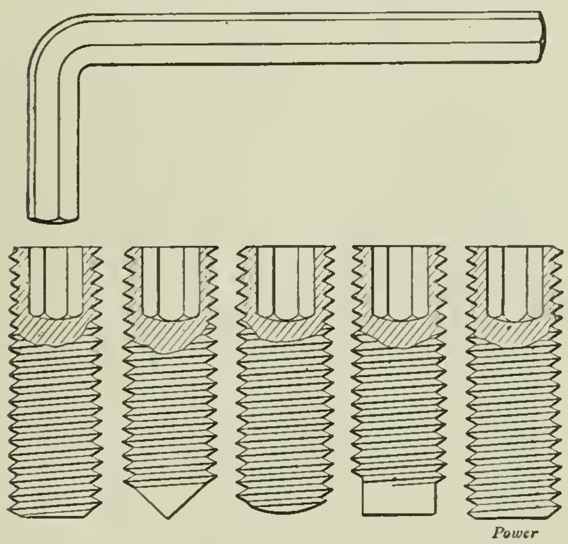
No. In order for steam or any other medium to flow from one region to another there must be a difference in pressure. In a one-pipe system the pressure is highest in the radiators in the upper part of the building.

New Power House Equipment

What the inventor and the manufacturer are doing to save time and money in the engine room and power house. Engine room news

The Allen Safety Set Screw

A safety set screw made from a solid bar of steel and guaranteed not to mushroom or upset in the hole has been recently placed on the market by the Allen Manufacturing Company, Hartford, Conn. These screws are made in a number of

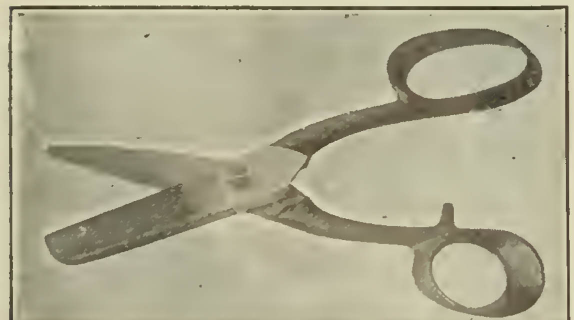


Group of Allen Set Screws

different sizes ranging from 3/8 to 1 inch long and with a variety of points such as cup, conical, oval, dog and flat which are shown in the figure. A hexagonal hole formed in the other end serves as a hold for the wrench which can be made by bending a piece of hexagonal steel of the proper size at right angles, as illustrated in the above drawing.

Scissors for Belting, Packing etc.

The cut shows a pair of scissors for cutting leather, rubber, packing, linoleum, etc., which are being put on the market by Schuchardt & Schütte, 90 West street,



Scissors for Belting and Packing

New York. The upper blade is a regular shear blade but with a longer handle than usual to give greater leverage.

The trouble with the ordinary scissors when cutting the materials mentioned is that the goods being cut is apt to be pushed along the blades instead of being cut. This is overcome in these scissors by having the edge of the lower blade serrated so that it prevents the material from slipping while the upper blade does the cutting.

These shears, known as "cogged scissors," are made in two sizes, 8½ and 11 inches respectively, and they will cut single-ply leather belting as easily as the ordinary scissors will cut cardboard.

The Stilwell Combination Water Heating and Softening System

In the illustration, Fig. 1, is shown a combination feed-water heater, filter and purifier built by the Platt Iron Works Company, Dayton, O.

This apparatus consists, as shown in Fig. 2, of a cast-iron heating chamber containing a system of pans over which the water and chemicals must pass, thereby thoroughly mixing the two and bringing them in direct contact with the exhaust steam. This heating chamber, which is fitted with an efficient oil separator, may be used either on the thoroughfare or induction principle. It is located on top of a large purifying and filtering chamber built of heavily ribbed cast-iron

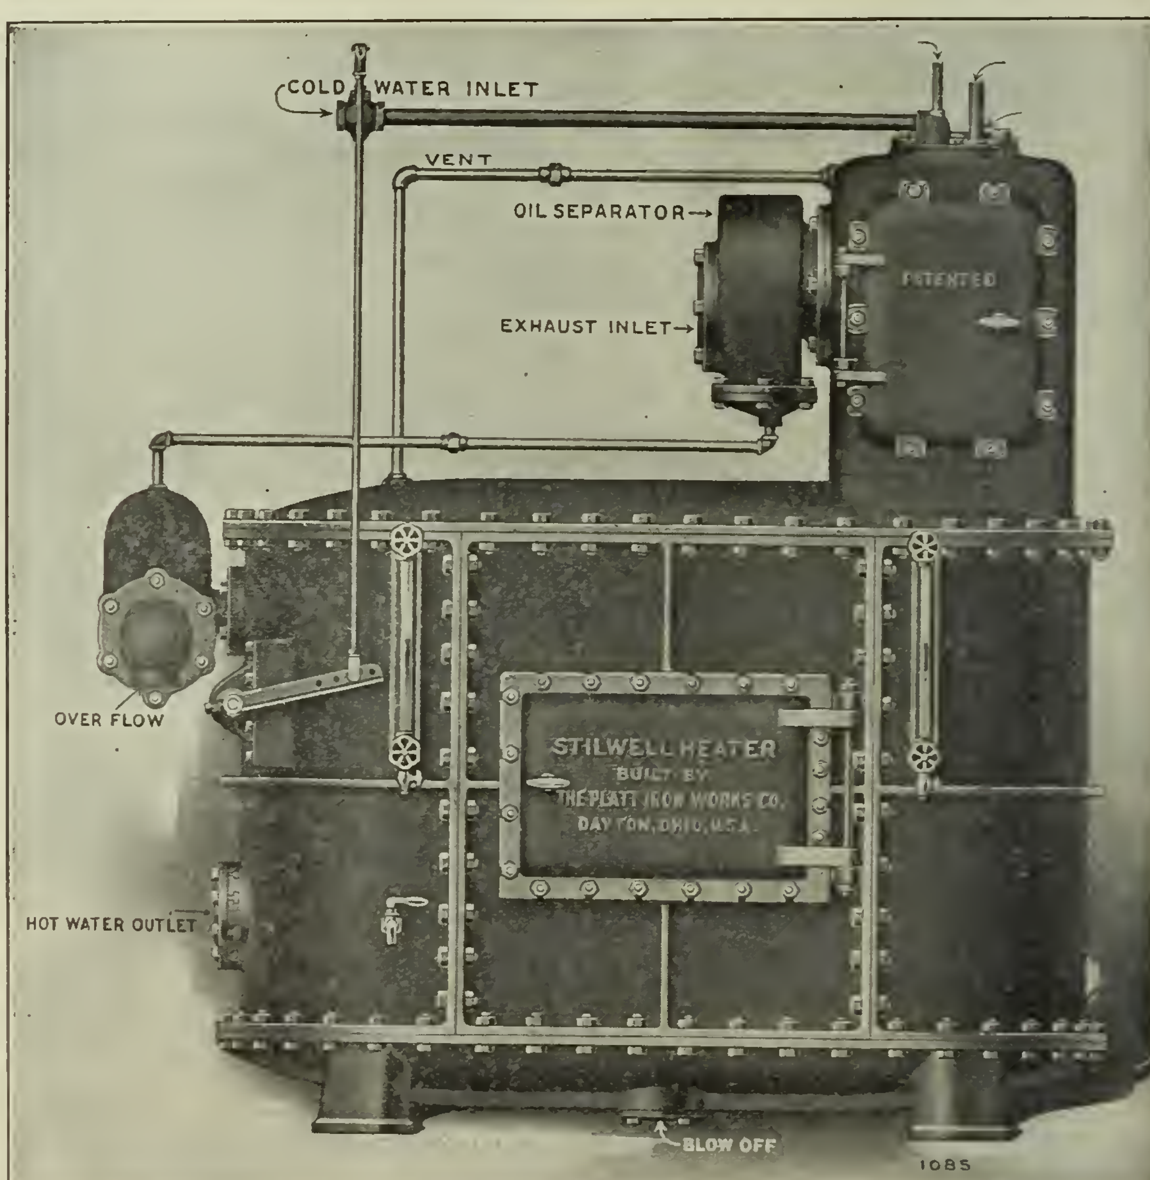


Fig. 1. Exterior View of Stilwell Heater

sections, with ground joints and permanent gaskets, and is designed to withstand ten pounds back pressure.

The system consists in using the heat

of the steam for removing the temporary hardness, such as carbonates, chemicals being used to remove permanent hardness caused by sulphates, chlorides, etc. In operation it is designed that the reagent will be fed continuously in proportion to the cold water, both entering the heating chamber at the same point, the reagents being handled by an auxiliary plunger on the feed pump.

After the water has passed through the heating chamber it reaches a settling chamber below, in which the greater portion of the impurities will settle to the bottom, from which they can be blown off. The water then passes upward through a blanket filter into the purified-water chamber from which the pump suction takes its supply.

A device recently designed and made part of this system consists of a water-sealed supplementary bypass which insures the delivery of hot treated water to the boiler-feed pumps in case the filter blanket, if neglected, should become clogged up. The bypass automatically operates when the water rises to the proper level in the heating and purifying chambers. This special feature, being water sealed, prevents any scum or floating particles from passing over into the purified-water chamber.

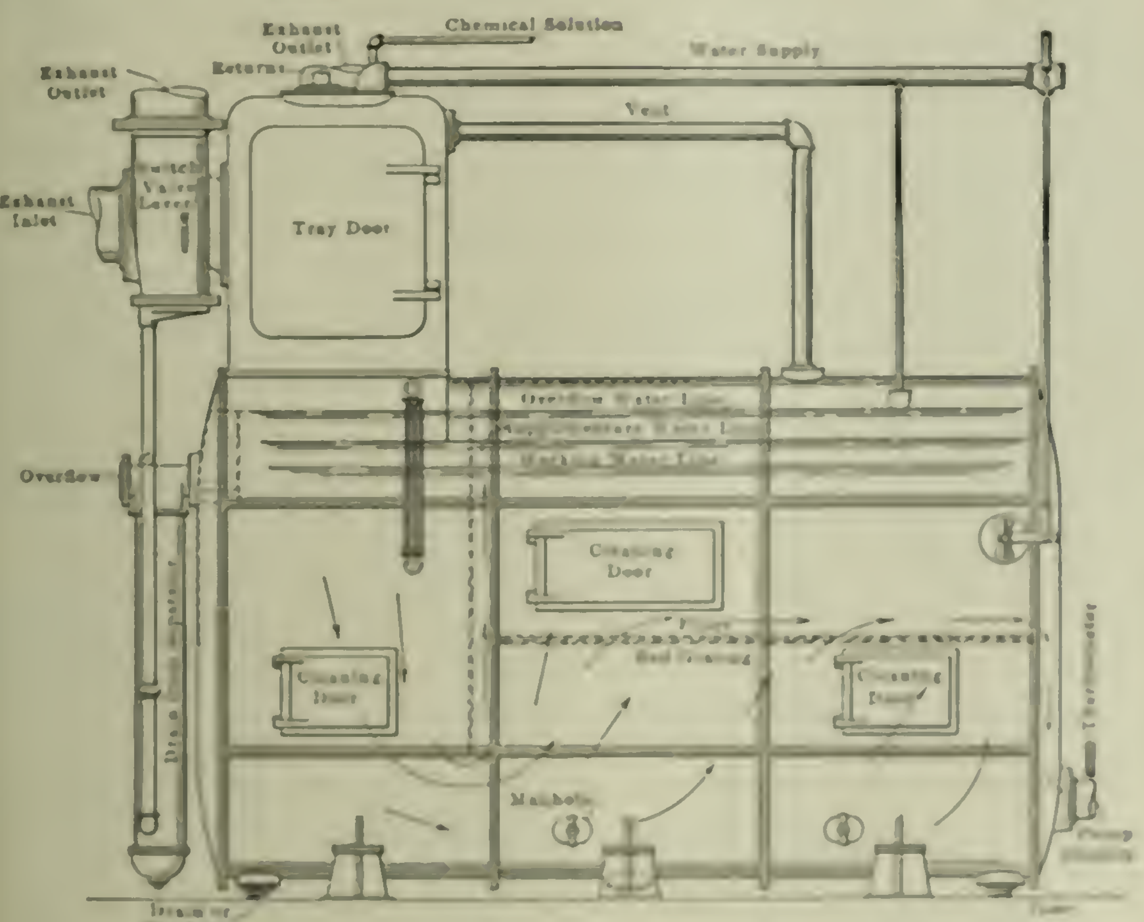

Fig. 2. View of Heater, Indicating Interior Construction

A skimmer is provided in the heating chamber for skimming the surface of the water, this skimmer also acting as a point of overflow into the trap. Large hinged doors are provided, permitting easy access to all parts and any internal part can be readily removed through these doors. Float valves, mixing tanks and auxiliary pumps for forcing chemicals in proper proportion to the feed water, make up the system, which is automatic when once installed.

The "Change Blade" Screwdriver

A new screwdriver is being put on the market by Kinckiner & Scott, 626 North Twelfth street, Philadelphia, Penn.

The handle is of red brass in skeleton form, with a covering of mahogany. The blades are of tool steel with a tempered cross pin, which engages with a slot in the brass handle and takes the strain of the work. The end of the blade, which enters the handle, is threaded to fit the cap nut which retains it in position in the handle. The blades are made in 3-, 6- and 8-inch lengths and are easily interchanged.

A change-blade screwdriver is made especially for electrical work. In it the entire handle and blade are insulated with the exception of the extreme end which engages the screw slot.

Congress of Refrigeration to Be Held in America

The executive committee of the American Association of Refrigeration held an important meeting at the Great Northern hotel, Chicago, on December 15, to perfect an organization and provide ways and means for the third international congress which the recent second congress in Vienna voted shall be held in the United States. Several members of the committee came from widely separated sections of the country. Rivalry for the privilege of entertaining the scientists who will represent the refrigerating interests of more than forty foreign countries is already active. New York, Washington, Philadelphia, Birmingham, St. Louis and Chicago are among the places advocated. Chairman Homer McDaniel, of Cleveland, was authorized to appoint a committee of five to prepare a budget of the necessary expenditures for conducting the congress, to decide upon the most suitable date and place for holding it, to prepare a general scheme of entertainment for the foreign delegates, and to report the results of their labors to the next regular annual meeting of the association. It was the general opinion of those present that the committee will without difficulty secure a sufficient fund to justify our Government in extending its invitation to foreign countries to participate in the congress by the appointment of official delegates, as was done by our Government for the Paris congress of 1908 and the Vienna congress of this year.

Brooklyn Engineers Hold Annual Dinner

The Brooklyn Engineers' Club held its annual dinner on December 15, 1910, at the Hamilton Club, Brooklyn; the fact that there was such a large call for tickets led the committee to arrange for greater accommodations than the club's own banquet room affords.

George A. Orrok, the retiring president of the club, who acted as toast master, briefly reviewed the work accomplished during the year.

The first speaker to be introduced was Dr. Rossiter W. Raymond, secretary of the American Institute of Mining Engineers. Doctor Raymond's talk was on the "Panama Canal" and was based on the information he obtained during the excursion which he and other members of the Institute of Mining Engineers recently made to the canal.

Dr. Alexander C. Humphreys, president of Stevens Institute of Technology, was next introduced. His topic was "Engineering Education, the Concrete Rather than the Abstract." He maintained that much valuable engineering knowledge can be learned only in the school of experience.

Major John F. O'Rourke, president of the O'Rourke Engineering and Contracting Company, spoke on "After-dinner Engineering."

After the dinner, the following officers of the club for 1911 were elected: President, Major Winfield H. Roberts; vice-president, John M. Stalnaker; secretary, Joseph Strachan (reëlected); treasurer, William T. Donnelly; directors, H. C. Keith and W. F. Wells.

There were about 100 members and guests present.

Steam Pipe Bursts in Lowell

It is reported in the daily press that on December 24 a steam pipe burst in the Perry street power plant of the Lowell (Mass.) Electric Light Company. Six men were injured and fragments of the pipe damaged the brickwork of the building to some extent. The plant was shut down for an hour.

OBITUARY

Rudolph Wolf, founder of the Great Engineering Works at Magdeburg-Bugkau, inventor of the Wolf compound engine and identified with the early use of superheated steam, died on the twentieth of November in his seventy-ninth year.

Matthew Kennedy, treasurer of the Kennedy Valve Manufacturing Company, Elmira, N. Y., died on November 26 at his home in Coxsackie. He was born in Ireland in 1840, and with his brother Daniel established the business with which he was so long identified.

BOOKS RECEIVED

DYNAMO ELECTRIC MACHINERY. By Samuel Sheldon. D. Van Nostrand Company, New York. Cloth; 328 pages, 5x7½ inches; 210 illustrations; indexed. Price, $2.50.

ELECTRICITY EXPERIMENTALLY AND PRACTICALLY APPLIED. By S. W. Ashe. D. Van Nostrand Company, New York. Cloth; 344 pages, 5x7½ inches; 422 illustrations; indexed. Price, $2.

BROOKES AUTOMOBILE HANDBOOK. By L. Elliott Brookes. Frederick J. Drake & Co., Chicago, Ill. Leather limp; 701 pages, 4x6½ inches; 320 illustrations; tables; indexed. Price, $2.

THE CONSTRUCTION AND WORKING OF INTERNAL COMBUSTION ENGINES. By R. E. Mathot. D. Van Nostrand Company, New York. Cloth; 554 pages; 5½x9¼ inches; fully illustrated; indexed. Price, $6.

DESIGN OF MARINE MULTITUBULAR BOILERS. By James D. McKnight and Alfred W. Brown. The Technical Publishing Company, Ltd., and D. Van Nostrand Company, New York. Cloth; 48 pages, 6x10 inches; illustrated; indexed. Price, $1.50.

NEW INVENTIONS

Printed copies of patents are furnished by the Patent Office at 5c. each. Address the Commissioner of Patents, Washington, D. C.

PRIME MOVERS

WATER WHEEL. Arnold Pfau, Milwaukee, Wis., assignor to Allis-Chalmers Company, Milwaukee, Wis., a Corporation of New Jersey. 978,335.

ROTARY ENGINE. John W. Larimore, Benton, Ill. 978,602.

WAVE MOTOR. Thomas Nixon, Santa Barbara, Cal. 978,628.

ROTARY ENGINE. Samuel Haudenshield, Carnegie, Penn. 978,743.

BOILERS, FURNACES AND GAS PRODUCERS

STEAM GENERATOR. James J. Bush, New York, N. Y. 978,135.

SMOKE CONSUMER. William McArdle, Montreal, Quebec, Canada, assignor to the Perfect Simplex Combustion Company, Montreal, Canada. 978,467.

SHAKING AND DUMPING GRATE. Chas. F. Hutchinson, Kingsville, Md., assignor to Hutchinson Bros., Kingsville, Md., a Corporation. 978,589.

GENERATOR AND SUPERHEATER. John G. Massie, East St. Louis, Ill., assignor to the Massie Generator and Radiator Company, East St. Louis, Ill., a Corporation of Illinois. 978,769.

OIL BURNER. John R. Pring, Shawnee, Okla. 978,780.

CRUDE-OIL BURNER. Emory A. Wales, Oklahoma, Okla. 978,797.

POWER PLANT AUXILIARIES AND APPLIANCES

GAGE COCK. Charles Wright, Youngwood, Penn., assignor to the Wright Specialty Manufacturing Company. 978,256.

ENGINE-STARTING DEVICE. Peter P. Au Buchnon, French Village, Mo. 978,264.

VALVE. John William Harkom, Melbourne, Quebec, Canada. 978,288.

AUTOMATIC CUTOFF VALVE. Francis Hodgkinson, Edgewood Park, Penn., assignor to the Westinghouse Machine Company, a Corporation of Pennsylvania. 978,294.

BOILER-TUBE CLEANER. William L. Miggett, Ann Arbor, Mich., assignor to Raphael Herman, Detroit, Mich. 978,326.

ROTARY PUMP. James Baguley, Evanston, Wyo. 978,350.

CONDENSER. Royal D. Tomlinson, Milwaukee, Wis., assignor to Allis-Chalmers Company, Milwaukee, Wis., a Corporation of New Jersey. 978,411.

VALVE AND VALVE-OPERATING MECHANISM. Fred Loedige, Chicago, Ill. 978,463.

OIL CUP. Verner J. Wahlstrom, New York, N. Y. 978,521.

PISTON-ROD STUFFING BOX AND LUBRICATOR. Walter McLain, Spiritwood, N. D. 978,611.

HOSE COUPLING. Bernard Morgan, Newport, R. I. 978,619.

PUMP. Garl Nicholls, McFall, Mo. 978,626.

PUMP. Edwin E. Slick, Pittsburg, Penn. 978,668.

CONDENSER. Evi W. Christie, Sewaren, and Tom Roberts, Roselle Park, N. J., assignors to Wheeler Condenser and Engineering Company, Carteret, N. J., a Corporation of New Jersey. 978,697.

STEAM TRAP. Vernon Bradley Convis, Toronto, Ontario, Canada. 978,701.

VALVE. James E. Davidson, Butte, Mont. 978,706.

ROTARY PUMP. Michael E. Durman, Detroit, Mich. 978,715.

GRAVITY VALVE CAGE AND VALVE FOR PUMPS. Jesse B. Garber, Salem, Ohio, assignor to the Deming Company, Salem, Ohio, a Corporation of Ohio. 978,729.

VALVE GEAR. Hiram P. Graves, Elmira Heights, N. Y. 978,737.

VALVE. Joseph Huebsch, Milwaukee, Wis. 978,752.

CENTRIFUGAL PUMP. Joseph Hurst, Louisville, Ky. 978,753.

CHECK VALVE. Jonathan Johnson, Lowell, Mass. 978,757.

DEFLECTOR FOR SMOKE-BOX SUPERHEATERS OR FEED-WATER HEATERS. Samuel M. Vauclain, Philadelphia, Penn., assignor, by mesne assignments, to Baldwin Locomotive Works, Philadelphia, Penn., a Corporation of Pennsylvania. 978,795.

LUBRICATOR. Carl Roberts Briggs, Ravenna, Ohio. 978,819.

ELECTRICAL INVENTIONS AND APPLICATIONS

APPARATUS FOR ELECTRIC SMELTING. Frank Creelman, New York, N. Y., assignor to the Wilson Carbide Works Company of St. Catharines, Ltd., St. Catharines, Canada, a Corporation. 978,137.

ELECTRIC MOTOR-CONTROLLING APPARATUS. Harry Ward Leonard, Bronxville, N. Y. 978,173.

COMBINED SWITCH SOCKET AND PLUG. William Pinkney McNeel, San Antonio, Tex. 978,322.

ENGINEERING SOCIETIES

AMERICAN SOCIETY OF MECHANICAL ENGINEERS

Pres., Col. E. D. Meier; sec., Calvin W. Rice, Engineering Societies building, 29 West 39th St., New York. Monthly meetings in New York City.

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

Pres., Dugald C. Jackson; sec., Ralph W. Pope, 33 W. Thirty-ninth St., New York. Meetings monthly.

NATIONAL ELECTRIC LIGHT ASSOCIATION

Pres., Frank W. Frueauff; sec., T. C. Martin, 31 West Thirty-ninth St., New York.

AMERICAN SOCIETY OF NAVAL ENGINEERS

Pres., Engineer-in-Chief Hutch I. Cone, U. S. N.; sec. and treas., Lieutenant Henry C. Dinger, U. S. N., Bureau of Steam Engineering, Navy Department, Washington, D. C.

AMERICAN BOILER MANUFACTURERS' ASSOCIATION

Pres., E. D. Meier, 11 Broadway, New York; sec., J. D. Farasey, cor. 37th St. and Erie Railroad, Cleveland, O. Next meeting to be held September, 1911, in Boston, Mass.

WESTERN SOCIETY OF ENGINEERS

Pres., J. W. Alvord; sec., J. H. Warder, 1735 Monadnock Block, Chicago, Ill.

ENGINEERS' SOCIETY OF WESTERN PENNSYLVANIA

Pres., E. K. Morse; sec., E. K. Hiles, Oliver building, Pittsburg, Penn. Meetings 1st and 3d Tuesdays.

AMERICAN SOCIETY OF HEATING AND VENTILATING ENGINEERS.

Pres., Prof. J. D. Hoffman; sec., William M. Mackay, P. O. Box 1818, New York City.

NATIONAL ASSOCIATION OF STATIONARY ENGINEERS

Pres., Carl S. Pearse, Denver, Colo.; sec., F. W. Raven, 325 Dearborn street, Chicago, Ill. Next convention, Cincinnati, Ohio.

AMERICAN ORDER OF STEAM ENGINEERS

Supr. Chief Engr., Frederick Markoe, Philadelphia, Pa.; Supr. Cor. Engr., William S. Wetzler, 753 N. Forty-fourth St., Philadelphia, Pa. Next meeting at Philadelphia, June, 1911.

NATIONAL MARINE ENGINEERS BENEFICIAL ASSOCIATIONS

Pres., William F. Yates, New York, N. Y.; sec., George A. Grubb, 1040 Dakin street, Chicago, Ill. Next meeting, St. Louis, Mo., January 16-21, 1911.

INTERNAL COMBUSTION ENGINEERS' ASSOCIATION.

Pres., Arthur J. Frith; sec., Charles Kratsch, 416 W. Indiana St., Chicago. Meetings the second Friday in each month at Fraternity Halls, Chicago.

UNIVERSAL CRAFTSMEN COUNCIL OF ENGINEERS

Grand Worthy Chief, John Cope; sec., J. U. Bunce, Hotel Statler, Buffalo, N. Y. Next annual meeting in Philadelphia, Penn., week commencing Monday, August 7, 1911.

OHIO SOCIETY OF MECHANICAL ELECTRICAL AND STEAM ENGINEERS

Pres., O. F. Rabbe; acting sec., Charles P. Crowe, Ohio State University, Columbus, Ohio. Next meeting, Youngstown, Ohio, May 18 and 19, 1911.

INTERNATIONAL MASTER BOILER MAKERS' ASSOCIATION

Pres., A. N. Lucas; sec., Harry D. Vaught, 95 Liberty street, New York. Next meeting at Omaha, Neb., May, 1911.

INTERNATIONAL UNION OF STEAM ENGINEERS

Pres., Matt. Comerford; sec., J. G. Hannahan, Chicago, Ill. Next meeting at St. Paul, Minn., September, 1911.

NATIONAL DISTRICT HEATING ASSOCIATION

Pres., G. W. Wright, Baltimore, Md.; sec. and treas., D. L. Gaskill, Greenville, O.

POWER

NEW·YORK, JANUARY 10, 1911

THE comparison of our progress through life to the scaling of a ladder is a much better one than we sometimes realize.

Often the comparison is borne out in ways that we do not stop to notice. For instance, take the man whom fortune has favored with a thorough early education. When he gets into the world of business—the steam engineering field, perhaps—he has a vast advantage over another man who has been less fortunate. He easily puts below him the first few rungs of the ladder.

The rise of the less fortunate man is slow and laborious; he must grope his way up, almost blindly, wasting much time and often losing hard-gained ground in testing false rungs. At length he reaches a point where there is a gap in the ladder—one or two of the rungs are missing because of his lack of early advantages.

The first man, looking down from his higher and more secure position, is able to see clearly just what the latter's difficulty is.

If the man higher up is worthy of the name—if he is a real MAN of 45-gage construction—he will reach down his hand and give the man below the "lift" that he so badly needs.

If the man above is only a pigmy, only 22-gage, he will kick the other man in the face and shake his hold, or he will ridicule and try to discourage him.

How often such things occur your own experience shows. How many times have you needed a "hand," sometimes to be disappointed by refusal and sometimes to be surprised by the unexpected source from which the aid was given?

How many "lifts" have you given and how many withheld? Are you 45-gage or only 22?

No man can attain such a hight on the ladder of success that he can afford to ignore the appeals for assistance of those lower down. The time is likely to come any minute when he, himself, will need a "boost" from someone in a humble position. But, even allowing that he may never need further help, common decency should prompt him to do what he can to help others along, for unless he had received aid from others, undoubtedly he never could have mounted as high as he did. So, to discharge his debt to his benefactors, it is his duty to help others where and when he can.

All this applies to you, be your station high or humble.

Edward Everett Hale, now dear to memory, originated a saying which contained more than many a long sermon ever did. The sense of it is: "Look out, not in; look forward, not back; look up, not down, and lend a hand."

Power Plant of the Raike Building

By Osborn Monnett

A plant of 160 kilowatts capacity furnishing power by means of electric drive to a number of manufacturing establishments located in the building. An interesting feature of the equipment is the arrangement of the combustion arches in the boilers.

In the Louis Raike building on Jackson boulevard, Chicago, is to be found a model little steam plant of 160 kilowatts capacity which furnishes power through a system of electric drive to the various manufacturing establishments occupying the building. In a plant of this capacity, although reliability must be attained, together with a certain degree of economy, it is not justifiable to burden it with an excessive first cost for complicated and elaborate auxiliary equipment, which, although saving labor and money in a larger plant, would not justify the expenditure in one of this size where an operating force of only two is required. In the present case these features have been worked out in a satisfactory manner.

Boilers

Steam is supplied by two Brownell horizontal return-tubular boilers 66 inches in diameter by 18 feet long, having quadruple-riveted butt joints. A pressure of 139 pounds is allowed by the city-boiler inspector, but 110 pounds is the pressure usually carried. A view of the boiler room is shown in Fig. 1. Undoubtedly, the most interesting feature of the boiler setting is the arrangement of the combustion arches at the bridgewall. In the end and side elevations, Fig. 2, the arrangement of these arches is indicated. They are built of the best grade of fire tile, the two central piers, together with the side walls, permitting a triple arch at this point, the top of which closely fits the boiler shell, compelling the products of combustion to pass through the arches and breaking up the current of gases. In this type of setting the heat radiating directly from the fire is taken advantage of for making steam. It is interesting to note that, although this plant has been in operation for about twelve months, using Pocahontas coal, it has never been accused of violating the smoke ordinance. Another interesting feature of the furnace construction is the fact that the dead plates immediately in front of the fire doors can be lifted, making an opening direct to the ashpit through which ashes and clinker may be raked when the fires are being cleaned, thereby keeping all the dirt and dust in the ashpit during this operation and not on the boiler-room floor, as is ordinarily the case with hand-fired stationary grates, such as are here employed.

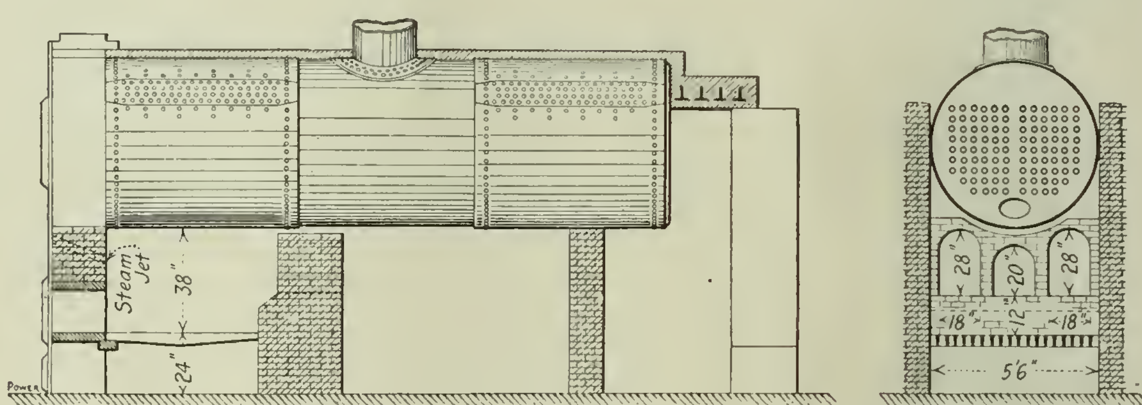

Fig. 2. Boiler and Setting, Showing Arched Bridgewall

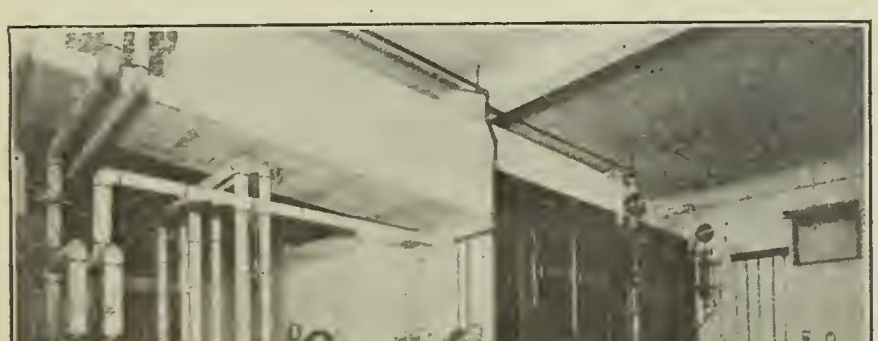

Fig. 1. Boilers and Feed Pumps

Fig. 3. Feed-water Heater, Surge Tank and Exhaust Connections

Provision has been made for a coal-storage capacity of twenty-five tons and coal is discharged from an alley in the rear of the building either direct to the coal-storage bin or onto the passageway between the boiler room and coal-storage bin, so that in the future, if desired, a coal conveyer may be installed which will deliver the coal to a point in front of the boilers.

Piping

The steam piping is laid out on an extremely simple though efficient system. Resting directly on the rear of the boiler settings is a short 12-inch header into which 5-inch steam connections from the two boilers enter through angle valves. These steam connections are provided at the boiler nozzles with angle stop valves and nonreturn valves, all valves and piping being extra heavy with screwed flanges. From the header, long-radius bends lead to the engines, with steam separators directly above the throttles.

The 10-inch main exhaust rests in a concrete trough in the engine-room floor, covered with iron plates. This leads to a Webster open feed-water heater, first passing through an oil separator and having a connection to the exhaust-heating system. An atmospheric relief valve is also located at this point. Fig. 3 shows this part of the equipment, and also the surge tank through which water for all purposes enters the plant. Dearborn feed-water feeders are installed on the feed-pump suction line between the heater and the pumps. Two 6 and 4 by 6-inch Dean-of-Holyoke pumps are used for boiler-feed purposes, one always being held in reserve, and another pump of the same size is used for house service. All of these pumps are cross-connected (see Fig. 1) and may be used either for feeding the boilers or for house service. Force-feed lubricators are installed on all pumps and also on the main engines.

The house service consists of a hot- and a cold-water supply, the latter coming direct by gravity from a tank on the roof, while the former is supplied from an auxiliary heater, using exhaust steam, but having a live-steam connection for use when necessary.

Heating System

The steam heating is done on the Bishop & Babcock air-line vacuum system and contains 8000 square feet of direct radiation. In this system there is a single steam-pipe connection to each radiator, and the air is removed through an automatic air valve into a vacuum maintained by a hydraulically operated pump. The operation of the vacuum pump will be apparent on reference to Fig. 4. The suction line of the pump connects with the main air line through a coil placed in an open condensing tank to which the discharge from the water cylinder of the pump is piped in such a manner that the amount of drip may be observed as shown at S. The overflow from the tank goes to the sewer. The tank is for condensing any steam that might be drawn through the air valves due to leakage or improper setting before entering the pump. A diaphragm valve is placed in the water supply and is connected to the pump suction and can be adjusted to maintain any degree of vacuum.

Engine Room

One 60-kilowatt and one 100-kilowatt Ridgway direct-connected generating units have been installed in the engine room. These are of the new Ridgway side-crank construction, but have slide valves of the single, balanced type, with a splash system of lubrication. On the acceptance tests made at the shops of the builders, they delivered a brake horsepower on slightly less than 29 pounds of steam per hour.

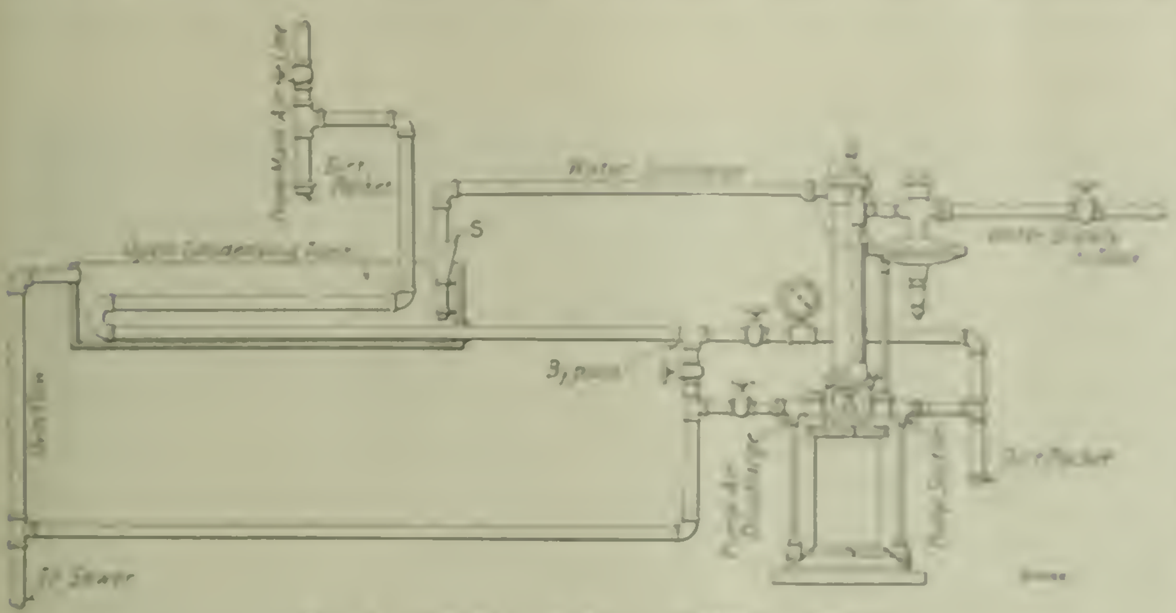

Fig. 4. Piping Layout of Vacuum System

Fig. 5 is a view of the engine room. The decoration of the room consists of a green-painted wainscoting with cream-colored walls and ceiling. The engines are finished in green enamel with gilt trimmings and harmonize well with their surroundings. The engine-room floor, which is usually a perplexing problem when made of concrete, has been treated with a cement-floor filling and covered with two coats of lead-colored paint, making a smooth, neat and easily cleaned surface which adds materially to the appearance of the room.

Fig. 5. General View of Engine Room

Electrical Equipment

The electrical equipment is of Thompson-Ryan make, direct current being furnished on two-wire system at 220 volts.

On the lighting circuits both tungsten and carbon-filament lamps are used; the latter are connected directly across the 220-volt circuits and the former are connected two in series, the series arrangement avoiding the necessity of using a balancer set and materially simplifying the lighting circuits. There is one light and one power circuit, the latter supplying a variety of motors ranging from ½ to 20 horsepower. This power is metered to the various tenants and on each floor are located two cut-out panels, one for power and one for lighting.

A record transmission voltage for Europe will be established by the Lauchhammer power station in Germany, which will transmit power at 110,000 volts. The different works of Messrs. Lauchhammer, Ltd., have heretofore been supplied from separate power stations. Finding that their works at Lauchhammer were situated on a rich lignite field, it was decided to build a central power plant to supply the various works. At the same time, a central station was being planned at Gröba to supply four districts of the kingdom of Saxony. Arrangements were accordingly made to utilize, instead, the power generated at the Lauchhammer plant. Three turbo-dynamos of 5000 kilowatts each are being installed, and two more units will be added later. The current is generated at 5000 volts, and raised by means of transformers to the transmission tension of 110,000 volts. The plant will have a capacity of 40,000 kilowatts, or nearly 50,000 horsepower.—Exchange.

A Slowly Moving Positive Valve Gear

By Dr. Alfred Gradenwitz

Separate steam and exhaust valves of the piston type arranged tangentially to the cylinder and operated by eccentrics on a lay shaft which revolves at one-half the speed of the main shaft.

E. Frikart, of the Alsatian Machine Building Company, at Mulhouse, Germany, has designed a novel valve gear for steam engines, in connection with which the admission and outlet piston valves are arranged separately at each end of the cylinder, tangential to the latter and at right angles to its axis, being actuated through an eccentric from a side shaft which moves only at half the speed of the crank shaft of the engine, so that the opening and closing of the steam channels, with two strokes of the working piston, occur during one stroke of the valve. The steam admission is controlled immediately by a governor acting on the admission piston valve of the high-pressure cylinder.

It is well known that the increasing speeds used in connection with modern steam engines entail a positive motion, gear and the waste spaces are reduced to a minimum, both in regard to their surface and volume. For the same reason an entirely positive valve gear can be used, in connection with which any spring for actuating the slide valves is dispensed with.

same side of the cylinder, is operated by the same eccentric mounted on a side-shaft, parallel to the cylinder axis, which is actuated from the crank shaft through a pair of gears at a ratio of 1 to 2. Thus the eccentric turns through only 180 degrees during each full revolution of the crank, so that the admission valve operated by it moves from right to left only. The eccentric then moves an equal distance during the ensuing revolution of the crank, thus performing a full revolution of 360 degrees, and causing the slide valve to return to its initial position from the left to the right.

Each full revolution of the eccentric thus corresponds to two full revolutions of the crank, or to put it in other terms, while the piston in the cylinder changes its direction of motion twice, the slide valve makes only a single change in direction. The channels in the valve box

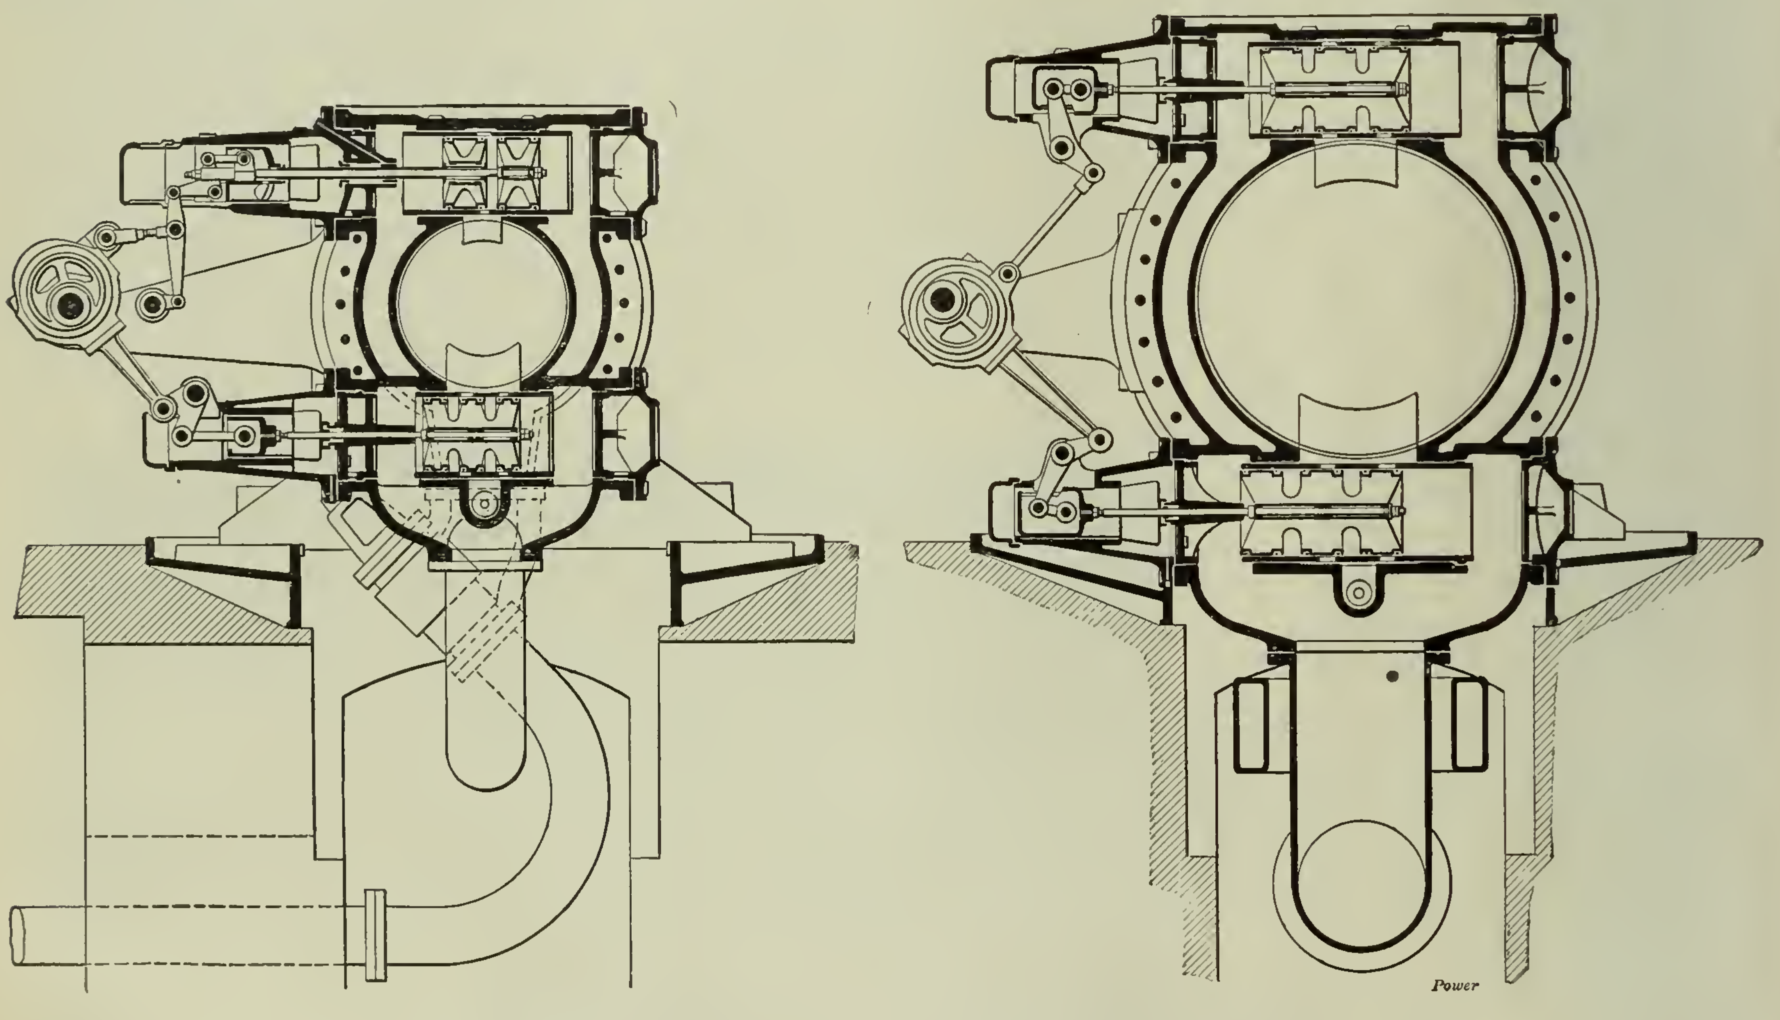

Fig. 1. Cross-sections through Valves of High- and Low-pressure Cylinders

while the high steam pressures and high temperatures require the arrangement of balanced slide valves, so as to insure a smooth working of the engine. Such valves are, for instance, piston valves with self-tightening obturating rings which slide in turned boxes arranged tangentially at the ends of the cylinder. These piston valves will grind themselves of their own accord into their boxes, so as to require no special grinding. The steam distribution, owing to the large lap, is entirely insensitive in regard to end play in the outside valve

This advantage is utilized in a most ingenious manner in connection with the positive valve gear described herein, which works at only half the speed of the steam engine. Fig. 1 shows a cross-section through the slide valves of the high- and low-pressure cylinders of the 1000-horsepower tandem-compound engine represented in Fig. 2. Figs. 3 and 4 show the corresponding diagrams of the valve gears.

Each system of two slide valves, the upper one of which admits the steam while the lower one exhausts it from the

are opened and closed by the slide valve in the following manner:

Supposing the admission slide valve in opening the channels to move from the right to the left, until the eccentric has completed its motion (corresponding to a full revolution of the crank), during the same time these channels should be opened by the slide valve, and closed again after the steam has been allowed to enter the cylinder. The opening, as represented in Fig. 3, is effected by the valve edge *e* and the closing by the edge *f*. The slide valve thus passes by the valve port in a constant direction both in opening and closing the channels. The latter will be opened entirely when the valve apertures of equal magnitude are situated exactly between the edges of the valve port. From this moment they again begin to close.

During the next full revolution of the crank, the steam admission in regard to the cylinder will be the same. However, the eccentric now moves through 180 degrees and the slide valve, without any alteration in its direction of motion, returns to its initial position from the left to right. During this motion of the valve, the edges *f* and *e* exchange their respective positions, the former effecting the opening and the latter the closing. The valve thus actually undergoes only half the number of changes in direction as the piston itself.

On account of the manner in which the path of the eccentric is utilized for the stroke of the piston, the motion of the eccentric can be transmitted immediately to the slide valve, thus dispensing with any spring or horizontal displacement as otherwise used with a view to reducing the lap. As the slide valves both in opening and closing maintain their sense of direction unaltered, their effective opening path is determined by the circumference on the eccentric circle intermediary between the opening and closing points, which in comparison with the whole path of the eccentric is considerably longer than the pitch of the arc between these points as otherwise used for actuating valve gears working at normal speeds.

The relation between the neighboring edges of a slide valve, and the width of the corresponding steam port in the valve box depends on the effective valve stroke for a given duration of steam admission and exhaust. Any alteration in this duration will increase or reduce the distance between these neighboring valve edges. This is how, by dividing the high-pressure admission valves into halves, Fig. 1, the steam admission to the high-pressure cylinder can be controlled, a considerable distance between the edges corresponding to a considerable admission and output of the engine, and vice versa. When the two halves of the slide valve come in contact so that the edges strongly strike one another, the steam admission to the cylinder is entirely discontinued.

In order to allow this valve distance to be regulated by the governor, each half of the valve is connected separately with the outside valve gear. The valve rod of the front valve is hollow, being traversed by the valve rod of the rear valve, Fig. 1, and both rods terminate in the outside valve guide box in slides connected to the gear by an angle lever, the motion of which will displace them relatively to one another, thus altering the distance between the slide valves, and accordingly the degree of admission.

As seen from the cuts, the two admission valves are actuated through a guide and a vertical lever immediately from the eccentric, the reciprocating motion of which is transmitted to the valves without altering their mutual displacement. The valves will move across the port in the box a constant distance with each piston stroke. Only when the guide, by turning the governor shaft around, lifts or lowers the vertical lever which connects the guide with the angle lever, will this distance be adjusted by the angle lever oscillating round its pivot.

The lifting of this vertical lever, as effected by adjusting the governor shaft, will increase the distance between the edges, and accordingly the duration of steam admission, while by lowering a diminution is obtained. This enables another alteration of the valve motion which is likewise of much importance for the regulation of the engine. Any alteration in the distance between the valve edges would in fact alter not only the

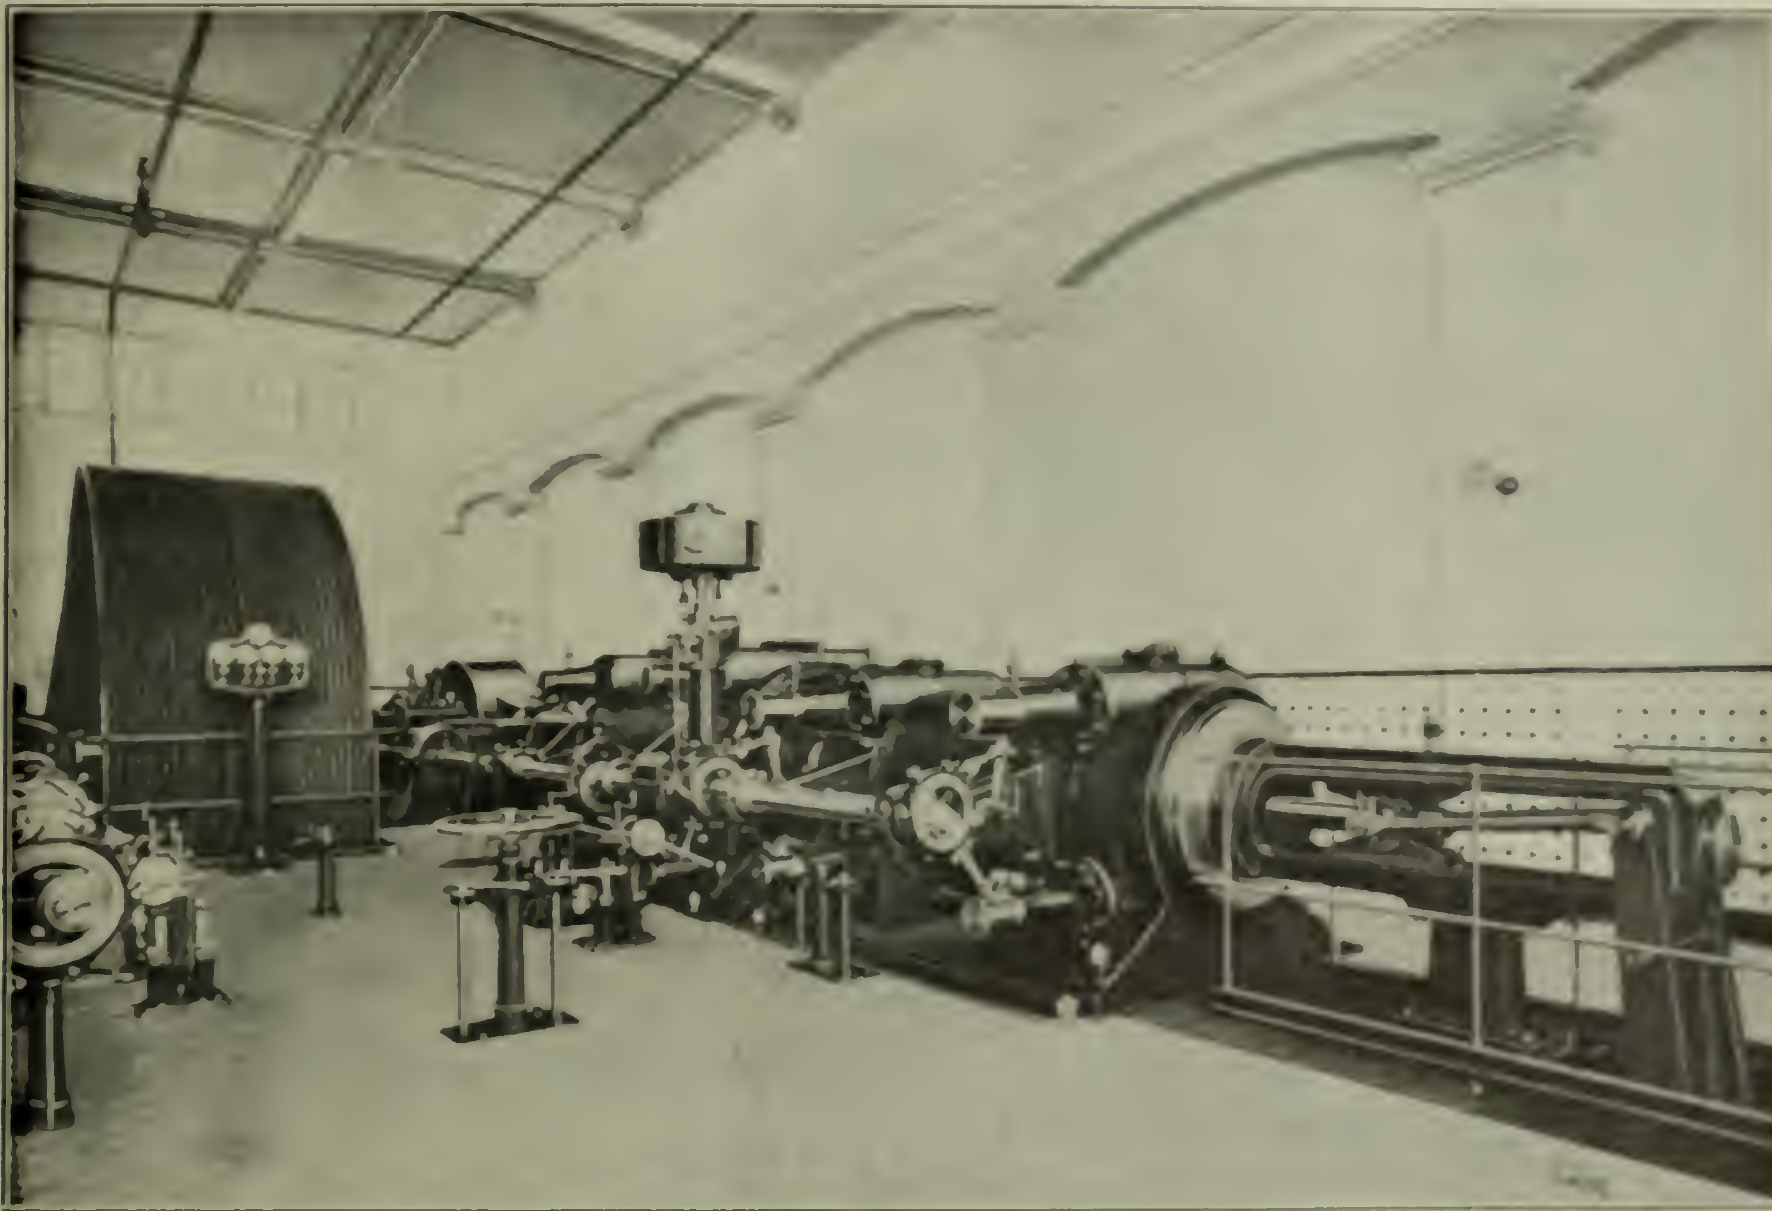

Fig. 2. 1000-horsepower Tandem-compound Engine with Frikart Valves

duration of steam admission, but the admission lead as well, an increase corresponding to a considerable admission, and a decrease to a small one. In order to prevent this the governor shaft by the action of the vertical lever raises the guide of the eccentric into a given position, corresponding to a constant advance in regard to the eccentric curve. In spite of any alteration in the distance of the edges, as adjusted by the governor to the duration of steam admission, the port opening thus commences

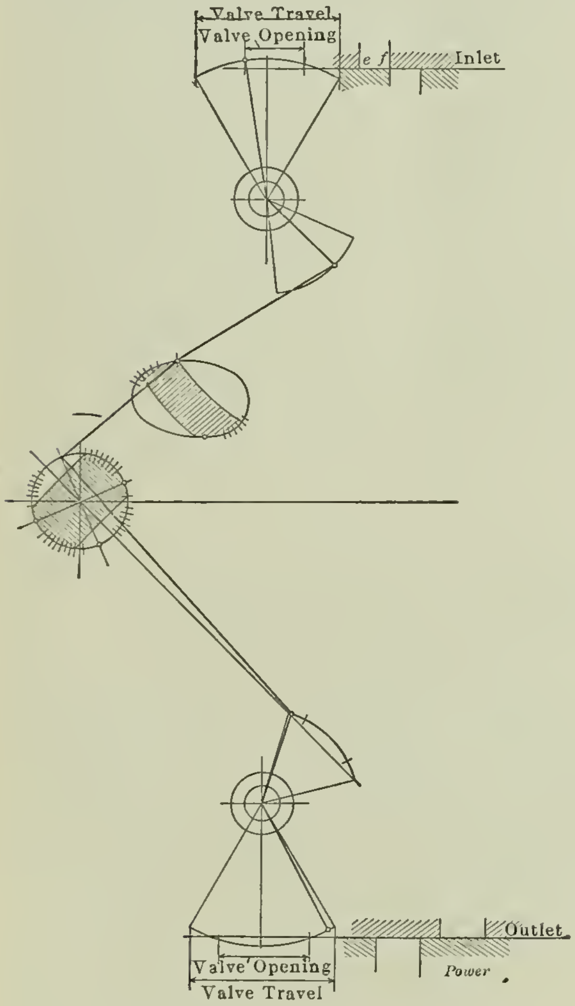

Fig. 3. Diagram of Valve Gear for High-pressure Cylinder

always at a given point of the eccentric curve.

The passage opening between the two valve edges corresponds, with any change, to a given ratio between the steam and piston speeds, so that even with the higher position of the governor, no throttling is noticed in the entering steam. As the piston valve is balanced while its frictional resistance, like those

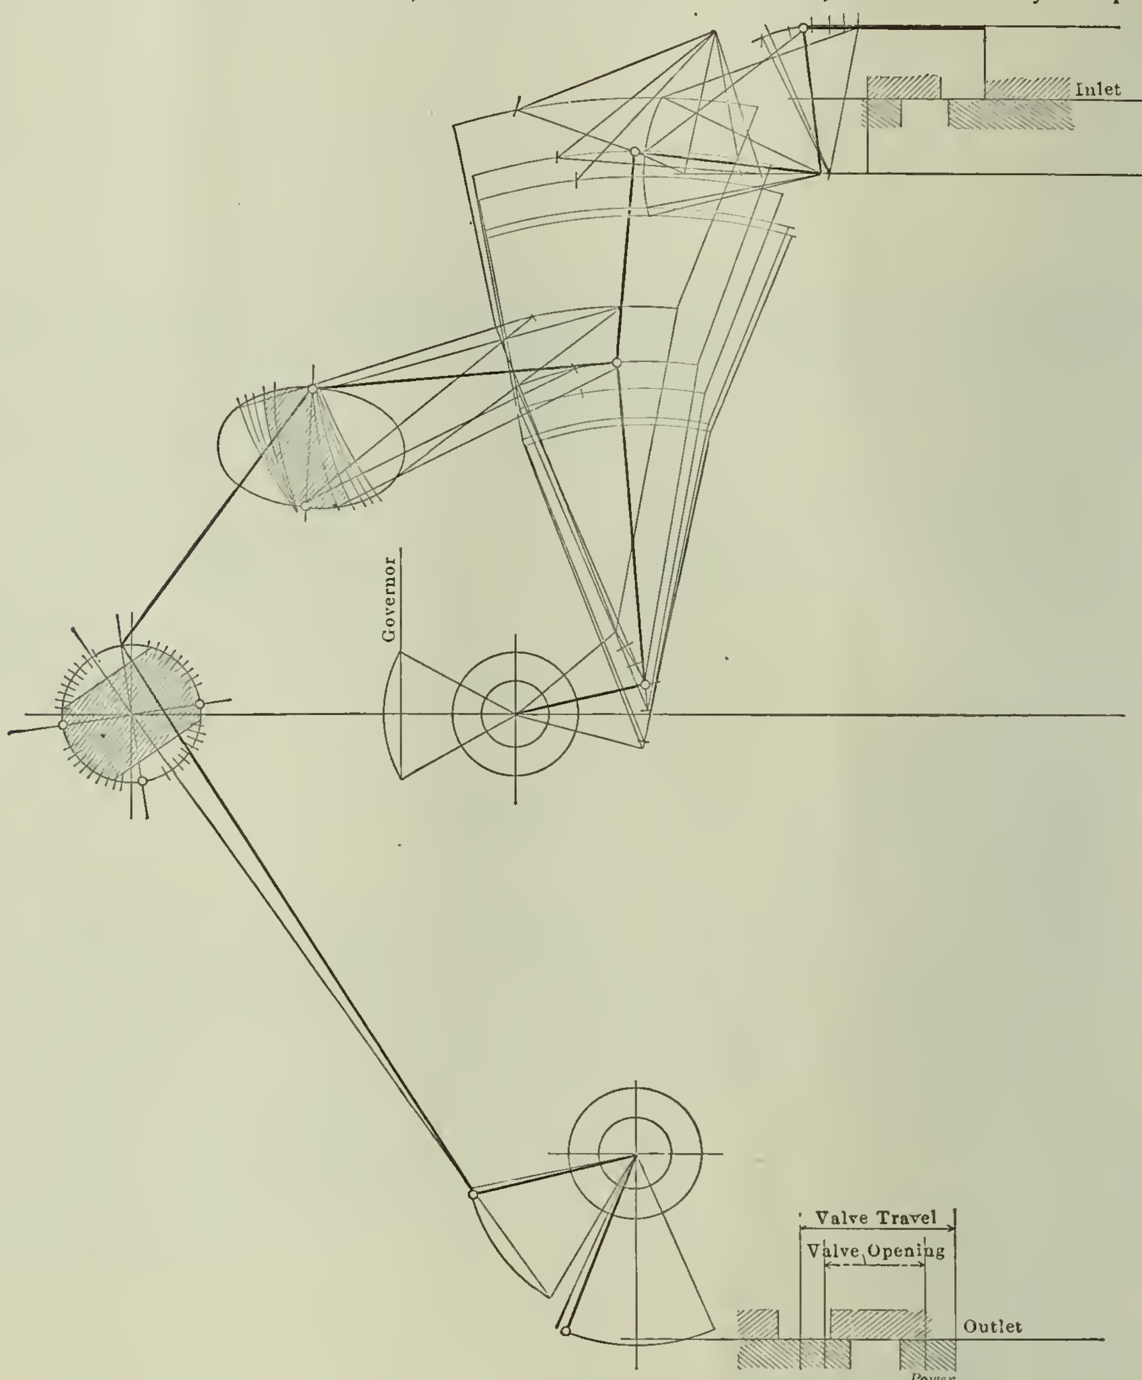

Fig. 4. Diagram of Valve Gear for Low-pressure Cylinder

of valve rods moving in metal stuffing boxes, is quite immaterial, the reaction on the governor is extremely slight, and owing to the absence of any spring actuating the slide valves, practically constant.

This half-speed valve gear is specially adapted for high-speed engines to which an entirely smooth running and increased efficiency are insured by the positive motion. As the slide valves are arranged tangential to the cylinder, no attention need be paid to the valve gear, all the parts of which are visible and accessible during the mounting and unmounting of the piston.

Water Hammer and Boiler Explosions

By A. Vincent Clark

Theories of cause of boiler explosions in which water hammer and the sudden liberation of large quantities of steam resulting from quick opening of a valve explain violence of some explosions.

In a previous issue a correspondent asked, "If water hammer is possible when a master valve is opened, even with haste, why is it not present with all of its alleged destructive effects every time that the safety valve blows?"

It is generally accepted that these two cases are not analogous. It must be borne in mind that the following explanations are theories, for it is practically impossible to obtain definite proof of the actual phenomena which occur when water hammer is set up or when a boiler or a steam pipe bursts. These theories, however, are the ones most easily reconcilable to the facts of the occurrences.

It is with explosions similar to that which recently occurred at Canton, where an apparently sound boiler exploded from a cause which could not definitely be ascertained, that these theories help toward a solution; it must be admitted that an engineer faces one of the most difficult tasks in his profession when he is called upon to give the cause of such an explosion, and there is not a subject upon which greater diversity of opinions is held by experts.

Water hammer in steam pipes is not an uncommon occurrence; it more often occurs when turning on steam to a line of piping, and its presence can be guaranteed if the steam is turned on too quickly; but it will also occasionally occur in pipes which have been conveying steam for some time; however, it is held by many engineers that this latter case is completely overcome if the steam-pipe line is arranged so that it has a continuous fall from the boiler-stop valve to the engine, with no sharp bends, and with all branches provided with a stop valve close to the pipe, or the branches efficiently drained.

In the only case with which the writer has had experience this opinion was found to be justified, for a most unmanageable water hammer, which occasionally occurred even when the main engine was running with a steady load, was completely cured by providing efficient traps for all of the branches of the steam line.

In all cases of water hammer the pipes are subjected to severe shocks, and when it is very violent, such as is caused by rapidly turning on steam, a broken stop valve or a burst pipe is the result.

There are two explanations of the phenomena which occur in this case which receive general acceptance: One is, that water lying in the pipe is caught up by the incoming steam and is blown like a shot until it is brought up by the end of the pipe or by the stop valve; the other is, that steam coming into contact with the cold water lying in the pipe is suddenly condensed, thus producing a vacuum into which this steam and water are projected with explosive force.

It will be seen that these two theories can account for all of the accidents due to water hammer, and it can be realized how important it is that the velocity of the steam first entering the pipe should be very low; for the attainment of this low velocity the boiler stop valve should be opened very slowly.

There is also another reason why the sudden opening of the boiler-stop valve is dangerous for the steam-pipe line; it is well known that a safety valve often discharges as much water as steam. The action of opening the stop valve quickly is exactly similar to the opening of the safety valve; therefore, it is quite probable that, by opening the stop valve quickly, water from the boiler enters the steam pipe at a high velocity and is shot along the pipe until it is brought up by the end of the pipe, thus causing a very violent water hammer.

Nearly fifty years ago D. K. Clark and Zerah Colburn advanced a theory regarding the violence of boiler explosions which, even now, is the best that we have and receives a general, although qualified, acceptance.

They held that in violent explosions the breaking up of the boiler is due to water being driven with great violence against the shell by the steam formed under the surface of the water directly the pressure is relieved.

It is admitted that this theory explains many of the violent explosions, but there are some exceptional cases which cannot be satisfactorily explained by it.

Taking cases of boiler explosions due to the corrosion of the plates, it may be assumed that in the case of the violent explosions the plates suddenly gave way, thus immediately allowing a great reduction of pressure and consequently, the very rapid production of a large volume of steam, whereas in the case of the less violent explosions the initial fracture of the plate might be small and simply produce an effect very similar to that of the opening of the safety valve, and the extension of the fracture be produced during the escape of the steam and water.

This explanation is probably correct, as it is well known that the intensity of any explosion is dependent upon the time. It, however, is only applicable to cases where the boilers gave way due to the weakness of their plates, and these are not a large proportion of the violent explosions.

Some explosions have been attributed to the steam generated by the pumping of cold water into a boiler when its flues have been overheated due to the water level getting low; in such cases, unless the flues are weakened by the overheating or by being bulged, it is difficult to conceive how a boiler can explode, for, when the mass of metal and the specific heats of the substances involved are taken into account, it may be definitely said that the red-hot flues would not generate more steam than the safety valve would carry off.

The probable result of the overheating would only be leaky seams and rivets, if, as is assumed, the strength of the boiler is not affected, and it seems that unless an inspection reveals signs of this the cause of the explosion must be sought elsewhere.

Another theory regarding the violence of boiler explosions and also their probable cause has been advanced from Professor Deluc's observations of the effect of absorbed air upon the boiling point of water. He found that water entirely freed from air by ebullition could be raised to 112 degrees Centigrade without boiling, but when it boils it does so with almost explosive violence. Boiling-nut water covered with a layer of oil can be raised to 120 degrees Centigrade without boiling, but above that temperature it suddenly begins to boil violently.

If this phenomenon is possible with water at atmospheric pressure then its occurrence should be possible when the water is under pressure in a boiler, and, if so, almost the ideal conditions for D. K. Clark's theory are attained, for the water next the flues would, without doubt, boil first and the water above it would be driven violently against the shell of the boiler.

A somewhat similar theory has been evolved from the knowledge that water will become spheroidal if there is a defective circulation. In this case there exists a film of steam between the water and the plates and, due to the retarded transmission of heat, the temperature of the latter will be increased; if the circulation of the water be now improved by suddenly reducing the pressure, by opening the stop valve or the safety valve, then the water coming in contact with the plates is rapidly evaporated and the steam thus formed drives the water above it violently against the boiler shell.

The last two cases are not at all similar to the one preceding them, for in that case there is no water above the steam that is rapidly generated by the overheated flue.

It is well known that it is extremely dangerous to suddenly connect a boiler to a live-steam main if there is a difference of pressure between the boiler and the main, and it is held by many engineers to be equally as dangerous to connect a boiler to a steam main quickly even if it is definitely known that the pressures are exactly the same in both cases.

Unless certain conditions are present, it is very difficult to conceive why this should be so dangerous, for in itself the connecting of two boilers at exactly the same pressure should be a safe proceeding however quickly it is carried out; even if the two boilers were not at exactly the same pressure it is difficult to see that anything other than the equalizing of the pressures would occur.

The branch from the stop valve to the main is usually not in the path of the steam from the other boiler and it is quite probable that condensation would occur in this branch, so it may easily be conceived that there may be an accumulation of water above the stop valve to be opened; by remembering one of the theories of the cause of water hammer it can be seen that these are just the conditions necessary to produce an explosion when the stop valve is suddenly opened. The steam from the boiler at once comes into contact with the water and becomes suddenly condensed, a vacuum is thus formed into which the steam and water are projected with explosive force; now, if the pressure in the main is higher than the pressure in the boiler, it is certain that the water which was above the stop valve would be driven violently into the boiler and might easily be the cause of an explosion.

Experience has changed the making of boilers to almost a science. And when the lessons of experience are learned as thoroughly by the operators then boiler explosions will be less common; an examination of the records of explosions shows that very rarely is the design of the boilers at fault, and that far too often the want of adequate inspection, or the want of care in the operation of the boilers, is the cause of the explosions which are occurring at an average of nearly two a day in this country.

The Steam Turbine in Germany

By F. E. Junge and E. Heinrich

For high economy at competitive prices a Curtis wheel in the high-pressure part, utilizing about one-third of the available energy, and Rateau wheels in the low-pressure part is the construction adopted as standard by the great majority of German builders of impulse turbines.

Rateau Wheels

The distribution of the whole drop of energy over the single stages is performed in various ways. Of importance is the consideration of the critical-pressure ratio (1.83 for superheated and 1.73 for saturated steam), a limit which one does not like to surpass as long as guiding apparatus with parallel walls are employed, though, today, the necessity of competing with other makes forces the designer, by decreasing the number of stages, to reduce the floor space of turbines, thereby lowering also the cost per horsepower. Thus it often becomes necessary to go beyond the above-named limit of critical-pressure ratio, especially in the last stages of turbines. Often a lower drop of energy is employed in the first stage in order to diminish the windage and friction work of the first wheel and to get as low pressures as possible upon the stuffing box.

Generally speaking, it is customary to divide the total drop of energy in such a way as to attain as far as possible equal outputs for each stage; that is to say, the effective velocities of issue from the guiding apparatus of each stage are then the same. In the case before us we have attempted to attain this condition for the sake of simplicity. In view of the fact that the sum of the respective energy drops of each stage becomes somewhat greater than the total theoretical drop of energy on account of the reheating of the steam—by the influence or rather influx of the heat caused by the losses—and further, in view of the other fact that to the energy drop of the second and third stages is added the exit energy $\frac{c_2^2}{2g}$ from the preceding stage, we have determined the energy drop in the single stages by way of experimentation.

Fig. 17 shows the Mollier diagram containing all the values of the steam in the various stages. Thus for the first stage the heat drop is found to be 52.2 B.t.u. Fig. 18 shows the velocity diagram.

The theoretical velocity of the steam leaving the first stage is

$$c_o = 223.8 \sqrt{52.2} = 1618 \text{ feet per second}$$

The effective velocity of issue

$$c_1 = 1618 \times 0.95 = 1537 \text{ feet per second.}$$

The circumferential velocity, as determined above, is $N = 515$ feet per second. By completing the entrance triangle we get w_1, while coefficient ψ, from Fig. 12, for a blade angle of 24 equals 0.82. Hence, $w_2 = 0.82\, w_1$, and by completing the exit triangle, $c_2 = 442$ feet per second.

Thus we get from equation 9 (January 3)

$$M = 0.6 \frac{442^2}{2g \times 778} = 2.3 \text{ B.t.u.}$$

The energy drop of the following stages we take as 49.9 B.t.u. and get as the energy of the steam issuing again $49.9 + 2.3 = 52.2$ B.t.u. The same result is attained in the third stage. As was said, this accordance of the velocities of issue and therefore of the outputs of the various stages cannot be quite exactly figured out beforehand, but must be found out by trial, more or less.

The indicated efficiency is found from the diagram to be

$$\eta i = \frac{2.515\,(1485 + 272)}{1618^2} = 0.69$$

hence,

$$R = (1 - 0.69)\ 52.2 = 16.2.$$

The windages are determined with the assumption of a mean admission diameter of $D = 3.28$ feet, and a mean blade length of ½ inch = 0.0416 foot. The specific volumes v and thereby the specific weights $\gamma = \frac{1}{v}$ are found from the Mollier diagram.

The losses through leakage on the wheel hubs were determined from equation 7 under the assumption $d_o = 190$ mm. = 0.624 feet, $s = 0.3$ mm. = 0.000985 feet (see Fig. 11), which corresponds to conditions as they obtain in actual practice. The results of the calculation of losses have been assembled in the accompanying table, the sum of losses being composed according to equation 11. The energy utilized in each stage is obtained as the difference of the converted energy and of the losses. (All amounts of loss in the accompanying table are expressed in B.t.u.)

Stage.	1	2	3
1.) R..........	16.2	16.2	16.2
2.) $\frac{V}{g}$..........	4.4	2.8	1.7
3.) $\eta_i h_o \frac{g_o}{g}$.......	....	1.9	1.1
4.) M..........	2.3	2.3	2.3
$L = 1 + 2 + 3 - 4$	18.3	18.6	16.7
Converted energy..	52.2	49.9	49.9
Utilized energy....	33.9	31.3	33.2

From this table the total amount of utilized energy is obtained as

$$H_e = 33.9 + 31.2 + 33.2 = 98.3$$

Therefore the internal efficiency of the Rateau stages:

$$\eta = \frac{98.3}{146} = 67.4 \text{ per cent.}$$

With the assumptions upon which we have based this calculation the thermal efficiency of the Curtis wheel is 64.4 per cent. and that of the Rateau wheels 67.4 per cent. As far as heat economy is concerned the Rateau wheels for the size of turbine in question appear therefore superior.

Additional Losses

To the above losses as determined by calculation is to be added a comparatively small amount of such losses, the heat of which does not reënter the steam but is carried off through conduction and radiation one way or another. These losses are: (*a*) the external mechanical losses through friction of bearings and stuffing boxes, as well as by the work which is consumed for operating governor and oil pumps; (*b*) the steam losses through the high-pressure stuffing box and other leakages; (*c*) the losses through radiation of the casing.

We note that the sum of these additional losses amounts for the size of turbines considered to some 10 per cent. of the total losses, which is about 3 per cent. of the total capacity of the turbine. Concerning loss *a*, both systems are on a par. As to the losses *b* and *c*, the Curtis system is somewhat superior, because it employs lower pressures and temperatures in the casing. Thus in consideration of these losses the comparison comes out somewhat more favorable for the Curtis wheel, more favorable at least than the above numeric result would imply. Yet, in view of the comparatively small amount of additional losses, the Rateau wheel after all appears undoubtedly superior.

Influence of Size of Turbine

So far we have only dealt with the high-pressure part of a turbine of 1000 kilowatts capacity. Considering equation 11 for the losses

$$L = (1 - \eta_i)\, h_o + \frac{g_i}{g}\, \eta_i\, h_o + \frac{\gamma}{g} - M$$

we find the amount

$$l = \frac{g_i}{g}\, \eta_i\, h_o$$

which occurs only with Rateau wheels, grows smaller with increasing steam weight g and therefore with increasing output of the turbine, provided that all the dimensions remain the same and only the cross-section of steam flow is enlarged. That is to say, with increasing output the efficiency of the Rateau wheels increases and therefore the superiority of the Rateau over the Curtis type. On the other hand, with decreasing capacity of turbines the influence of the leakage losses of Rateau wheels will be more pronounced and the Curtis wheel appears more advantageous.

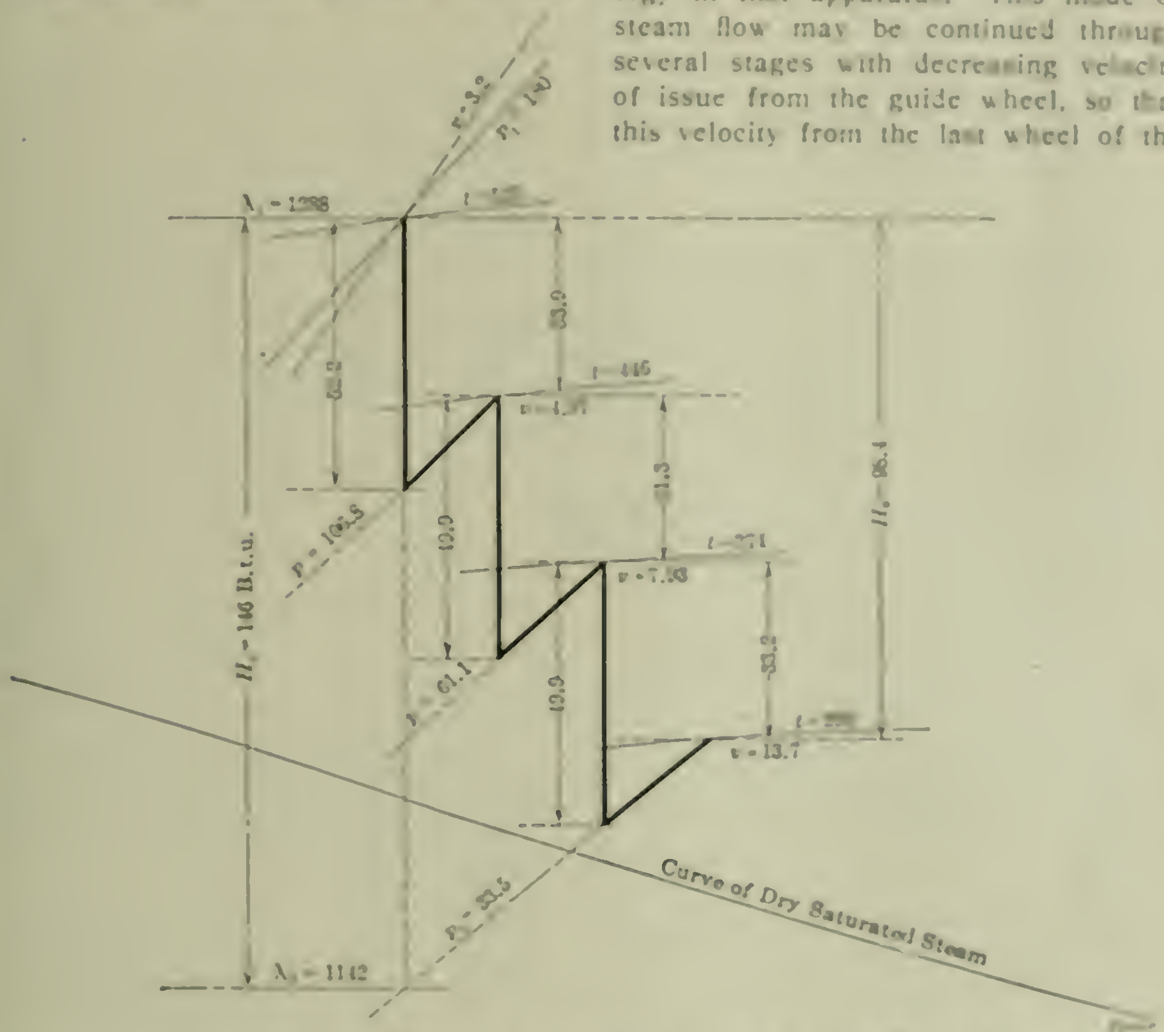

FIG. 17. MOLLIER DIAGRAM OF THE RATEAU WHEELS

COMBINATION OF CURTIS AND RATEAU PRINCIPLES

Some designers, who apply the constructive principles of Rateau and Zoelly according to Fig. 14, have adopted the Curtis principle as far as the flow of steam is concerned. They use the following mode of design: In order to expand down to lower pressure immediately with a view to keeping the windage of the first wheel and the losses through the high-pressure stuffing box as low as possible they provide in the first stage a high steam velocity by using conically diverging nozzles. In this case the velocity of issue from the first revolving wheel is still considerable and must be utilized in the following guiding apparatus to the highest possible extent. But in contradistinction to the pure Curtis principle a certain amount of heat is at the same time converted in the second guiding apparatus.

One expects from this conversion in the second guiding apparatus a better avoiding of losses by whirling than is possible without transformation of energy in that apparatus. This mode of steam flow may be continued through several stages with decreasing velocity of issue from the guide wheel, so that this velocity from the last wheel of the group is very low. Thus the ultimate loss of energy of issue is kept comparatively small.

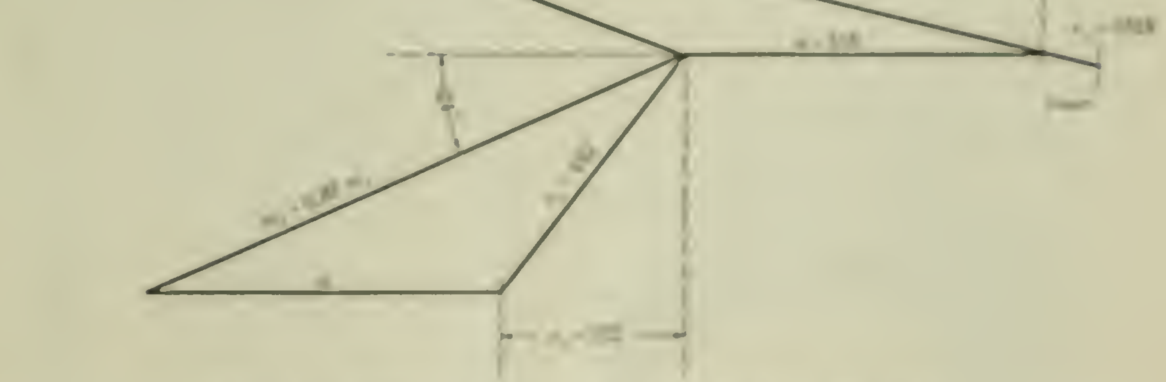

FIG. 18. VELOCITY DIAGRAM OF THE RATEAU WHEELS

This system affords a combination of velocity and pressure stages which, however, in our notion does not offer tangible advantages. It possesses the constructive features of the Rateau type, having the disadvantage of higher weight and higher initial cost of building, while as an advantage is claimed a good economy. But the latter can only be attained with very careful design of the guiding apparatus and equipment with limit blades or, what we call "profiled blades," which, of course, augments the first cost against the pure Rateau type, provided that both have the same number of stages.

RESUME

Summing up the results of our investigation we may say: At the present state of the art of steam-turbine building it appears unreasonable to point to any one system of steam turbine as the one best fitted for all sizes and conditions. There are questions of size, first cost, fuel economy and operation which should determine the selection of the system. Generally speaking, one may say that the Curtis system is superior for the smaller sizes of stationary turbines, as regards heat economy and first cost, while for the larger sizes the Rateau system, certainly in the low-pressure part, is superior in heat economy. Yet even in the larger sizes the somewhat cheaper cost of construction, lower weight and smaller floor space may swing the decision in favor of the Curtis type. In the case which we have considered above, high-pressure part of a turbine of 100 kilowatts capacity, the Rateau system apparently is more advantageous as far as heat economy is concerned. All points considered, the arrangement: Curtis wheel in the high-pressure part, utilizing about one-third of the available energy, Rateau wheels in the low-pressure part, utilizing about two-thirds of the available energy, which is now being adopted by the overwhelming majority of German builders of impulse turbines as standard construction for a wide range of outputs, appears justified for stationary practice whenever conditions demand high economy at competitive prices.

Device for Preventing Smoke

By W. H. Odell

Some of the excess air in the flue gases is drawn from the breeching by means of a jet of superheated steam and directed into the combustion chamber. This hot blast aids in the combustion of the particles which would otherwise escape up the stack unburned.

Much has been written and many devices used in the hope of finding some practical method of burning bituminous coal in steam boilers without producing an undue amount of smoke, but, because of the numerous failures, the problem is looked upon by many mill and factory owners as a joke. There are many arrangements of furnaces on the market at present that accomplish the desired result if properly handled, but the great drawback is their excessive first cost and lack of durability. However, there is a method by which at small first cost any mechanic can equip a horizontal tubular boiler having a flush front in such a manner that with proper care the results will equal if not surpass the expensive outfits installed in many large plants.

The immediate cause that led to the construction of this device was the fact that some years ago a large manufacturing company had been induced to buy a cargo of 500 tons of Nova Scotia coal, and if there is anything that can beat it as a smoke producer, I have yet to learn what it is. I was called upon to devise a means for overcoming the difficulty and accordingly installed practically the same device as here shown, except that there was no coil in the breeching to superheat the steam, and cold air was taken in from the fire-room floor and fed in through the jets, whereas in the system herein described the air is drawn in from the breeching at a temperature which averages about 600 degrees Fahrenheit and there is always enough oxygen in the uptake to support combustion. This has been proved repeatedly in some of my later installations by closing the ashpit doors, and opening only the fire doors when feeding the furnace.

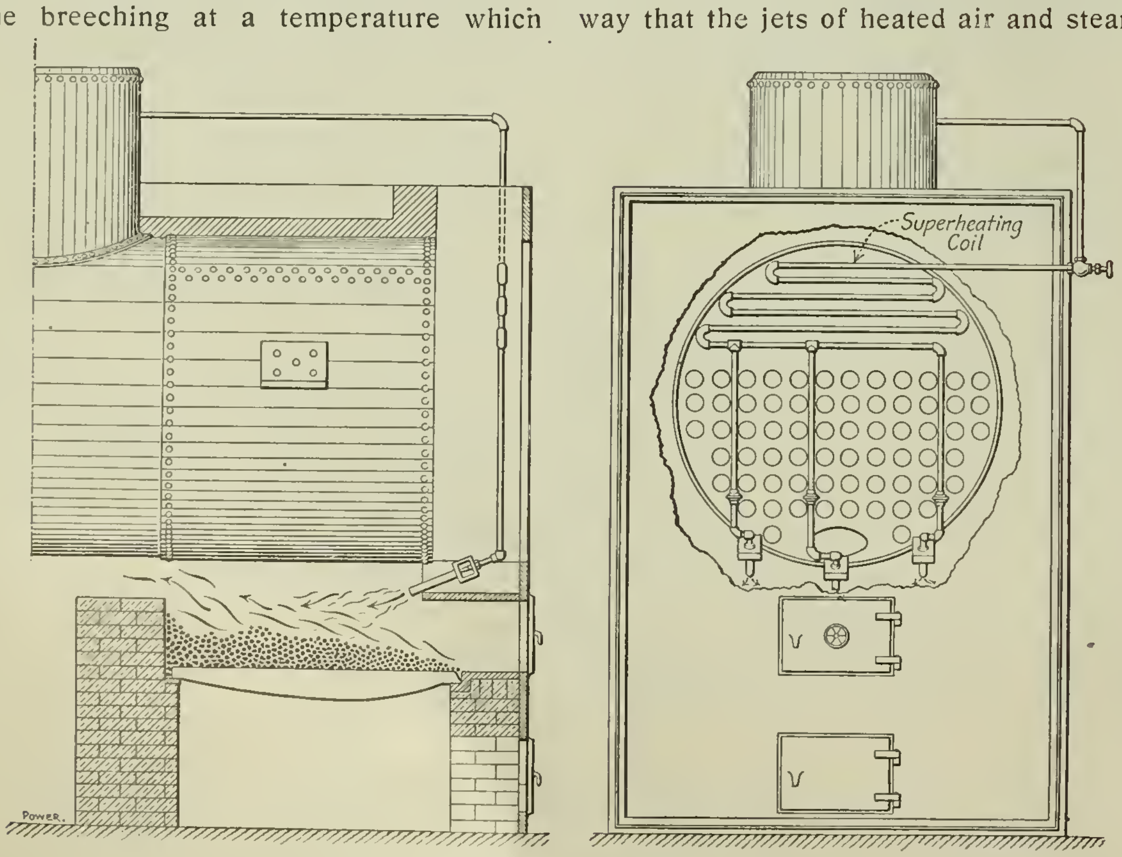

Fig. 1. Coil in Place

Some years ago an inventor made the claim, and apparently proved that there were two currents of air in a smokestack, the heated air or gases ascending the center of the stack while a thin film of cooler aid descended at the outer edge of the stack, and my experience with the ashpit doors closed seemed to confirm this theory.

I have never tried this device for economy with bituminous coal, but have tried it with anthracite coal and found a gain of about 6 per cent. when supplying the furnace with the heated air. The steam consumed by the device is about 1 per cent. of the total steam generated by the boiler.

As shown by Fig. 1, three small cast-iron boxes open at two sides are placed in the bottom of the uptake and are connected to the superheating coil in such a way that the jets of heated air and steam can readily be directed at any desired angle, although the best practice seems to be to direct them at an angle to meet the junction of the grate bars with the bridgewall. An enlarged view of the steam jet is shown in Fig. 2 in order that its construction may be more readily understood. These jets are of cast brass about four inches long with a ½-inch pipe thread cut on the outside, well down so that adjustments can be made if desired and then fixed by means of a locknut. The connection to the steam jet is made with a ½-inch tee in one end of which is a plug; this is to permit the insertion of a wire for removing any obstruction that might get into the jet.

This device was patented during 1880 but as the life of the patent ran out many years ago there is nothing to prevent anyone from using it. I did not make any serious effort to put this device on the market because of the fact that about the time it was perfected I became engaged in other work which was more pressing; but as an object lesson to some young engineers it may be of interest to relate some of my experiences with it, as they show what many inventors have to contend with.

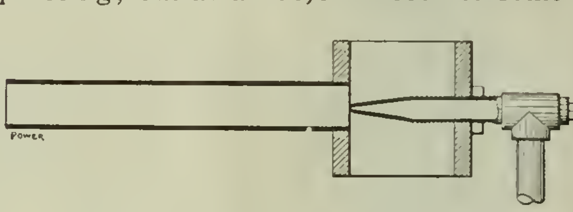

Fig. 2. Section through Jet

At the plant for which this device was gotten up there were six horizontal-tubular boilers, and as the service required only five of the boilers, it was arranged that I should have the spare boiler upon which to experiment. I took the precaution to insert a piece of 2-inch pipe through the back wall of the boiler setting about 6 inches below the bottom of the shell and as the outer end of this pipe was covered with glass we had a convenient peep hole without admitting any air.

When all was ready the five boilers were fired with anthracite coal, leaving the spare boiler to be fired with bituminous coal. Previous to cutting in with the hot blast at every firing a volume of dense black smoke would issue from the top of the stack and would continue for several minutes.

When one of the partners of the firm reached the factory about 9 o'clock, he immediately came to the fire room and began to upbraid me, saying he had been watching the top of the stack all morning and there was as much smoke as when all the boilers were fired with soft coal. I replied that my device had not been tried as yet and that I wanted him present when it was turned on for the first time. Then I asked him to take his station at the peep hole; a heavy charge of coal was put on the grates, the fire door was closed and nothing could be seen through the peep hole except an occasional tongue of flame showing dimly through the smoke. However, the instant the hot blast was turned on the effect was as if a gas jet had been lighted in a dark room.

In about a minute the blast was shut off and the smoke appeared again at the top of the stack, apparently as dense as ever. We made this change from dense smoke to no smoke at all, four times before this first charge of coal was of no further use to us.

Leaving the device for a few days that it might be tried out to the full satisfaction of the factory owners as well as any of their interested employees, I finally called on them for the $75 which had been promised if the device were a success, also to learn when it would be convenient to have their other five boilers fitted in a similar manner; but this time I met with the other partner, who, in this case, was also the purchasing agent, and who assured me that their engineer had told them he could fit the remaining boilers up for about $35 each. I admitted that this was approximately the cost of the material used and as they would not have to pay anything extra for the engineer's services it could probably be done at the figure named, but reminded him of our agreement. He replied that he did not care about the agreement, and as I had not made any move toward patenting my invention at that time I could do nothing but order my helpers to take the device out.

My second experience at smoke prevention was while representing a boiler manufacturer at the cotton exposition at Atlanta, Ga. I there met a couple of young fellows who owned a small cotton mill at Selma. They had heard of this device and wanted me to install it on their two boilers as they were greatly annoyed by heat and smoke. My engagements at the exposition prevented, but in order to help them out I made drawings, told them to go ahead and install it themselves and if after three months' trial it proved satisfactory they could send me their check for $25. I did not hear from them until several months later when I received a letter saying my device made such a hot fire that it had burned their boilers and they wanted me to pay the bill.

Notwithstanding these experiences, this simple device which any ordinary workman can install in a few hours is one of the most efficient yet produced, and much of its efficiency depends upon the use of the heated air.

Notes on Riveting Boiler Plates

By H. S. Jeffery

Suggestions as to the proper clearance between the rivet and the hole, and the means used to upset the rivet so as to fill the hole. Methods of forming the rivet head and of obtaining a tight joint.

The first consideration in driving rivets is the pitch for a given size of rivet and a given thickness of plate. Rivet holes should be spaced close enough to permit of good calking of the seam; at the same time, they should be spaced far enough apart to give the strongest joint obtainable for a given thickness of plate. In a triple-riveted double-strapped butt joint, the outer row of rivets has a wide pitch, and in order to insure efficient calking, the outside butt strap should be heavy enough to withstand the calking without springing between the rivets.

Most boiler rules stipulate that the thickness of the butt straps shall not be less than five-eighths of the thickness of the shell plate, but with boilers having shell plates from ¼ to ½ inch, the better practice is to make the butt straps the same thickness as the shell sheet. The chief difficulty with the light butt strap is that it will spring between the rivets under the necessary calking, forming small water chambers between the sheet and the butt strap, and tending to loosen the sheet around the rivets.

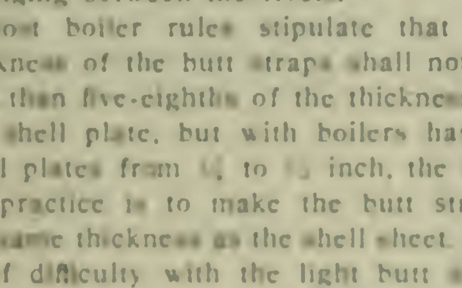

Fig. 1. Incorrect Way of Forming Rivet Head

It is almost universal practice to make the rivet holes 1/16 inch larger than the diameter of the rivet, the adoption of this clearance being traced back to the early days when only iron shell plates and rivets were used. With modern progress, however, the diameters of rivets are more uniform, and this, coupled with the fact that rivet holes are now drilled or reamed, permits less clearance, and some modern shops are now allowing only 1/32-inch clearance.

With hand-driven rivets, the rivets are upset from one end only, and if the clearance between the rivet and the hole is large and the rivet passes through several thicknesses of plate, the rivet will not be upset its entire length so as to fill the hole completely. This, together with the scale which every rivet has to a greater or lesser degree, causes rivets to leak under the breathing of the boiler. The main consideration in order to have steam-tight rivets is to fill the rivet holes. The rivets should be hit heavy blows for the purpose of upsetting them their entire length, if possible. Knocking the rivets with light hammers results in upsetting the rivet only a short distance, as that part of the rivet which should be driven into the hole is just formed there by the use of light hammers, and, therefore, becomes a part of the rivet head, which becomes larger than intended. Some boilermakers, when the rivets are too short for the upset and the head, upset the rivets so as to have sufficient metal for the rivet head, regardless of how the hole is filled.

Snap riveting, in which the rivet head is formed with a cup-shaped rivet set by striking the set several blows from steel mauls, is usually finished by knocking the rivet down with the same mauls as used for striking the rivet set. With this kind of riveting the rivet usually projects beyond the hole considerably more than with hand riveting, and the heavy blows delivered by the mauls upset the rivet a greater length. The set should be held erect during the formation of the rivet head, and to tuck in the edges it should also be held erect, holding the center of the set to one side of the center of the rivet and working around the

Fig. 2. Correct Position of Holding-on Bar

rivet in this manner until the entire edge is chased. Rolling the set around the rivet, that is, tipping the set in an effort to trim the edges, usually results in a ring or groove being cut in the sheet around the rivet head, and this should by all means be avoided.

The same rules which govern snap

riveting also govern pneumatic riveting to a great extent. With hydraulic riveting, it is possible to upset the rivet from both ends, this being accomplished by converting a cone-headed rivet into a button-headed rivet. With hand, snap and pneumatic riveting, the newly formed rivet head is usually on the outside of the boiler, while with hydraulic riveting it is usually on the inside of the boiler. In the former cases the rivet hole is filled in the outer sheet, and in the latter it is filled in the inner sheet. But, by converting the rivet head as mentioned, the rivet hole is usually filled in both the inner and outer sheets.

Regardless of the manner of riveting, the sheets should be metal to metal, for, if apart, the rivet will upset and form a ridge between the sheets, which will keep them apart and also require the rivets to be longer than would be necessary if the plates were metal to metal.

The manner of holding the rivet when driving is equally as important as the manner of driving. The rivet head should at all times be well up against the sheet at all points. The holding-on bar should bear against the rivet so as to not shape the rivet head as shown in Fig. 1. With snap riveting there is a tendency for the rivet heads to crack, and to overcome this the usual practice is to cup the holding-on bar to suit the rivet head, but the depth of the cup is made from 1/8 to 3/32 inch less than the depth of the head so that the holding-on-bar will not come in contact with the plate; this is indicated in Fig. 2.

An Investigation of Bearing Metals

By H. B. McDermid

Actual conditions under which tests were made of seven different bearing metal mixtures of tin-lead-antimony and copper-tin-antimony alloys.

The choosing of his materials of construction, in the face of modern competition, often becomes a serious problem to the manufacturer of machinery, and is worthy of serious study.

The use of some 400 tons of babbitt metals per annum, by a company engaged in the manufacture of heavy power-plant prime movers, was deemed to be a sufficient reason to justify a thorough investigation of the physical properties of those metals. In consequence, a series of friction tests were carried on, of sufficient length to quite completely determine the running characteristics of a number of different mixtures.

The object of the work done was largely to determine whether or not the cost of making bearings could be reduced without lowering the factor of safety to a dangerous point.

The cost of materials for the different mixtures varied from about 7 to 33 cents per pound. In view of this fact, some of the results obtained were decidedly interesting. There are many places in modern machine construction where the designs can be made such as will permit of low unit pressures on bearing surfaces, so that a cheaper bearing metal can be safely introduced.

Cheaper Construction

In many instances, pressures now used will permit of less costly construction, especially as, in some instances, the higher-priced metals do not show as high-grade performance as some mixtures whose costs do not exceed 40 per cent. of their more costly competitors. This is markedly true of bearings running under good lubricating conditions, with the pressure constant and always in one direction, as in many forms of motor bearings, generators, steam turbines, etc.

An example of this is a 6500-kilowatt dynamo running in two bearings 14x48 inches each, where the unit pressure due to dead load is but 70 pounds per square inch, and where, being direct connected to an hydraulic turbine, the pressure is always steady and in one direction. This machine was furnished with a supposedly high-grade babbitt at a cost of some 25 cents per pound, when test results proved an 8-cent mixture to be superior in every case under those conditions, and showed it to be fully capable of carrying the load at all times, even when the magnetic pull due to an unbalanced air gap was taken into consideration.

Conditions of Tests

The tests were run, for the most part, upon a homemade machine, so arranged

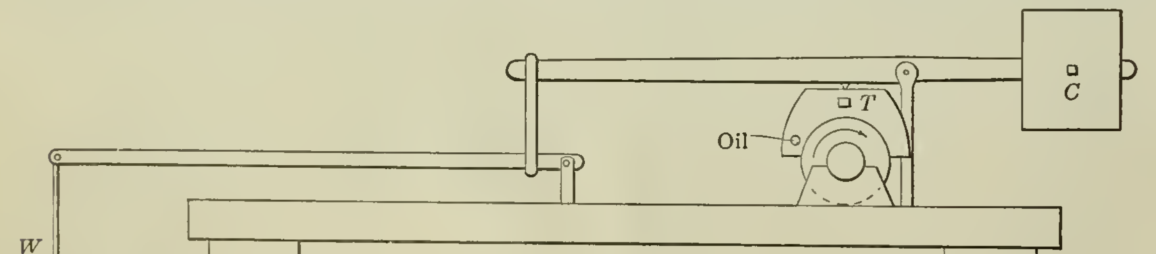

Fig. 1. The Testing Machine for Bearings

that any desirable load could be placed upon the test piece, which was made in the form of an upper half box, covering a full half of a 7-inch journal. The journal was carried in side bearings of ample area to insure their safely carrying all loads imposed upon them. The surface speed at the test piece was 480 feet per minute and at the side bearings 220 feet per minute.

No appliance was provided for the direct measurement of the friction developed, so that the rise in temperature was taken as the only indication of the friction of the rubbing surfaces, and with cool running side bearings so that no outside error could creep in to any extent. This method was found to be amply accurate and satisfactory for the comparative tests desired.

The Test Machine and Bearings

The general arrangement of the machine is shown in Fig. 1, where C is an adjustable counterweight used to balance the system of levers shown, and W is a weight pan used for loading the test piece T. The ratio of the force exerted at W to that at T was 1 to 70. It was thus comparatively easy to get relatively high unit pressures on the test piece, which measured 7 inches in diameter and 2 inches long.

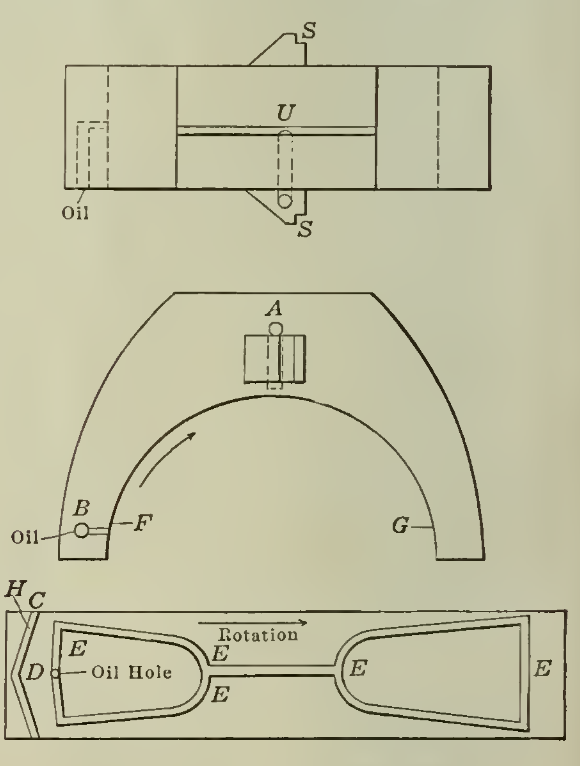

Fig. 2. The Test Bearing

A side elevation and plan, and a developed plan of the test bearings is shown in Fig. 2. Here A indicates a thermometer well, drilled diagonally down through the stop piece S which is on each side. During actual work, this stop piece rests against the frame of the machine in such a manner as to prevent rotation about the shaft. To render the sketch clearer, this portion of the frame is not shown in Fig. 1. The thermometer well was drilled so the bulb of the instrument would rest at a point ½ inch above the bearing surface of the babbitt and in the middle of the test piece, as measured along the axis of the shaft. B is the place for introducing the lubricating oil, which was fed from a drop-feed oil cup during the final tests.

In the developed plan, a system of air and oil grooves is shown. These were the same for each specimen, and were cut so as to finish 3/16 inch half round in section. The air groove was found necessary in order to carry off air that was drawn in by the rapidly rotating shaft, which otherwise was forced out at B in quantities great enough to render uncertain if not absolutely destroy the lubricating of the piece. In order to have it in proper working condition the edges of this groove must tightly fit the journal at the inside edge D and be loose and free at the outer edge H. The mixture of air and oil that adheres to the shaft is then scraped off by edge D and deflected to the sides of the piece, thereby insuring undisturbed lubrication of the rubbing parts. To insure thorough spreading of the entering oil, the oil channels are well relieved at the sides E.

Precautions Taken

Every precaution possible was taken to insure uniform working conditions for each test piece, so that the test might be dependably accurate, at least for comparative results. It was ascertained that after minute and careful inspection two test pieces might appear exactly alike, might be of the same material, have apparently identical smoothness of glazed surface, be treated as closely alike as possible, and yet run widely different final tests.

To this end, then, the babbitt was carefully melted, in clean ladles, so no dross nor undue burning or overheating might form gritty or abrasive spots or surfaces that might cause friction and heating; the metal was carefully anchored in the shells so that it might always have solid, positive, uniform backing to transmit the heavy pressures of the system of loading levers with no springing, breaking, or pinching; it was closely bored to fit the journal, and machined to exact dimensions; and the journal was ground straight and cylindrical, so that for each piece tested, the conditions were made as nearly uniform as good mechanical skill could make them.

The test piece was fitted to the machine by placing it upon the journal and fitting the stops SS, until both bore equally upon their stops on the frame of the machine within the limit of 1/1000 of an inch, thus eliminating the possibility of any sort of side twist being introduced. The casting at U was so beveled that the load perforce had to bear vertically downward and thus eliminate all pressures not in a vertical plane passing through the center of the bearing, normal to the axis of the test journal.

By these means it was believed that reasonable accuracy in conditions had been obtained and correspondingly dependable results were secured.

Preparing the Bearings

The bearing was next "spotted in" upon the slowly revolving shaft and scraped to as close a fit as possible, the oil and air grooves were then cut and finished and the journal placed in an oil bath and run at full speed. The bearing was placed under very light loads at first and this gradually increased, as the thermometer record showed it could stand it, until the bearing possessed a perfect glazed contact with the journal from F to G, and would run at a cool uniform temperature under heavy loads.

This latter point was very important as two bearings may apparently have an equally good fit and glaze, and yet even though of the same material, one will easily stand up under a load that would shortly ruin the other, due to minute differences which even the closest inspection must fail to detect, and which cannot be detected except by a running test under identical conditions.

This preliminary "running in" occupied from ten to thirty hours, according to the material tested and to the care with which the preliminary and subsequent fitting had been done. During this preparatory stage the temperature was never allowed to rise above 220 degrees Fahrenheit, so the oil would not carbonize upon the rubbing surfaces under any conditions and so permanently injure them.

TABLE 1. CHEMICAL ANALYSES OF ALL MIXTURES

T	[illegible]	[illegible]	[illegible]	[illegible]	
T	[illegible]	[illegible]		[illegible]	

The run was kept up as continuously as convenient with each specimen until it would stand from 900 to 1000 pounds per square inch under oil bath conditions and still run fairly cool. The machine was then allowed to cool down over night to practically the temperature of the room, and without anything occurring that could disturb the accuracy or perfection of the fit of the rubbing surfaces of either the journal or test piece, the final test was begun.

Final Tests

The following rules were closely adhered to in conducting the final tests after the specimens were fully prepared:

1. All tests to be started with the whole machine and testing system practically at the temperature of the room.

2. The oil to be a standard high-grade engine oil with a sufficient supply on hand to permit of the whole series of tests being run with the same lubricant.

3. A standard sero oil cup to be used and the oil fed upon the bearing at 45 drops per minute; the rate of feed being checked every ten minutes.

4. Each bearing to be loaded at the start with a pressure of 200 pounds per square inch. Readings of time and bearing temperatures to be taken every five

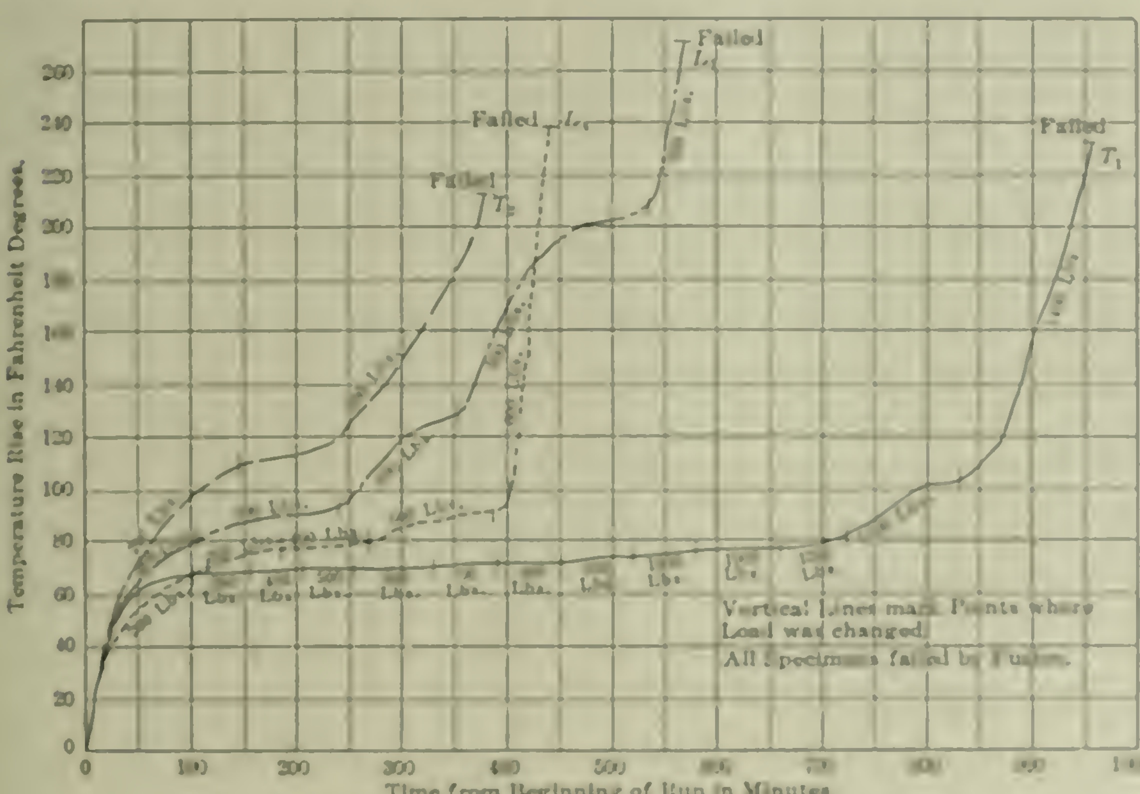

Fig. 3. Average Test of the Four Highest Mixtures

minutes, until the temperature of the bearing became constant within two degrees Fahrenheit for three-quarters of an hour. The load then to be increased to 300 pounds per square inch with temperature readings taken as before. The load then to be increased to 400 pounds, and so on until failure occurred by fusion of the mixture under test.

5. All tests must be judged by the same thermometers. The thermometer well must be filled with oil at starting so the heat from the bearing will be readily and accurately transmitted to the bulb of the instrument.

6. Care must be taken to have all parts of the machine in proper adjustment and kept so. All other conditions must be kept as nearly standard as possible, so the working will be thoroughly reliable as a comparative test.

Duplicate Tests

After the test had been run to the finish by "failure," a process that necessarily had to be completed without interruption of any kind, and which lasted from 3 to 15 hours with varying grades of metals, the machine was dismantled, and the journal taken out and reground until it was again perfectly true, straight and cylindrical. A second bearing was then put through its preliminary preparation and its final test run under the same conditions as the first had been, as nearly as care and skill could reproduce them.

Each mixture, as it was physically tested, was also chemically analyzed so that the effect of the various ingredients could be noted and recorded. Its price was also taken into account, so that a comparison of worth per dollar of cost could be made. In every case several duplicate tests were run in order that checks on each of the earlier tests could be had, with each mixture and in every case, and the average of several tests is used in compiling the accompanying data:

Four mixtures containing high percentages of lead were used, and three containing high tin percentages. Table 1 gives the chemical analysis of all the mixtures used. The capitals *L* and *T* indicate the major portion of each alloy, as being either lead or tin.

Details of Tests

The chart, Fig. 3, of the final test performance is plotted with time as abscissas and differences between room and bearing temperatures as ordinates. The first section represents the record under 200 pounds load, the second that of 300 pounds load, etc.; the point where the load was changed being indicated by a short vertical line. The sudden vertical break in the last section indicates the point where lubrication failed and the oil grooves smeared over, resulting in the complete and rapid destruction of the piece under test. To avoid confusion and undue crowding only the four most representative records are plotted.

Table 2 summarizes the increases in temperature for each load, the duration of run under each load and gives an approximate price per pound of each mixture.

The behavior of these bearings under the preliminary tests as well as in the final tests was very interesting. For instance, the high-lead mixtures, which, of course, would not stand peening into the shell, gave considerable trouble at first in obtaining a good support or backing for the bearing metal to the shell. This was because of their high shrinkage coefficient. The high tin alloys which do not shrink so much, in case of the anchors not being sufficient, could be peened solidly into the shell, and so eliminate troubles of this sort.

The high-lead bearings being the softer, were brought to a good running fit easier, but they would not recover when neglected or abused, with anywhere near the facility of the high tin mixtures.

The Mixture to Choose

Those mixtures showing a high content of antimony, as *L*3, were naturally hard and took a considerable length of time to come to their running fit. They were, therefore, somewhat less desirable than the softer materials, since any of the mixtures, well lubricated, will wear well enough for ordinary machine work, and the important quality of a babbitt mixture is its ability to adapt itself quickly to a deformed or roughened journal without undue heating or cutting.

The tenacity of the tin and copper in mixture T_1, combined with the ductility, render it easily the best of the group, but the high-lead mixture *L*4 seems the best of the combinations here listed, for ordinary work.

The high cost of mixture T_1 puts it entirely out of the question, except where special service requiring high quality to stand rough hard usage is demanded, or where the type of service makes uninterrupted running so important as to overshadow the item of first cost. In all other cases, of ordinary service, the tests show such an alloy as *L*4 to be very satisfactory, especially where, under reasonable conditions, a bearing may be expected to have good ordinary care, and a steady load in one direction, without violent and sudden reversals of pressures.

Even under such conditions, some practical master mechanics of long and varied experience in heavy rolling-mill work, have assured me that they would just as soon have a mixture like *L*4 placed in the bearings of a number of 3000-kilowatt gas-engine units, then under discussion, as to use the mixture sim-

ilar to *T2*, which was furnished. They also assured me they had cured obstinate cases of hot bearings, where several varieties of tin mixtures had failed, by replacing them with a high-lead mixture. This ran very cooly from its first start and thereafter gave no further trouble.

SUMMARY

It is not my purpose to enter into any long or intricate discussion of the problems of bearing design, but in these days when forced and ample, even excessive, lubrication is daily becoming more popular, it would seem as if the conditions such as were used in the test could be closely approximated in most cases and thus the cheaper bearing be safely introduced.

If the experience of master mechanics of some of the largest steel plants is such as to find the high-lead bearing acceptable for the rough usage of heavy rolling-mill and the heaviest gas-engine practice known, it would seem at least worthy of a fair trial.

It is my own experience that a mixture similar to *T2* has stood the test for years of generator service at from 60 to 90 pounds dead-load unit pressures, with the possibility of a magnetic pull, due to an unbalanced air gap, doubling that pressure. It is also used with success in engine main bearings where the pressures withstood vary from 200 to 250 pounds per square inch and in crank-pin boxes where the momentary pressures at the point of admission of steam to the cylinder reach a maximum of 1400 pounds per square inch.

If a mixture of as poor a test record as recorded above, has so good a record in years of actual service under widely varying conditions, should not a mixture of a highly superior test record, with an initial cost of less than one-third of that of its rival, be given at least a fair opportunity to make a record by which it must stand or fall? It would seem so, and I will venture to predict that such will quite generally be the case in the near future and that under the policy of ample lubrication now gaining ground daily in power-plant service, the results will amply justify the experiment.

Compression in Steam Engines

By Armand Duchesne

The principal loss in the reciprocating steam engine is that due to the exchange of heat between the metal and the steam. In the ordinary case over 20 per cent. of the steam admitted is condensed to warm up the containing surfaces, and a large part of it is not reëvaporated until after the exhaust valve opens. Georges Duchesne did some original and notable work at Liége in measuring the variation of temperature of the cylinder surface and the author, his brother, tells of his own continuation of that work.

It has been demonstrated by the laboratory of applied mechanics of the University of Liège that the law of compression of steam in the engine is not the same as that of expansion, and it is not necessary, it appears to us, to search further for the loss of economy, due to the compression of the steam in the clearance spaces, discovered experimentally by Professor Dwelshauvers-Dery.*

There has been a collection of facts which have been brought to light at the laboratory of Liège, where I have the honor to labor under the orders of the learned professor, and in collaboration with my lamented brother, Georges Duchesne, which do not permit of any doubt upon this subject.

The genius of Hirn had led him to foresee a thing which we find at present very simple and very natural. He imagined that the temperature of the metal of the cylinder varied between limits much more narrow than those of the temperature of the working vapor, and the conclusion which he immediately deduced was that the vapor was dry at the end of the exhaust, since the hot metal had had the time to reëvaporate the film of water which had been deposited upon it. This probably appeared too simple and was not generally admitted, when Georges Duchesne gave a striking demonstration of the fact that it could not be otherwise, in such a way that only those who wished to remain ignorant of these proofs of the laws of physics who did not acquiesce in them.

Georges Duchesne had already determined the temperature of the metal during the exhaust of the steam,† and the comprehension of the phenomena depended only upon a knowledge of the properties of the saturated vapor of water. What would happen to several drops of water at the temperature of 110 degrees if they were placed suddenly under the receiver of an air pump where there existed a vacuum of one-tenth of an atmosphere? This is just what happens in the case of an engine operating condensing.

The hypothesis of Hirn was, therefore, demonstrated. The steam is dry at the end of the exhaust, and Georges Duchesne proved that it was even a little superheated.

An experimental verification of this fact would be of great interest, and we have been occupied for several years in obtaining it. The problem which we set for ourselves was to trace the diagrams of the temperature of the steam and of the metal for the two strokes of the piston forming a complete revolution. Our method has been already discussed,‡ but it has been modified, and we will describe it such as it is at present.

We needed evidently a thermometer which had no heat capacity, in order that there might be no lag, and we chose a thermo-electrical pyrometer, furnished with a platinum-silver couple, of which the elements had a diameter of 0.02 of a millimeter. This thermometer had a large number of junctures, which gave us consequently the mean temperature of all the steam in the cylinder. As to the walls, we used a pyrometer, made of two plates, one of silver and the other of platinum, of 0.002 millimeter thickness, applied to the walls of the clearance space in such a way that the junctures remained entirely free. In this way we are in command of two systems, one taking immediately the temperature of the steam, and the other the temperature of the walls. How could we register at each instant the temperature of the steam and the temperature of the metal?

By delivering the current of the pyrometer into a ballistic galvanometer during a determined time, one-tenth of a second for example, we have a deviation which, according to an established calibration, will furnish us the average temperature during this one-tenth of a second. This condition is realized by the fall of a weight, suspended by an electromagnet, the height of that fall being calculated to continue for the required time. This corresponds with a speed of 30 revolutions per minute to one-twentieth of a revolution of the engine. It is necessary, there-

*Revue de Mécanique, 1907, pp. 925 and 1260; Power, June 28, 1910.

†Revue de Mécanique, July, 1909.

‡Revue de Mécanique, Dec. 1909.

fore, only to bring about the fall of this weight at the commencement of each one-twentieth of a revolution to arrive at the average temperature during the successive twentieth.

In order to realize this we have divided the two strokes of the piston into subdivisions, which correspond to the twentieth of a revolution (Fig. 1), and an electric contact could be broken by the crosshead itself at each of the subdivisions, in such a manner that the weight during the entire time of its fall will send the current furnished by the pyrometer into the galvanometer during the twentieth of a revolution, corresponding to that division and giving, therefore, the average temperature during this twentieth. It will be seen, therefore, that we could obtain points on the curves of the temperature of the steam and of the metal for an entire revolution of the crank, and it was necessary only to make these diagrams correspond to the corresponding two strokes of the piston in taking account of the obliquity of the connecting rod.

It goes without saying that if the speed is other than 30 revolutions per minute, one can calculate what must be the hight of the fall of the weight, in

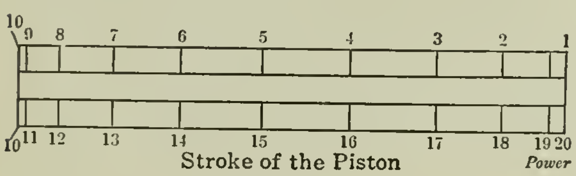

FIG. 1.

order that it shall continue through one-twentieth of the revolution of the engine. If the speed is only 15 revolutions per minute, the hight of fall of the weight should be calculated for a value of two-tenths of a second in order that it should correspond to one-twentieth of a revolution. Before undertaking specially the study of compression, we will describe an example of a test made without steam jackets, and which was made under the following conditions:

Expansion, commencement, 0.1; end, 0.95.

Compression, commencement, 0.9; end, 1.

It will be seen that the admission continued for one-tenth of a stroke of the piston, and that the compression was also one-tenth of the stroke.

The diagrams of the temperature are traced in Fig. 2, and we have added to these experimental curves those representing at each instant the temperature of saturation corresponding with the pressure shown by the indicator and the tables of saturated steam. It is seen at once that, excepting during the admission, the metal is always considerably warmer than the working fluid. The points of temperature of saturation are marked by small circles, and the diagram which unites them is traced in a dotted line. It is easy to prove that the steam is superheated well before the end of the exhaust stroke, with the result that at the commencement of the compression the degree of superheat attains 45 degrees.

During the expansion the two curves of the temperature of the steam experimentally determined and that of saturation taken from the tables correspond absolutely, and this suffices already to show us clearly that the fluid which is compressed is very different from that which operates during expansion. But we will show in that which follows the loss which is occasioned by compressing the vapor in the clearance space, when one exceeds a certain degree of compression.

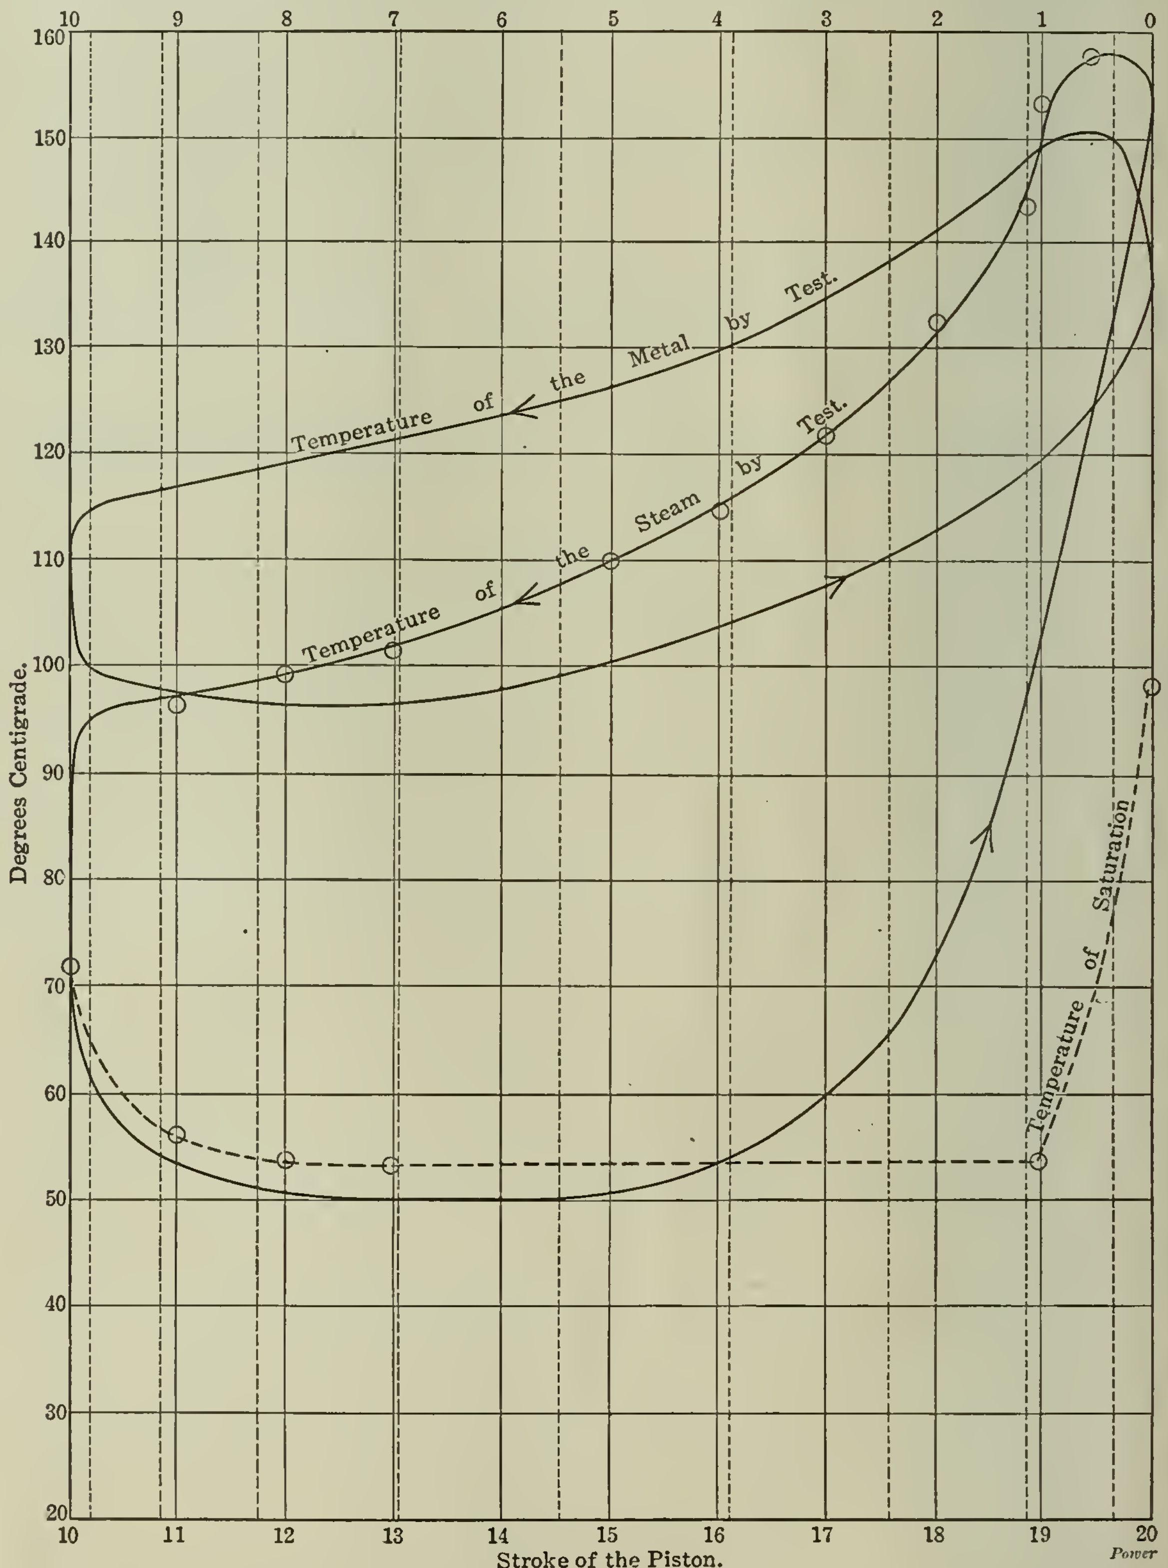

FIG. 2.

To this end we have arranged our engine to realize a high degree of compression—nine-tenths of the stroke. In order, however, to more nearly comply with ordinary conditions, this long compression diminishing the time of exhaust, we have so adjusted the engine that the cylinder would remain in communication with the condenser during the same time as if we had a compression of only three-tenths. This was necessary in order to be able to draw the conclusions which we were after, the assumption being made that during this long compression we should have thus about the same weight of steam M_c, as if the compression had been shorter.

In Figs. 3 and 4 is given only that which concerns the compression. First, in Fig. 3, the experimental temperatures of the steam and the cylinder wall, as a function of the path followed by the crank pin, and in Fig. 4 these temperatures refer to the path of the piston. There is given also in a dotted line the curve of the temperatures of saturation.

And now there exists no doubt that a perfect gas is being compressed, the temperature of the steam going up to 450 degrees, while the maximum temperature of saturation is above 140 degrees, and this demonstrates that the theorem of Zeuner cannot be applied to the case of the steam engines. We can, therefore, conclude at once that under the conditions in which we compress this steam it will require exterior work, considerably greater than that which it can produce, especially during the expansion, since at that time it operates under the form of saturated steam.

Let us try now to examine the loss of efficiency due to the compression in the case under consideration. We will suppose that the operation is adiabatic.** Let us take as the average specific heat of the superheated steam the figure 0.485, which we will suppose constant to the limit; that is to say, to the point of saturation. Leaving to one side the end of the curves, which show a sudden fall in the temperature of the steam and which will be explained later, we notice at $A A'$ that the compression has raised the temperature from 86.5 degrees to 450 degrees. Upon the assumptions which we have made this operation has required an external work equal to

$$425 \times 0.485 \; (450 - 86.5) \; M_c \, Kgm$$

This would be nothing if the equivalent heat of this work could be retained in the fluid to be utilized in the following cycle. But what happens in reality beyond the point $A A'$ is that the temperature of the fluid falls suddenly, the metal commences to cool the steam because the difference of temperature is enormous and the piston is moving very slowly; and if, under these conditions, certain portions of the metal remain cooler than the temperature of saturation, the cooling will produce condensation, and condensation means an exchange of heat extremely intense. It will be seen, therefore, that the heat which comes from the exterior work enters into the metal and will not be reimparted to the steam except in part during the expansion, but under unfavorable conditions of efficiency, since the temperature will be considerably lower than that at which the walls absorb the heat, and another part during the exhaust stroke, which is absolutely lost upon the efficiency.

Our remarks on the properties of the superheated vapor of water permit us to calculate M_c.

M_c [illegible]

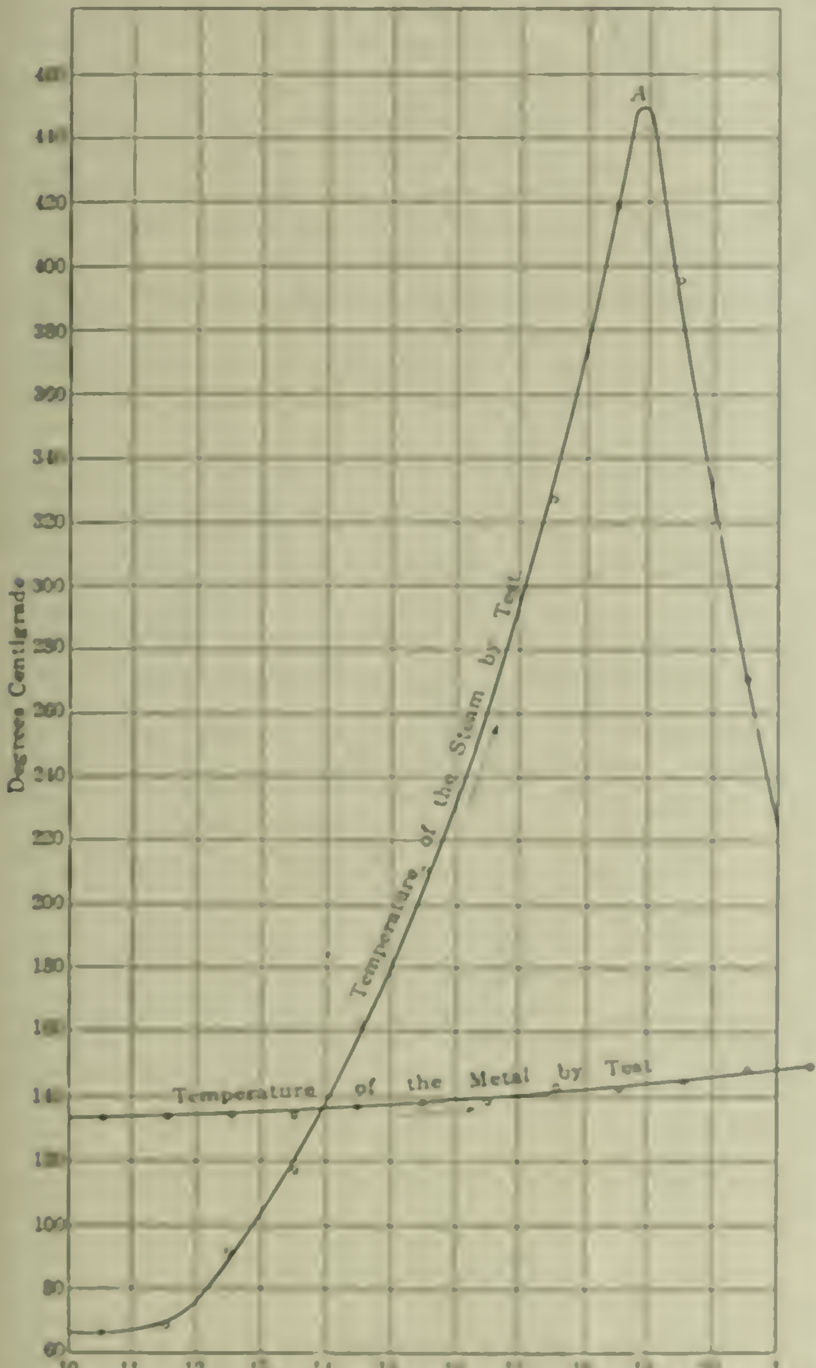

FIG. 3

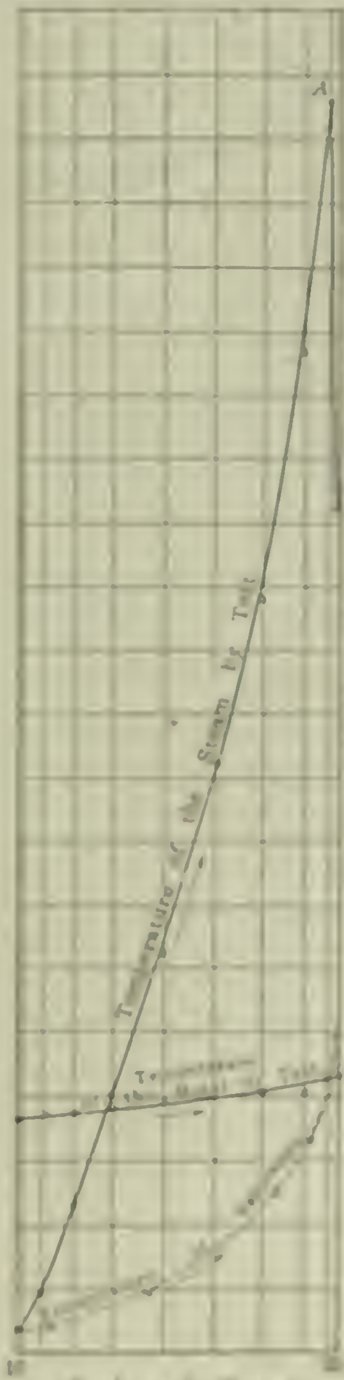

FIG. 4

According to the preceding, we find that the compression has produced work of which the heat equivalent is

$$0.585 \; (450 - 86.5) \times 0.00445 = 0.784 \text{ calorie}$$

of which the action of the walls will lose to us a great part of the benefit.

We have a verification of this figure. By measuring the area under the compression curve of the indicator diagram we should obtain the same results. By the aid of the planimeter we find that the mean hight of the curve of compression is 15.06 millimeters, the scale of the spring is 1 millimeter, or 496.1 kilogram per square meter. We have, therefore, during the compression a mean pressure of 7471 kilograms per square meter, the volume generated during compression being 0.04245 cubic meter. The work of compression measured up to the point $A A'$ will be 317.1430 kilogram-meters, which corresponds to

$$\frac{317.1430}{425} = 0.746 \text{ calorie}$$

This figure is sufficiently near to that (0.784) found above to assure us of the exactitude of our measurements.

If we calculate the work per stroke by measuring the area of the indicator diagram, we will find 713.200 kilogram-meters, which correspond to 1.678 calories. We may, therefore, conclude that the loss of energy due to the compression by the mechanism which we have described is an important fraction, and that the 0.784 calorie, found as above, has a marked influence for this amount of heat, 0.784 ... certainly not negligible as compared with the 1.678 calories, which represents the work developed upon one stroke of the piston.

But it may be said that we have chosen a compression of nine-tenths of a stroke, which would never be used in practice. Very true, but a long compression shows the influence much more markedly, and can we not deduce from it that we would reach the same results, but in a less marked degree, by a more feeble compression?

There will remain one point to be cleared up. For a given set of conditions Professor Dwelshauvers-Dery has found an increase of economy up to a certain degree of compression, and this is very simply explained if we consider a compression such that the temperature of saturation corresponding to the final pressure remains always less than the temperature of the metal. The effect will be that if at the end of the stroke the steam is somewhat cooled, it will not condense, but will remain superheated, and instead of producing a loss will contribute to diminish the initial condensation.

It is in this way that the measurements of the temperatures of the steam and of the containing surfaces permit the phenomena which occur during compression to be interpreted.

**In view of the fact that the steam is superheated, we will not depart widely from the truth in making this assumption.

Primer of Electricity

By Cecil P. Poole

The Compound-wound Dynamo

In the lesson of November 8 it was explained that the electromotive force at the brushes of a shunt-wound dynamo remains almost constant between no load and full load, but that the drop in the wires between the dynamo and the load makes it necessary to increase the voltage of the machine, when the load increases, in order to keep the voltage right at the load.

The series-wound dynamo, on the other

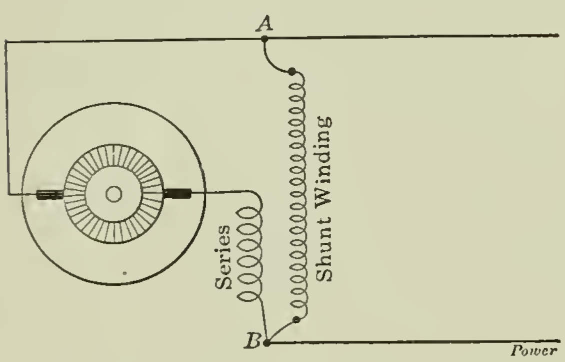

Fig. 82. Circuits of a Compound-wound Dynamo

hand, increases its voltage when the armature current increases, because the armature current passes through the field winding. This feature of the series-wound machine supplies just what the shunt-wound machine lacks for constant-potential work, but a simple series-wound dynamo cannot be used for this kind of work because its voltage varies too much with load changes.

Therefore, a field winding has been developed which is a combination of the shunt and series windings—in fact, there are two separate and distinct windings, one a shunt winding and the other a series winding, as indicated in Fig. 82,

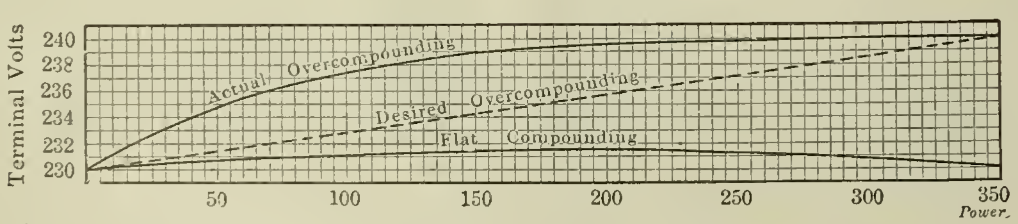

Fig. 83. Curves Showing Voltage at Different Loads

which is only an elementary diagram of the main circuits of a compound-wound dynamo, with regulating devices omitted. The shunt winding supplies the excitation necessary to generate the rated voltage and the series winding adds the excitation necessary to generate the extra electromotive force required to make up the drop in the dynamo and, if required, that in the wires of the external or load circuits.

For example, suppose the internal resistance of an 80-kilowatt dynamo were 1/35 of an ohm, the rated e.m.f. 230 volts and the full-load current 350 amperes. Then, at full load, the drop within the dynamo itself would be

$$350 \times \frac{1}{35} = 10$$

volts, and if it were not compound wound the voltage at the terminals would be only 220 volts at full load, unless the field excitation were strengthened.

In order to make the series winding strengthen the field excitation enough to make up the 10 volts lost in the windings, it would be proportioned so that with 350 amperes flowing through it, the ampere-turns would produce enough additional magnetic flux to enable the armature to generate 10 volts more than it would with the shunt winding alone. That is, the magnetism produced by the shunt winding would cause the armature to generate 230 volts and that produced by the two windings together would make it generate 240 volts.

In other words, if the machine required 8000 ampere-turns per pole to generate 230 volts and 8700 to generate 240 volts, the shunt winding would have to give 8000 and the series winding (at full load) 700 ampere-turns per pole.

A machine built in the way described—to give the same voltage at full load as at no load—is called "flat compounded," because a curve showing the relation between the load and the voltage at the dynamo terminals is practically flat, as shown by the lower curve in Fig. 83.

Most compound-wound dynamos, however, are "overcompounded"; that is, when full-load current flows through the series winding the field strength is increased *more* than enough to enable the armature to generate the extra voltage required to make up for the drop in the windings of the machine itself. This is done to make up partly or completely for the drop in the circuit between the dynamo and the lamps.

For example, suppose the drop in the external circuit supplied by the 80-kilowatt dynamo were also 10 volts at full load and the machine had to be over-

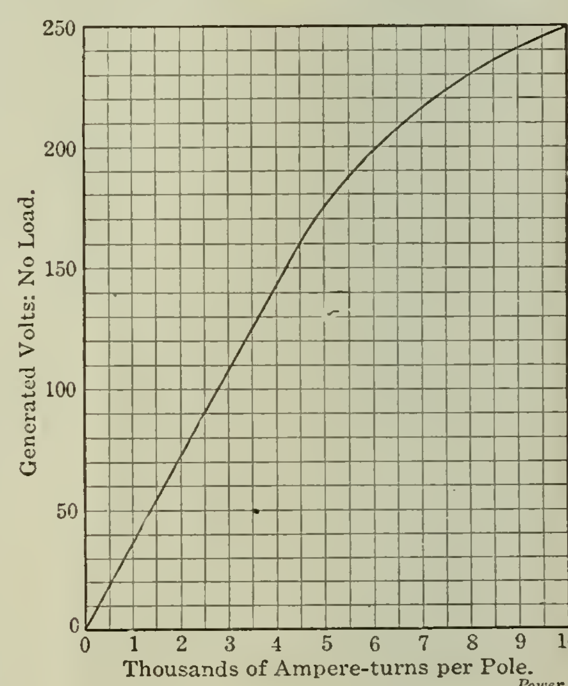

Fig. 84. Excitation Curve

compounded to cover that drop. Then, at full load, the armature would have to generate 250 volts in all, 10 of which would be used up in the windings and 10 in the line, leaving 230 volts available at the lamps. If the machine required 10,000 ampere-turns per pole to generate this 250 volts, the series field winding would have to supply 1650 ampere-turns at full load because the shunt winding, which supplied 8000 ampere-turns when the e.m.f. at its terminals was 230 volts, would supply 8350 ampere-turns when subjected to 240 volts, which would be the terminal pressure when overcompounded 10 volts.

As Fig. 83 clearly indicates, the compound winding does not do accurately what is intended, that is, maintain constant terminal voltage* with flat com-

*Terminal voltage is that at the terminals or circuit connections on the dynamo: *A* and *B*, in Fig. 82.

pounding or a rise in exact proportion to the load with overcompounding. In the case of the flat-compounded machine just described, the e.m.f. at the terminals, instead of being constant at all loads, goes up to 231½ volts when the load reaches 200 amperes, and gradually falls, as the load increases, to 230 at full load. In the case of 10 volts overcompounding the terminal volts increase rapidly with the load up to about half load and then increase slowly as the load increases, as shown by the upper curve in Fig. 83 marked "Actual overcompounding." What is desired is a regular increase in voltage, as indicated by the broken line.

The reason for this departure from constant voltage in the one case and a regular increase in the other is that the magnetism produced by the field excitation is not proportional to the excitation. This was explained in a previous lesson, and is illustrated by Fig. 84, which is the excitation curve of the 80-kilowatt machine now being considered. Referring to this curve it will be evident that the generated volts, which vary exactly with the field magnetism, increase exactly with the ampere-turns up to about 4500 ampere-turns; thus, 1000 ampere-turns produce 35.55 volts, 2000 produce 71.11 volts, 3000 produce 106⅔ volts, 4000 produce 142.22 volts and 4500 give 160 volts. Beyond this, the additional volts produced by each additional 1000 ampere-turns are less than 30 volts, instead of continuing at the rate of 35.55 volts per 1000 ampere-turns.

Fig. 85, which is the upper part of Fig. 84 plotted to a larger scale, shows more distinctly the relation between the ampere-turns and the generated volts of the 80-kilowatt machine, within the working range. This shows that 8000 ampere-turns of excitation enabled the armature to generate 230 volts; 8300 ampere-turns produced 235 volts; 8700 ampere-turns, 240 volts; 9000 ampere-turns, 243 volts; 9500 ampere-turns, 247 volts, and 10,000 ampere-turns produced 250 volts. If that part of the curve above 230 volts were a straight line instead of a curve, then the curves in Fig. 83 would be straight lines, so far as the machine followed them, but, as explained in a previous lesson, the machine would be unstable; that is, it would not stop at any particular voltage but would either increase to an infinite voltage and destroy itself or drop to no voltage at all and remain "dead."

For the reason just explained, it is impossible to get a straight-line excitation characteristic* from a dynamo. The curves shown in Fig. 83, however, are unusually bad and were selected because of that fact; they serve to illustrate the departure from a straight line better than curves taken from a well proportioned compound-wound dynamo would. The machine from which these curves were plotted was really a 240-volt shunt-wound dynamo.

The field magnet of a compound-wound dynamo would be "worked" farther down the curve shown in Fig. 85, say along that part from 220 volts up to 240 instead of from 230 up to 250. The difference in

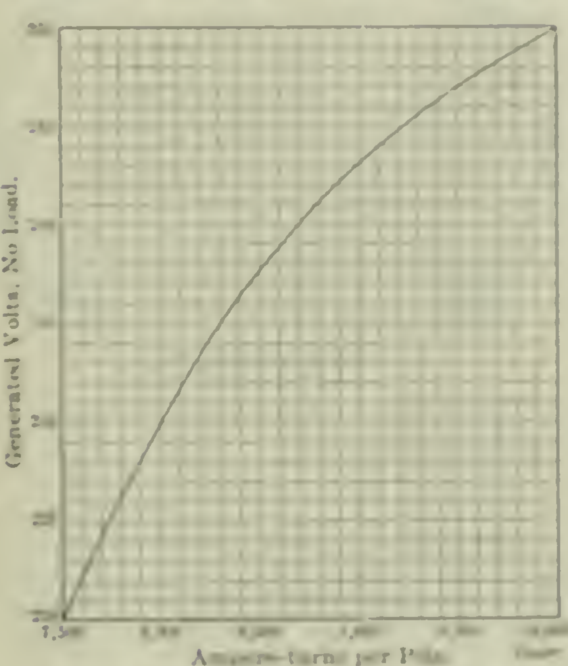

FIG. 85. UPPER PART OF FIG. 84

regulation is quite remarkable. For example, if the full-load drop of the machine were 8 volts and it were compounded for a 12-volt rise at the terminals —that is, the terminal voltage at no load to be 220 volts and at full load 232 volts, the following results would be obtained:

	Ampere-turns			Generated Volts	Drop	Terminal Volts
	Shunt	Series	Total			
No load	[illegible]	0	[illegible]	[illegible]	[illegible]	[illegible]
Full load	[illegible]	791	8700	240	8	[illegible]

These results are deduced very easily. If the terminal voltage at full load is 232 volts and the internal drop is 8 volts, the total generated voltage at full load must be 232 + 8 = 240 volts. Fig. 85 shows that 7500 ampere-turns are needed to generate 220 volts and 8700 to generate 240 volts. The shunt winding must contain 7500 ampere-turns when 220 volts are applied to it; therefore, it will contain 7909 ampere-turns at 232 volts. The series winding must contain at full load the difference between the 7909 supplied by the shunt winding and the 8700 required; this difference is 791 ampere-turns. Without going farther into details it is sufficient to say that the terminal voltage of the machine at one-fourth, one-half, three-quarters and full load would be as follows:

Load	Generated Volts	Drop	Terminal Volts	Desired Terminal Volts
0	[illegible]	0	[illegible]	[illegible]
¼	[illegible]	[illegible]	[illegible]	[illegible]
½	[illegible]	[illegible]	[illegible]	[illegible]
¾	[illegible]	[illegible]	[illegible]	[illegible]
Full	[illegible]	[illegible]	[illegible]	[illegible]

Here, the greatest excess of terminal voltage over the desired voltage is 4 volts, as compared with 4½ volts excess in Fig. 83.

*A curve or line on a chart showing the relation between different features of operation is called a "characteristic."

LETTERS

Water in Transformer Oil

"You had more transformers burn out in your little district during the last three months than we had in any of the larger districts in the same time."

The foregoing statement by the superintendent of construction to the superintendent of the little district mentioned caused me to do some thinking and investigating. I was the engineer of the plant and had nothing to do with the line work, but my natural curiosity prompted me to find out why so many transformers burned out. First I sought the lineman who had charge of the transformers and asked him in a casual way why so many transformers had burned out lately. As the burnouts occurred in transformers set up last and usually after a rain, he thought it was the wet weather that caused the trouble, but could not understand why, as the rain did not affect the transformers when hung on the poles.

Continuing the investigation I went into the building where the transformer oil was kept. The supply was contained in a steel barrel or drum which was placed on a bench high enough so that the oil could be drawn into a can set on the floor, from this can, which the lineman usually kept full or nearly so, he would pour the oil into the transformer cases because this took less time and he often had a hurry call for a transformer. I took this can out and poured out slowly the oil that was in it, then I saw that there was a considerable quantity of water in the bottom of the can. Following this clue I discovered that the roof of the building where the oil was kept was leaky, and when it rained the can caught its share of the water, which was afterward poured into the transformer cases along with the oil. This impaired the insulation, ultimately producing short-circuits which burned out the transformers. The roof was repaired and the trouble ceased.

JAMES W. BLAKE.

New York City.

This is the season when the lecturer stands in the lantern's glare and fulminates upon everything from entropy to boiler-feed compounds for the benefit of the operating engineer. There is much to be gotten out of these lectures, and the opportunity to learn is not satisfied by the fact that the lecturer may have as a motive the exploitation of his wares. One cannot know too much about the things he may be called upon to use, and discussion and a chance to hear the other man will bring out points about those that one never thought of.

Gas Power Department

Everything worth while in the gas engine and producer industry will be treated here in a way that can be of use to practical men

Elementary Lectures on the Gas Producer

By Cecil P. Poole

Fuel Bed Temperature

It is probably not clear to the student why the fuel bed in a gas generator does not become red hot all the way through, instead of being divided into "zones" as indicated roughly in Fig. 12. There are three reasons, each rather mixed up with the other; in the first place, the fuel bed is very deep—seldom less than three feet and usually from four to seven feet, according to the size of the generator; largely because of this, the principal reason exists, which is that not enough air goes through the fuel bed and into intimate contact with the particles of coal to burn it completely to carbon dioxide; the third reason is that the air is mixed with steam, as described in the first lecture last June, and this steam absorbs a lot of heat from the burning fuel in the combustion zone which would otherwise be transferred to the coal immediately above and raise the temperature of that zone.

This will be better understood, perhaps, if you will think over what happens when you pour water on a fire. If a little water be thrown on the fire it will be evaporated into steam and this will take heat away from the fire, dimming it considerably. If enough water be thrown on the fire all the heat will be absorbed and the fire will go out. The heat effect of putting steam through a bed of red-hot coal is the same, though the physical results are different. The steam is decomposed into hydrogen and oxygen and this process takes an amount of heat away from the burning coal equal to the heat that would be liberated by burning hydrogen to form the same amount of steam. This amounts to 62,000 heat units for each pound of hydrogen, or 6890 heat units for each pound of steam.

For example, each pound of carbon burned to CO_2 unites with 2⅔ pounds of oxygen, which is taken from 11½ pounds of air. The heat liberated by this combustion is 14,600 B.t.u. Now if, say, 9/10 of a pound of steam be admitted with the 11½ pounds of air, that will be decomposed into 1/10 pound of hydrogen and 8/10 pound of oxygen and the decomposition will absorb 6200 heat units of the 14,600 set free by combustion; this will leave only 8400 B.t.u., instead of 14,600, available for raising the temperature.

The coal in the second zone has to be heated by the heat from the fire in the first zone, and if the temperature there (in the second zone) is kept at 1900 degrees, each pound of coal will absorb about 400 B.t.u. in "sensible heat" (see the December 6 lecture). Therefore, if there were 8½ pounds of coal in the second zone for each pound of carbon burned in the fire zone, about 3400 B.t.u. would be absorbed in heating it up to 1900 degrees, so that instead of 8400 B.t.u. there would be only about 5000 available for heating the gases.

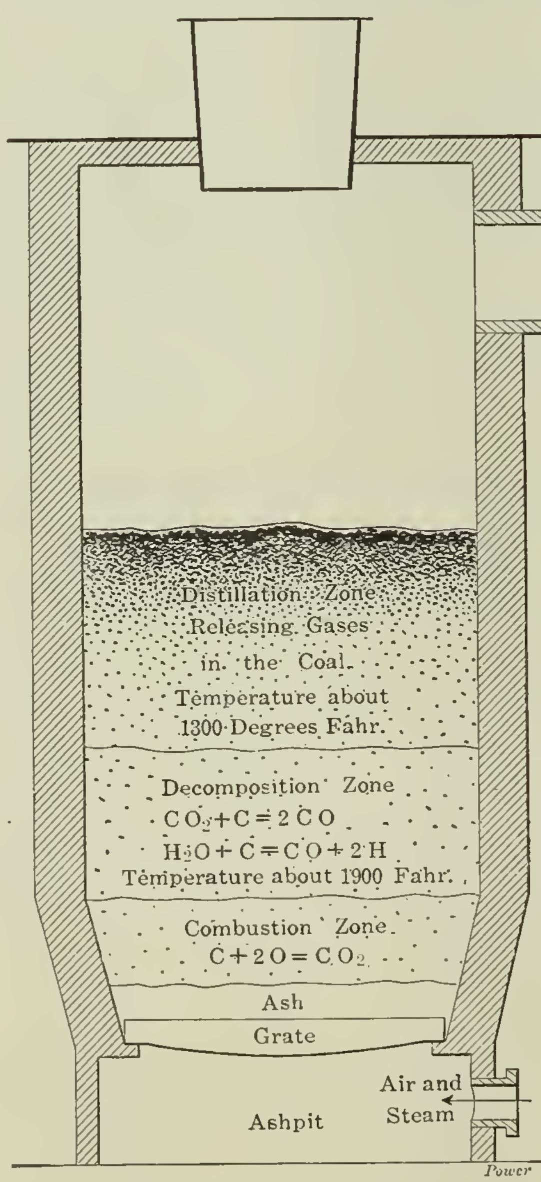

Fig. 12. Approximate Character of the Zones of a Fuel Bed When Steam Is Admitted with the Air

But in addition to the processes described there are two others which affect the generator temperature. The CO_2 formed in the fire zone "picks up" carbon in the second zone and is converted into CO; and the oxygen from the decomposed steam also combines with carbon to form CO. The first process absorbs heat and the second one gives out heat. For each pound of carbon united with CO_2 to form CO, there are absorbed 5700 B.t.u. and for each pound of carbon burned to CO with oxygen 4450 B.t.u. are given up.

Now, if we assume that all of the CO_2 formed in the fire zone is converted to CO in the second zone, that 9/10 pound of steam is admitted with the 11½ pounds of air, that all of the oxygen from this steam unites with carbon to form CO, and that 3 pounds of coal are heated to 1900 degrees in the second zone for each pound of carbon burned in the first one, the burning of that pound would produce the following results:

1 pound carbon burned to 3⅔ pounds CO_2 gives out	14,600 B.t.u.
3 pounds coal heated to 1900 degrees absorb	1,200 "
Leaving	13,400 "
3⅔ pounds CO_2 united with 1 pound carbon to form 4⅔ pounds CO absorb	5,700 "
Leaving	7,700 B.t.u.
$\frac{9}{10}$ pound steam decomposed to $\frac{1}{10}$ pound H and $\frac{8}{10}$ pound O absorbs	6,200 "
Leaving	1,500 B.t.u.
$\frac{6}{10}$ pound carbon burned to 1.4 pounds CO with $\frac{8}{10}$ pound of oxygen gives out	2,670 "
Net heat remaining	4,170 B.t.u.

The final products of these processes are 6.067 pounds of CO, 8.84 pounds of nitrogen and 1/10 pound of hydrogen, and the specific heat of this mixture is 0.267 B.t.u. per pound or 4 B.t.u. for the whole 15 pounds. Therefore these gases will be at a temperature theoretically $\frac{4170}{4} = 1042\frac{1}{2}$ degrees above that of the atmosphere when they pass from the decomposition zone to the upper part of the fuel bed. The green coal there will absorb considerable heat from the gases so that when they finally leave the generator their temperature may be as low as 600 or 800 degrees, Fahrenheit. Of the 3 pounds of coal heated in the second zone, about 1¾ pounds have been used to make CO and the remaining 1¼ pounds pass to the fire zone to keep up combustion.

Many conditions other than those mentioned affect the temperature, such as the heat absorbed by the ash and that radiated through the generator walls. The calculations just given are intended only to indicate the way in which the fuel-bed thickness and steam supply affect the temperatures of the fuel and products of combustion and gasification. In practice it is impossible to convert all of the CO_2 into CO, and a considerable amount is always contained in the gases finally delivered by the generator.

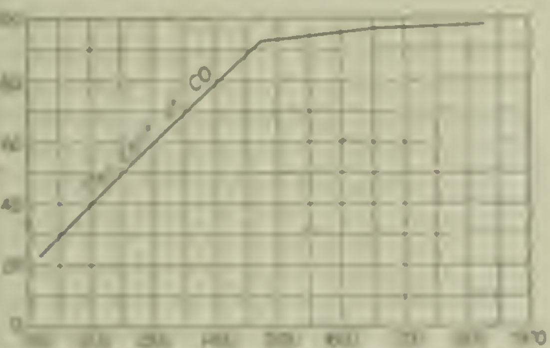

Fig. 14. Effect of Temperature on Production of CO

As the object of operating a producer is to make gases that will burn in an engine, and not to develop heat as a boiler furnace does, the less carbon dioxide it delivers, the better. Therefore, the aim is to completely burn just as little carbon as possible and to convert as much as possible of this back into CO, as described. It is necessary to make CO_2 in order to obtain the heat required to make CO; a fuel bed cannot be kept hot by burning all of the carbon incompletely, and it must be kept very hot to get the greatest proportion of CO in the outgoing gases. The conditions are contradictory to a certain extent. The quantity of CO_2 made in the fire zone must not be so great that much of it will go through the second zone unconverted; yet the second zone must be kept very hot in order to convert the greatest amount of CO_2, and in order to keep it hot a good deal of CO_2 must be made in the fire zone by complete combustion. The ideal fuel-bed depth and air supply are those that will burn just enough coal in the fire zone to heat the second zone up to that temperature at which the most CO_2 will be converted into CO. The deeper the fuel bed, the more coal must be burned in the fire zone to keep it hot and the more coal is burned to CO_2, the more steam can be admitted with the air without cooling the bed too much.

Boudouard, a French investigator, found that at 1112 degrees Fahrenheit, carbon dioxide passing through a bed of coal would combine with carbon to form 23 per cent. of CO, and at 1832 degrees the CO produced was slightly over 90 per cent. Fig. 14 was plotted from the results of Boudouard's tests. It shows that the percentage of carbon monoxide rose regularly with increasing temperatures up to 1475 degrees, beyond which point the increase was much less rapid. This chart indicates that the best temperature range for the second or decomposition zone is from 1800 to 2000 degrees.

As already explained, the temperature of the second zone depends on the depth of the fuel bed and the proportion of steam admitted with the air. Reducing the depth of bed will reduce the quantity of coal through which the CO_2 from the fire zone passes; the coal, therefore, will be heated to a higher temperature, and if the bed is too shallow it will increase in temperature until complete combustion occurs, unless the air supply is checked enough to prevent that. If that is done, the quantity of gas made will, of course, be reduced.

On the other hand, if the fuel bed is extremely deep the coal above the second zone may absorb so much heat from the rising gases that the temperature in the top part will fall low enough to allow some of the CO to be converted back to CO_2. This can happen either by the loss of the carbon "picked up" in the second zone or by the combination of CO with oxygen in steam which has been reformed or has escaped decomposition. In ordinary work this condition cannot arise because the generator is not high enough to contain any such depth of fuel.

It is asserted by some authorities that a slight conversion of CO to CO_2 occurs in the scrubber and gas passages due to the loss of carbon by cooling; this is said to account for the soot found in the scrubber water and the gas pipes, but the writer is more inclined to believe that that is merely coal dust swept from the upper parts of the fuel bed by the outgoing gases. However that may be, it is clear that the higher the temperature of a generator up to that which gives the second zone 1900 degrees, the larger will be the percentage of useful gases and the smaller the percentage of CO_2 delivered. Any temperature above that merely wastes heat by increasing the temperature of the outgoing gases and also tends to fuse the ash in the coal and form clinkers.

A New Diesel Engine in Small Sizes

The "original Diesel small motors" shown at the International Motor Boat and Motor Exhibition in Berlin and at the Brussels World's Fair this year indicate that the development of the Diesel motor has been extended to the broad field of small high-speed motors.

This new type of Diesel motor, which is built at present in sizes of from 5 to 30 horsepower with one to six cylinders, is primarily intended to meet the needs of small industrial plants, and for this reason the aim of the builders has not been to obtain the greatest possible reduction of weight, but rather to provide a strong machine adapted to use by unskilled persons. Nevertheless, the new machines are lighter than is usual in stationary-engine practice. For instance, the weight of the 30-horsepower engine complete for service, including bedplate, air tanks, fuel holder and exhaust head, amounts to 32 kilograms per brake horsepower; this is about one-tenth of the weight of the old stationary Diesel engine of like efficiency, but greater than the weight of the submarine-boat engine, which, at any rate, must be lightly built. For installation in ordinary vessels the "original Diesel" small engine is provided with a modified crank case and the heavy foundation plate is omitted entirely, so that the weight of the engine for marine service is less than that of the land engine.

The speed of the small engine is normally 600 revolutions per minute, at which the combustion is complete and the exhaust invisible and odorless. The

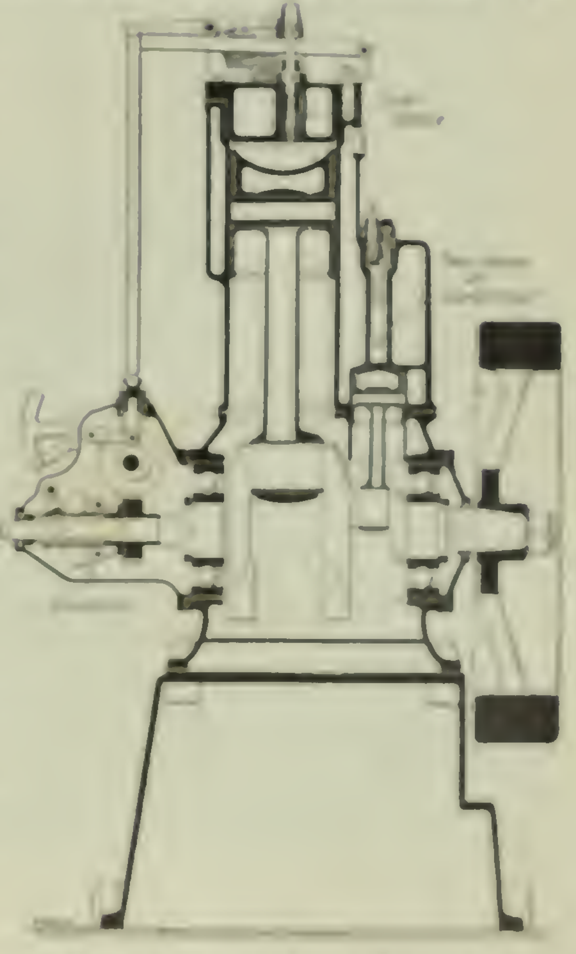

Fig. 1. Small Diesel Engine

speed of the engines built for marine service, however, can be varied from 200 to 1000 revolutions per minute. The stationary engine is kept within 10 per cent. of the rated speed by means of the usual centrifugal governor. The problem of reliably controlling the injection of the very small quantities of fuel required is said to have been solved in the "original Diesel" small motor in a very satisfactory manner.

The machine shows several differences from the usual form of construction, some of these being characteristic features that have been developed in modern automobile practice. The cylinder head contains all valves and valve mechanism, and it extends from the cylinder body, being packed by means of conical seat surfaces, metal to metal. Thus it has been possible to bring the larger piping, such as suction, exhaust and water pipes, to the cylinder instead of the cylinder head, and, consequently, the cylinder head is made very light and can be removed or replaced in a few minutes without dismounting clumsy piping or valve gearing. The arrangement of the valve-actuating levers on the cylinder head corresponds in general to that of the large types of Diesel motor; the cam shaft is, however, located directly above the crank shaft in an extension housing, as shown in Fig. 1, relieving the cylinder head still further of heavy parts. Fig. 2 shows a single-cylinder 5-horsepower Diesel small motor coupled to a direct-current dynamo.

For stationary service, in which constant speed is desired, the motor, as already stated, is provided with a governor, which is inclosed in the extension housing of the cam shaft and controls the length of stroke of the suction valve of the fuel pump. The marine engine is regulated by hand adjustment of the fuel pump.

Fuel-consumption tests at normal continuous loads have shown the exceedingly favorable result that the consumption differs only a little from that of the large engines. There have been obtained figures of 238 grams [8.4 ounces] consumption per brake horsepower-hour, so that 250 grams [8.8 ounces] may be taken as a guarantee figure.

According to data thus far obtained, the fuel costs for the Diesel small motors are only one-fifth to one-fourth of those obtained in gasolene-motor practice, and in marine service there is also the saving of fuel weight carried, which on the average is cut down to half of that required for the old motors. The radius of action of boats equipped with small Diesel motors, therefore, as affected by the fuel weight, is doubled.

As in the large engines, the fuels used are heavy oils of relatively "slow" inflammability; even with the most sluggishly inflammable oils, however, combustion is said to be so rapid that the indicator diagrams are indistinguishable from those of the large Diesel engine. The diagram shown in Fig. 3 was taken at reduced speed in order to avoid the distortions that would be caused by inertia of the indicator piston.

The inlet and oil-jet air is forced into steel tanks by the air pump, which, in its smallest type, is cast in one piece with the cylinder and is surrounded by the common water jacket. These steel tanks resemble the carbonic-acid flasks which for years have proved reliable. The ends of these tanks are shown projecting from the bed casting in Fig. 2.

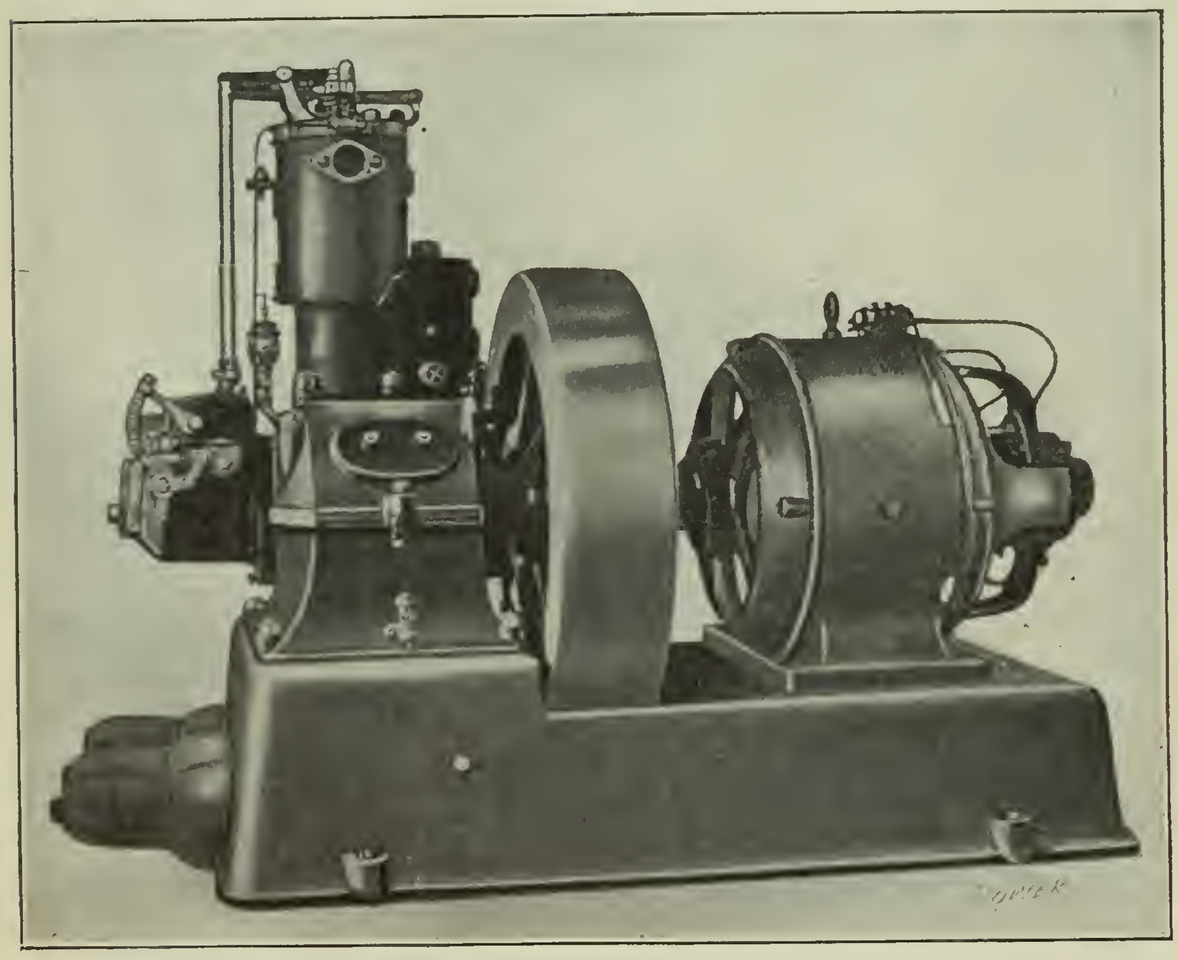

Fig. 2. Small High-speed Diesel Engine

The engine parts subjected to excessive stress, such as the crank shaft, crank pin, connecting rod and crosshead pin, are made of the best chrome-nickel steel; all bearings are ball bearings.

An improvement valuable in small service of all kinds is the automatic regulation of the air pump, which renders unnecessary any supervision of the air pressure in the various reservoirs. Since, also, the lubrication of the engine does not need special attention, this new small motor is a completely automatic machine.

These little machines are built by the Société Anonyme St. Georges, of Zurich, Switzerland. They are designated "original Diesel" small motors because they have been so named by Herr Diesel himself and their construction is carried out under his advice.

The Future of the Gas Engine

Dugald Clerk, the well known English authority, recently delivered a lecture at Manchester University on "The Phenomena of Explosions in Gas and Other Internal Combustion Engines." Mr. Clerk, in conclusion, expressed the opinion that so long as expansions remain as at present, no great further increase in the thermal efficiency of the internal-combustion engine can be expected. Increasing expansions mean increasing engine weight very largely to gain a small increase in efficiency. It is quite possible to design and construct an engine working with coal gas which would give an indicated thermal efficiency of about 50 per cent.; but such an engine would probably have a lower mechanical efficiency—probably about 80 per cent.—so that the brake efficiency would be only about 40 per cent. It is not likely, he said, that such an engine would be commercially successful, because the increased first cost would not be justified by the greater economy. Unless some other method can be adopted of increasing power by utilizing the exhaust heat, coal-gas engines are likely to remain at their present standard. The principle of compounding, it is true, might be applied to the gas engine, and longer ranges of expansion obtained; but such complication would be justified only in comparatively large engines.

So far as the small gas engine is concerned, a close approach has been made to a standard type. Practically all difficulties have been overcome, both from the engineering and the commercial standpoints. Small gas engines are now even more reliable than small steam engines, as may be proved by comparison of results given by various insurance companies. Scientific work is more vitally required in the case of the large gas engine, where the conditions as to temperature, pressure and unequal expansion due to heat are of the severest kind. Study of the various problems of volumetric heat, heat flow, radiation, incomplete combustion, dissociation, etc., are all required to produce better conditions of operation while maintaining or increasing thermal efficiency. Inventors of this generation may not succeed in producing sufficiently favorable conditions for commercial success in very large gas engines; but their work and that of the scientific investigator of the present will undoubtedly provide the engineer of the future with means of solving problems so far unsolved by the engineer of today.

Readers with Something to Say

Practical information from the man on the job. A letter good enough to print here will be paid for. Ideas, not mere words wanted

Trouble with a Heating Plant

While putting in a steam-heating job of about 30,000 square feet of radiation, nearly all indirect, I ran across a problem that gave me some trouble to master, and the solution may interest some reader.

The building contained many wings and ells and as the several parts of it were built at different periods there are many changes of floor level; so that the steam main, all of which was run in the basement, had to rise, fall and rise again according to the various elevations of the basement ceiling. Altogether there are 1800 lineal feet of main steam pipe in the job, running from 10 inches at the boilers to 2½ inches in diameter at the extreme ends.

The boilers are located in the center of a court around which the building was built, and the main steam pipe ran in opposite directions from the boiler plant, feeding the north and south parts of the building.

The water line in the boilers was some 40 feet above the water line under the lowest radiators, so it was necessary to resort to the use of automatic feed pumps and receivers in order to return the water of condensation to the boilers. Two of these pumps were installed, one of them being kept as a reserve unit.

Accompanying is a diagrammatic sketch, Fig. 1, showing the general arrangement of the part which gave trouble and how it was piped.

Soon after starting to heat the buildings it was found that the returns would come back to the automatic feed pump in slugs. The pump would run very fast for a few minutes, filling the boilers to the top of the glass gage before it slowed down, and then run very slowly for a while. The trouble was located at the point *A*, Fig. 1. A steam gage and a water glass gage were put on at *B*. The gage showed that for some reason, never clearly understood, the pressure in the pipe *C* was so much reduced at varying intervals that the pressure in the radiators *X X X*, which was constant, forced the water lying in the return risers and in the main return pipe over the trap seal at *A*.

This made an artificial water line in the highest of the several sections into which the system is divided, as before alluded to, notwithstanding the pressure from the equalizing pipe which was run from the steam main to the top of the trap in the usual manner.

FIG. 1. ARRANGEMENT OF HEATING SYSTEM

All sorts of devices were tried to remedy this rush of condensed steam in the return pipe, but none of them did any good until the following plan was adopted.

There were on hand an old 2-inch steam governor and a 1½-inch flanged strainer which came from an abandoned reducing valve. With these to begin with, a device was made as shown in Fig. 2, in which the balanced valve of the old governor is set by the spring plate *F* at such a point as will allow the ordinary flow of condensation to pass. Whenever the reduction of pressure in pipe *A*,

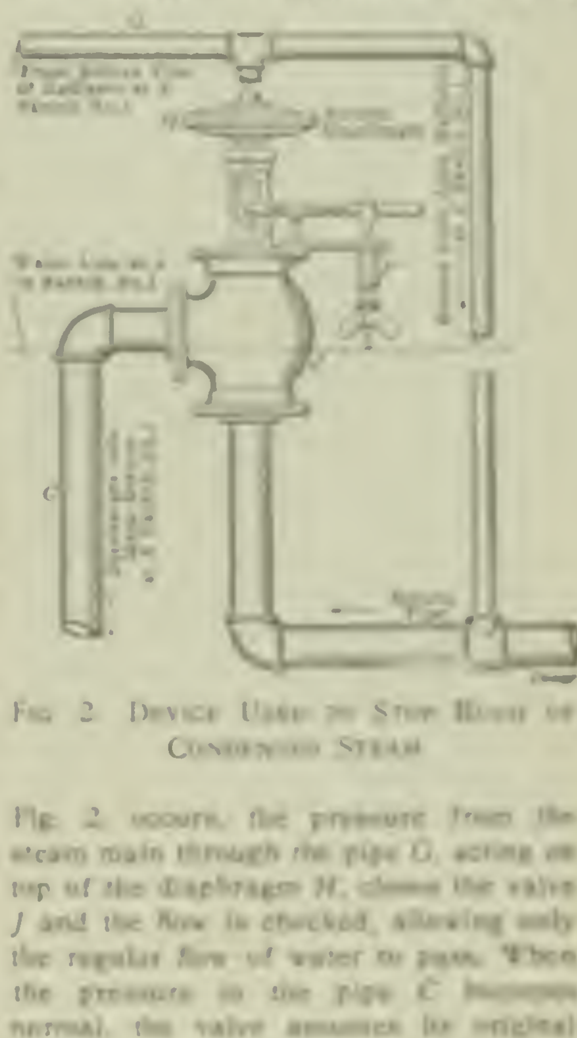

FIG. 2. DEVICE USED TO STOP RUSH OF CONDENSED STEAM

Fig. 2, occurs, the pressure from the steam main through the pipe *G*, acting on top of the diaphragm *H*, closes the valve *J* and the flow is checked, allowing only the regular flow of water to pass. When the pressure in the pipe *C* becomes normal, the valve assumes its original position and the regular flow of water continues.

There have been two of these valves in use for ten years and they have operated perfectly, the only attention required is the renewal of the rubber diaphragms once in about every third season.

I have never been able to understand just why the pressure was reduced periodically in the pipe *C* and I would like to hear from engineers having experience along this line.

T. H. De Saussure.

Milledgeville, Ga.

Simple Methods of Binding "Powers"

Each issue of POWER contains much valuable reading matter and information which ought to be preserved for reference. I have just completed a satisfactory job of binding the issues for three months in one volume. This makes a volume that can be easily handled, and a stronger and better job can be made than by making the volume of larger size.

To bind Power proceed as follows: First arrange the various copies according to their dates, and pile in three sections containing one month each. Then remove the covers and lift the ends of the binding wires and take off the advertising pages, after which turn down the ends of the wires again.

Next take the first and second issue of the first month and glue them together; then glue on the third issue and so on until the whole of the first month's issues are securely glued together. Proceed with the second and third month's issues in the same way, taking care to make as neat a job as possible.

Next take the first month's issues, which form one part of the volume and glue it to the second part, and to this glue the third part, which will complete the volume in the rough.

Then take a piece of strong cloth and cut it a size equal to the depth of the book and wide enough to stretch across the back, and lap one-half inch over on the front page and the same on the last page. Cover the cloth well with glue and stretch it across the back of the volume as tight as possible, as it is the cloth that gives strength to the volume and keeps the parts firmly held together.

Take a clean cover of Power and glue it in place, and the volume is finished. It is best to place the finished volume under a heavy weight for a few hours to allow the glue to set. The finished volume will look like an ordinary copy of Power, only it will be about one inch thick.

George E. Lambowin.

McKeesport, Penn.

Two Methods of Lacing Belts

Belts may be joined by lacing, riveting, sewing or cementing. A method of lacing a belt that may be relied upon is shown in Fig. 1.

First cut the ends of the belt square, using a sharp knife and try square. Then punch a row of holes exactly opposite each other in each end of the belt, using three holes for a 4-inch belt and five holes for a 5- and 6-inch belt. The number of holes in the row should always be uneven for the style of lacing shown.

A represents the outside of the belt and *B* the pulley side. The laces should be stretched as much as possible before using, and should be drawn half way through one of the middle holes, from the under side, as at *C*, and before proceeding see that the belt is not twisted, or, in the case of a crossed belt, that it has not been given a wrong twist. Then pass the end of the lace on the upper side of the belt through the hole *D*, under the belt and up through *E*, back again to *D* and *E*, through *F* and up through *G*. Then an incision is made in one side of the lacing which forms a barb that will prevent the end from pulling through. Then lace the other side of the belt in the same manner. This method may be used for belts up to 6 inches wide, but soft wire should be used instead of laces on belts smaller than 3 inches in width. If a lace is used on a small belt it makes

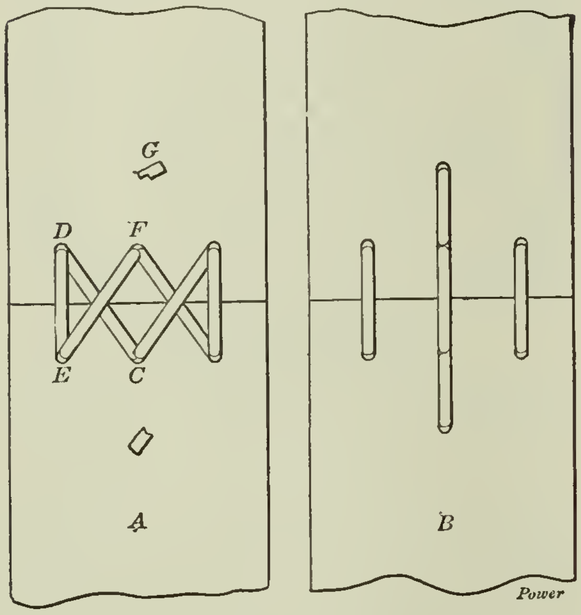

Fig. 1. A Reliable Method

the joint clumsy looking and the belt will travel unevenly over the pulley.

For belts wider than 6 inches the lacing shown in Fig. 2 is good. Two rows of holes should be punched. The number of holes in the row nearest the joint should exceed by one the number of holes in the second row. For 6-inch up to 7-inch belts I have always used four and three holes respectively. For larger belts make the total number of holes in

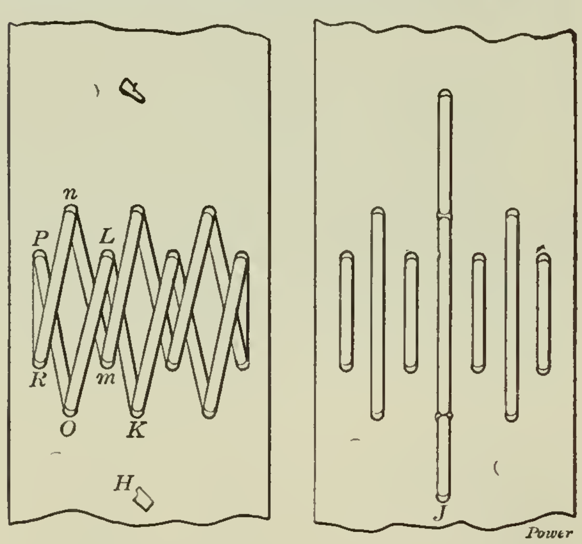

Fig. 2. Lacing for Large Belts

each end either one less, or one for each inch of belt width. I never care, with large belts, whether the number of holes near the end of the joint is odd or even. In a 10-inch belt, for example, nine and eight holes are used respectively. The outside holes of the first row should not be nearer the edge of the belt than ¾ inch, nor should the first row be nearer the joint than 1 inch. The second row should be at least 2 inches from the end of the belt. In Fig. 2, *H* is the outside and *J* the pulley side of the belt. Begin at one of the center holes, always in the outside row, as at *K*, and continue through *L*, *m*, *n*, *O*, *P*, *R*, *P*, *R*, *n*, *O*, *L*, *m*, etc.

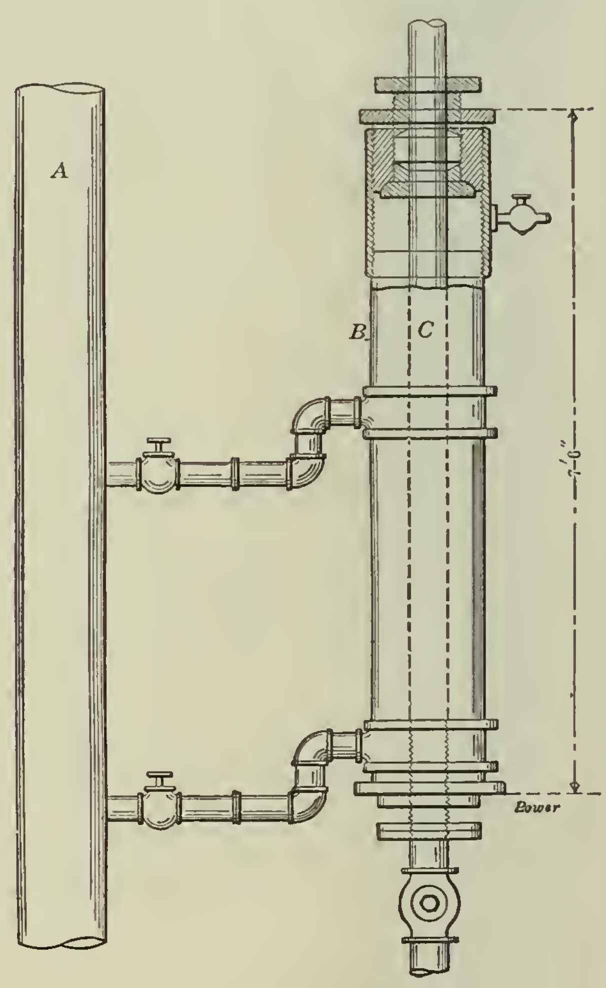
The lacing may also be started on one side instead of at the middle, and it should not be crossed on the pulley side of the belt.

William L. Keil.

Philadelphia, Penn.

Hot Water Reheater

Some time ago I had difficulty with the hot-water circulation in one of the buildings, due to the circulating pipe being placed about 6 feet below the lowest hot-water fixture, which is 12 feet below the main circulating pipe. This formed a trap and prevented the circulation of the water. There was also



Hot Water Reheater

danger that the line would freeze up in cold weather as the lower section was exposed to severe draft of cold air.

Therefore, I made a reheater on the riser pipe to the main, as shown in the accompanying sketch.

The steam is taken from a heating riser *A*, which is close by. The packing boxes of the pipe *B* are made of bushings which were filed out to fit the brass pipe *C*.

A swing check valve is placed below the reheater and at the lowest point on the brass pipe. This simple device reheats the water in the pipe *C* and establishes a satisfactory circulation.

George Peters.

New York City.

Patching a Second-hand Boiler

Some years ago the company I worked for traded their old boiler for a larger, second-hand boiler. After it was in place and all the pipe connections made, I filled it with water and built a fire, but before the boiler was warm, I noticed water dropping on the grates. Drawing the fire I found that the boiler was leaking at the first girth seam over the fire. This boiler was built, as shown in the illustration, and consisted of three sheets with single-riveted lap-joint seams. Securing a calking tool and hammer I tried to stop the leak, but was not successful.

After emptying the boiler I cut out a rivet and, holding a candle in the rivet hole, found that the under sheet was cracked in the rivet hole. Cutting out a rivet on each side of the first one, I found that the crack still extended beyond the remaining rivets. Considering this a job beyond me, I got a boilermaker to come and look over the boiler. He continued cutting out rivets until he got past the crack, which extended through twelve rivet holes.

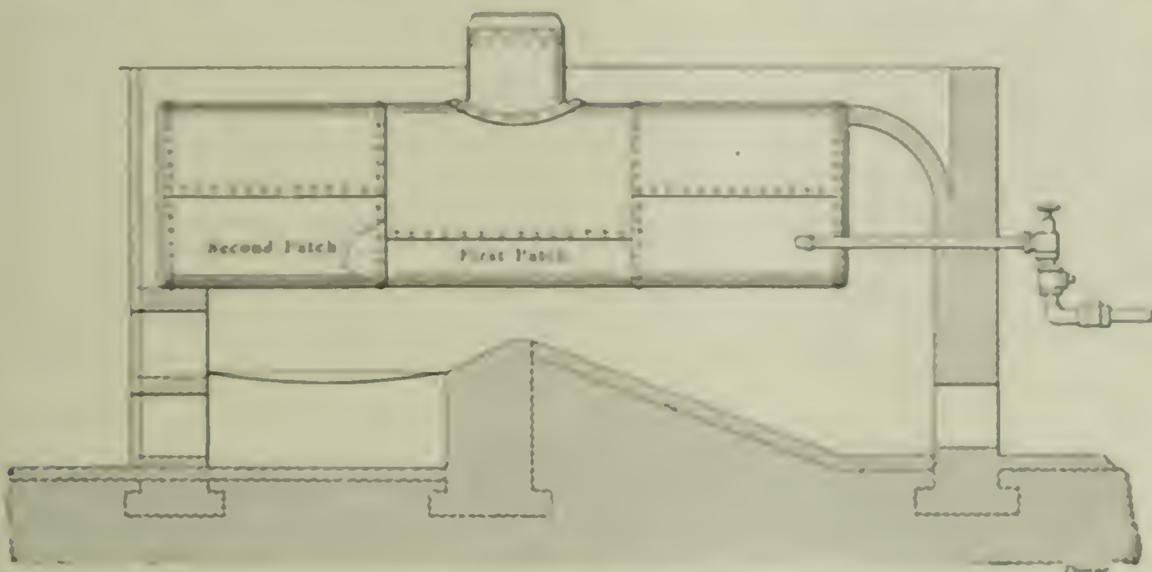
We then cut out a piece of plate back to the next girth seam, as illustrated, and put in a patch.

After this job was complete, I filled the boiler again and got up steam, when I found that the tubes were leaking at the back end. By means of a tube expander and a trip into the back end about twice a week, I managed to keep things going for a while, but I soon reached the limit with the expander as the tubes were rolled so thin that it was impossible to stop the leaks by further expanding. I also discovered that the back head was in two pieces and that there was a seam about 2½ inches above the top row of tubes. When the water level dropped below this seam, I had trouble with the tubes leaking.

It became necessary in order to keep the plant running at all to consume a lot more fuel than should have been necessary. Then the boss agreed to get a new set of tubes and I cut out the old and put in the new ones. I found it necessary, in order not to roll the new tubes too much at the back end, to insert thin strips of copper around the tubes to help fill up the holes which had previously been enlarged. After this job had been completed, there was no trouble for about 6 months.

One morning, when starting a fire, I noticed a wet spot on the firebricks but not being able to discover anything wrong I fired up, but did not neglect to keep my eye on this part of the boiler.

During the day I noticed that there was a thin spray of steam and water coming from the seam near where I had noticed the wet bricks, and at once let the steam pressure drop. I found that the first sheet was cracked through nine rivet holes. A section was cut out and a patch put on as shown. This disgusted the owner so much with second-hand boilers that he purchased a new boiler.



Patched Boiler

William G. Walters.

Stratford, Can.

The Way to Do It

Down at the big plant where they develop about 150 horsepower with 300 horsepower of boilers, with stationary grates and natural draft, they wheeled in one day a number of loads of screenings instead of the usual nut. The engineer in charge called the chief, and he in turn called Mr. Anti, the purchasing agent, who said that the screenings cost the company only the price of hauling and that they would burn them if they tried. He was taken at his word, but at about 4 o'clock in the afternoon every wheel stopped, and when the "big show" gathered at the power plant they found the engineer and fireman trying to dig out what was left of those screenings. Mr. Anti seized upon the occasion to introduce some observations with regard to the advisability of an engineer learning to fire during his apprenticeship, and how the sawmill of which he was president in the old country, never had as good coal as that. But here was where the worm turned, and the grimy engineer, wiping the sweat from his brow and handing the bar to the fireman said, "Do you know I have been figuring all the morning how to make steam with that stuff. How do you think it would work, Mr. Anti, if we were to lower the safety valve, close the quick return and feed it lightly on the crown sheet, with the crosshead wide open?" Whereupon Mr. Anti, whose dignity was sorely hurt at being led into a discussion with a common engineer, answered, "Why, any fool would have tried that at first. That's the way we used to burn it over in the old country."

A. Greenshaw.

Edmonton, Alta., Can.

Brine Foamed

When pulling ice from our tank, trouble was had with the brine foaming. The foam was very thick and resembled soap suds, and when it overflowed into the cans the water was spoiled for ice making.

Upon investigation it was found that too many cans were pulled before any were filled and put back in the tank. This allowed the brine level to fall to the top of the pipe *A* and air was drawn in at the open end, and this air caused all of the trouble.

Piping of Can Tank

Now, the men pull fewer cans at a time and there has been no more trouble with foaming brine.

Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

Steam Boiler Economy

I have noticed several articles in recent issues of POWER on the subject of flue-gas analysis and CO_2 recorders. The main object of these seems to be that of inducing engineers to write of their experiences with CO_2 recorders and of what success or failure they have had with such instruments.

In view of the fact that flue-gas analysis is almost essential to high furnace efficiency, and that the largest part of the expense of operating a plant is concentrated in the boiler room, very few engineers are making any progress in the study of saving fuel and building up furnace efficiency.

I have tried to learn from several engineers who do not use CO_2 recorders or flue-gas analyzers, just why they have never given this subject more consideration and have most of their reasons embodied in the following answers:

One engineer says that not having sufficient knowledge of the chemical composition of flue gases caused him to lose interest in the economical combustion of fuels. He took an interest in steam-engine indicators because his plant was equipped with them, and likewise was familiar with all other instruments at his disposal.

Another says that lack of training in chemistry prevents the average engineer from understanding chemical analysis and he does not like to believe anything beyond his knowledge.

Another states that apparently his furnaces are giving full efficiency and all the available heat is utilized and to purchase the necessary apparatus would be a waste of money.

Still another says that the required information on the fundamental principles of flue-gas analysis has not been obtainable in the columns of POWER or in textbooks so that the average engineer could educate himself to the point where he would be adequately qualified to handle this work. The results of several tests have been published but nothing which would aid the man unfamiliar with this work to take the necessary elementary steps toward possessing himself with the ability to economically burn the fuels and consequently reduce the coal bills by virtue of the proper use of instruments. Progress in this direction has not been as rapid as we would expect for a problem of so great importance. Good results are, however, being obtained from some of the later models and coal is being saved in appreciable quantities and if engineers would write their experiences or ask for information, thereby benefiting all interested, the chance would be lessened for readers of POWER to return answers similar to the above when approached on the subject of CO_2 recorders and the economical burning of coal in their boilers.

CHARLES M. ROGERS.

Detroit, Mich.

The editorial in the November 22 issue on CO_2 records should have the effect of awakening engineers to a sense of what their duty is in this age of advancement. The day is past when an engineer was judged by his ability to shovel coal and employers are beginning to realize that the engineer is one of the most important men in their establishment. The other branches of mechanics (with the improvements of machinery of this age) are gradually falling away and the mechanic of the past is now just a link of a great machine. With the engineer it is different, for with the improvement of machinery and with the substitution of machines for manual labor his duties are increased by the responsibility for and care and management of these machines which come under his direct charge.

It is, then, up to the engineer to meet his duties and to educate himself so that when the demand is made he will have the ability to fill the position which calls for the assumption of increased responsibilities.

The engineers of Ontario, Canada, are probably up against a harder proposition than the engineers situated in any other part of America. The transmission of electricity by the government throughout the province of Ontario brings electrical energy from Niagara into direct competition with the steam plants. It is up to the steam engineer to demonstrate his ability and compete with this new form of power. In many establishments where heat is required and where the exhaust steam can be utilized for heating purposes, if the engineer can put up any kind of a showing with the steam plant, Niagara power will never get a foothold. Many large companies, after going into the matter thoroughly and taking into consideration the fact that the climate makes it necessary to heat the buildings during about seven months of the year, have installed steam plants and are generating their own current and using the exhaust steam for heating purposes, and have demonstrated to their own satisfaction that, after taking into consideration the heating of their establishment, the ledger comes out right by a large margin in favor of the steam plant.

Now a word along the line of the editorial. It is true that the great savings in the future are to be made in the boiler room. But, as the average engineer is not very proficient as a chemist, it will require considerable agitation to get him started along that line. I have been thinking of the subject for some time and on reading the editorial I commenced to look through the advertisements, but I am unable to see what I wanted there. POWER would certainly be conferring a favor on the engineers who are interested along this line, and would draw into interest those who are not, if it would enlarge on this subject and give us a lesson along this line every week, and also intimate to the manufacturers of recording instruments that a little printer's ink used judiciously would have a tendency to increase their business. If the engineers can be awakened to take an interest in this subject and also along the line of keeping complete records in every line in the steam plant, it will certainly increase their interest in the profession, and will benefit them financially and cut down the operating expenses to such a degree that we need not be afraid to enter into competition with any new development that may enter the field of industrial progress.

W. G. WALTERS.

Stratford, Ont.

Boiler Room Emergencies

One of the most common and least dangerous emergencies in boiler-room practice is the breaking of gage glasses. With the steam rapidly escaping into the boiler room, it is only necessary that the inexperienced fireman keep his wits about him. The lower gage valve should be closed first, thus stopping the flow of water, after which it is an easy matter to close the upper valve, from which steam only is emerging. Until time can be found to renew the glass, the water level can be determined by means of the try cocks. The upper cock should show dry steam, the lower water, and the middle one steam and water. Spare glasses should be, and usually are, kept on hand for such emergencies.

Another emergency to be met is that of finding the water either too high or too low. The boiler is in no danger from high water, but a wrecked engine is liable to be the penalty for such carelessness. The remedy for high water is to blow down the boiler. This, however, is not necessary if the engine has shown no signs of getting water, and it is known that no sudden load will be thrown on. Under such a condition it is only necessary to stop the feed pump until the water is down to normal.

To suddenly discover that the glass contains no water is an emergency which calls for quick action on the part of the attendant. If it is definitely known that the glass contained water only a very short time before, and that no sudden demand for steam has been made on the boiler, which could possibly have lowered the water sufficiently to expose any of the heating surface, and that the boiler has sprung no leaks, the attendant may feel reasonably safe in opening up the feed supply and raising the water level to normal. However, if there is any doubt as to whether or not the water has reached a dangerously low level, no time should be lost. The fire should be deadened, using ashes or green coal. The damper and ashpit doors should also be closed, and the furnace doors opened. If the boiler is in a battery, the pressure on all should be lowered as much as possible without interrupting the service, after which the boiler should be cut out, cooled off and inspected for burned plates. If no signs of overheating are found, it may be fired up and placed in service.

Another emergency which calls for very quick action is the sudden discovery that the steam pressure is considerably higher than it should be. This is not liable to occur in a well kept plant, or when the boilers are in a battery, where each is protected by its own safety valve. The present practice of equipping boilers with two safety valves further limits the probability of excessive pressure.

When, from any cause, the pressure in a boiler is found to be abnormally high, the first thing to be done is to deaden the fire, thus preventing a greater rise in pressure. The practice of drawing the fires is not to be recommended as it is sure to increase the furnace temperature. The better method is to smother the fires, as for low water. No valve connected with the boiler should be touched; this especially applies to the safety valve, before the boiler pressure has dropped to normal.

Perhaps the most severe emergency to be met in the generation of steam is the rupturing of any part of the boiler. Under this condition the attendant must be governed entirely by the circumstances and surroundings. Stopping the generation of heat and increasing the water flow are the two things most essential to be done, until the pressure is sufficiently lowered and the boiler cooled.

Fort Flagler, Wash.

Trouble with Water Column

I read with a good deal of interest the short article on "Trouble with Water Column" in the November 29 number. I lately had a similar experience to that described therein. I came to the conclusion, however, that the trouble was caused by the condensation of steam in the upper part of the column which caused the pressure to fall at that point and hence the pressure in the boiler, acting on the water in the column at the bottom forced it to the top of the glass.

To anyone who has experienced trouble of the kind I would recommend the following remedy. Make a box of either sheet iron or light wood and fasten or hang it in some way to the boiler front and thus inclose the whole column leaving only the glass exposed. Then, fill the box with, say, charcoal dust. Leave the glass in connection with the boiler both at the upper and lower end during the time when the boiler is banked. When steam is again raised, the trouble will be gone.

John Zetterlund.

Eskilstuna, Sweden.

The "Trouble with Water Column" described in the article under that head in the November 29 issue was undoubtedly caused by the filling up of the lower connection with mud or sediment. In many boilers trouble is caused in this way, to a greater or less extent. Last year the water columns on my boilers began to get a little slow. They were piped with 1½-inch top and bottom connections, with a ½-inch blowoff connection under the 1½-inch cross valve. The cause of the trouble lay in the small size of the blowoff line, which would not let the water move fast enough to dislodge the mud in the lower connection when blowing off the column. I removed the ½-inch line and substituted 1½-inch pipe in its place, and connected it to the main blowoff line. With this arrangement, when I blow off the column, the water passes through the lower connection with force enough to carry off any and all sediment that has found lodgment in the column.

Exhaust Steam Regenerators

In the issue of November 8 there is an article by Charles H. Smoot under the above title. In one instance, the article seems to contain an inaccuracy. In the last column on page 1983 the statement is made that the efficiency of a well designed injector for boiler-feed purposes does not exceed 20 per cent.

When an injector is used only to lift water and the heat put into the water by the steam passing through the injector is wasted, it may be true that the efficiency cannot exceed 20 per cent. But when an injector handles boiler feed, all of the heat imparted to the water goes back into the boiler. In such cases the efficiency is very high, possibly 98 or 99 per cent. It seems to me that the set of similar conditions surrounding the use of the injector principle in a regenerator would permit a high efficiency to be obtained.

Karl [illegible]

Lowell, Mass.

Water Gage Connections

With regard to Mr. McGahey's letter in the December 13 number, I believe that I am right when I say that fully 90 per cent. of the engineers favor valves placed in the water-column connections. It has been said that a careless boiler attendant might close one of the valves for some reason and forget to open it again. Just so a careless boiler attendant might do any of a hundred other possible things, but it is the duty of the head to see that no careless boiler attendant is allowed on the job.

James E. Noble.

Toronto, Ont.

Experience of an Indicator Man

In the December 6 issue of Power, W. E. Hopkins makes a few comments on how easy it would be to get an even cut-off on a corliss engine, by stating that if the cutoff was equal, both steam valves would stop cutting off at once. Does he not know that if the dashpots both raised to the same height before cutoff took place that the engine would have the late cutoff at the head end? Mr. Hopkins certainly knows that the piston of any reciprocating engine travels faster in either direction in the head end of the cylinder than in the corresponding position in the crank end, after the crank pin is past the quarter mark on the crank-end side; and a thinking man can easily see that the steam valve on the crank end would have to remain open longer to get a steam line equal to the head-end steam line. The only way to secure this longer interval is to have the pot lift higher before cutoff takes place.

Emmetsburg, Iowa.

Installing Globe Valves

For a number of weeks past there has been a discussion on in the columns of Power as to the proper method of installing a globe or an angle valve.

For several reasons, the chief of which is that I believe it to be the only safe method, I am strongly in favor of having the pressure come under the disk, tending to open the valve and throwing the stress of the steam pressure on the threads of the stem, when the valve is closed.

About ten years ago I witnessed an incident which came near being an accident, and which convinced me of the danger of having the pressure come over the disk.

In the plant of which I am now in charge we had at that time six horizontal return-tubular boilers, all 66 inches in diameter. Nos. 1 and 2 were lap-joint iron boilers 15 feet long; the other four were lap-joint steel boilers 18 feet long. All of these boilers were fitted with 5-inch lever safety valves on the front nozzles, and 5-inch angle stop valves on risers from the rear nozzles. The stop valves were placed with the stems horizontal and the boiler pressure came above the disk, tending to hold it to its seat.

On No. 1 boiler the safety-valve lever was turned toward No. 2 boiler and reached nearly half way over the setting. There was a 1¼-inch steam pipe which came down between the front of boilers Nos. 1 and 2 and passed horizontally close to the end of the No. 1 safety-valve lever. This pipe was used for tube blowing and the steam blowers under the grates.

Now, we have great difficulty, out in the country here, in getting good men for night watching and boiler tending. Nobody wants the job at any price; we have almost to beg men to take the job. Importing men from the neighboring city is a dead failure; about three days is the average city man's stop on the job. Nothing doing, you know; and they come and tell you, "It's too lonesome here," and can they get their pay? So, generally, our night help on the boilers is pretty poor. At the particular time to which I am referring, our night men were particularly thick in the head.

One morning in January, 1900, the man on the fires in some way or other got the 1¼-inch blower pipe moved or sprung over the end of the No. 1 safety-valve lever, thus holding the valve tightly to its seat. The Nos. 1 and 2 boilers had been banked during the night and the stop valves closed. When the watchman had raised the pressure in these boilers to equal that in the line, he opened the stop valves, or supposed that he did, and as it was cold he started to build up some pretty big fires.

These two boilers were 20 years old and insured for 90 pounds pressure. They had had considerable repair work done on them at one time and another and were not considered to be very safe for pressures over 100 pounds. It was lucky indeed that the master mechanic, who had charge of the boilers at that time, got down earlier than usual that morning. When he got into the boiler house, the watchman told him that the No. 1 pressure gage was out of order; the pointer was loose, he thought. It was a 150-pound gage and when the master mechanic looked at it the pointer was where the 155-pound mark would have been if the scale had extended that high. He got a ladder to get at the gage, and then noticed that the pointer was vibrating stiffly and was evidently tight on the spindle. Just then his eye caught sight of the pipe over the safety-valve lever and he jumped up and tried the stop valve. From the feel of the valve he concluded that the disk was off the stem and that the boiler pressure was holding the valve closed. Then, he got excited and jumped for the safety valve, sat on the lever and sprung the steam pipe free and then got off and let her blow. She did; considerable. No, there was no water hammer, and the boiler did not go through the roof. It stayed right where it was and blew down to the regular pressure in a commonplace but noisy manner.

The fire was drawn, the pressure reduced and the valve bonnet removed. The disk had pulled off the stem, the stem collar pulling through the nut.

Now, if this valve had been put on the "other end to" with the boiler pressure under the disk, there would have been no dangerous trouble at all. It would not have been necessary to shut down the boiler to fix the valve at that time; it could have been left for a more convenient time. Of course, the stop valve was not responsible for the blocking of the safety valve; it was merely a coincidence that the safety valve was useless when badly needed. That steam pipe was moved before noon that day. All the stop valves on the other five boilers lost their disks in the same way a number of times after this, but as the safety valves worked, nothing exciting or dangerous happened.

As soon as I was given charge, I had all of these valves turned so as to bring the boiler pressure under the disks; and I never had any trouble with them. The No. 1 boiler was apparently not hurt by its experience of high pressure, for we ran it hard for four and a half years after the occurrence until the insurance company lowered the pressure to 50 pounds. Boilers Nos. 1 and 2 were replaced in November, 1904, with two 72-inch by 17-foot butt-joint steel boilers of the same make. The old boilers were 25 years old when replaced, and were cut up right away. We never sold an old boiler, as a boiler; it was always cut up for junk; if it was not safe for us, it certainly was not safe for anybody else.

Now, a globe or an angle valve with the pressure under the disk may fail in two ways. The threads on the stem or in the bonnet may strip, or the disk may split in two. In either case the valve would be open for the passage of steam and if the disk is whole and only the threads stripped, the valve may be closed by means of a lever over the top of the stem; the steam pressure will open it again when the lever is released.

When the pressure is over the disk, the valve may fail by stripping the stem or bonnet threads, by the stem pulling in two or by the disk coming off the stem, caused either by the stem collar pulling through the retaining nut or by the threads of this nut stripping or the nut backing out. In all of these cases of failure the valve would be closed to the passage of steam, and it would be impossible to open it under pressure except in the one case of the stem or bonnet threads stripping, in which case the valve may be opened by means of a lever under a collar or lathe dog on the valve stem. However, when the pressure comes over the disk, 75 per cent. of the failures are caused by the disk in some way coming loose from the stem.

In the December 13 number of Power, J. W. Parker speaks of two throttle valves in which water hammer had upset the stems, and says that he advised reversing the valves. I do not think that this advice was good, for if the water hammer was severe enough to upset the valve stems when acting from under the disk it would quickly drive the disk off the stems if it acted on the top of the disks, and then the valve could not be opened at all and he would be in a worse fix than the upset stems put him.

The inspection department of the Factory Mutual Fire Insurance Company would quickly make him change the fire-pump throttle so as to bring the pressure under the disk. They will not accept a gate valve on a fire-pump steam line; it must be a globe or an angle valve with the boiler pressure under the disk.

As to feed valves, they should be placed so that the feed-pump pressure comes under the disk, and an extra valve should be placed between the check valve and the boiler so that the check valve can be reground or the feed valve repacked while steam is on the boiler.

Never place a valve on the feed line in such a way that if the disk comes loose the pump pressure will close the valve and obstruct the feed line.

Angle blow-down valves may be the one exception that goes to prove the general rule, but in all other cases I want the pressure to come under the disk of a globe or an angle valve. Blow-down valves are constructed so as to protect the seating surfaces of the valve body and disk, and the position the valve is placed in depends a great deal on the method used to protect the seats from the cutting action of boiler scale. I heard of a case in one plant where they had lots of trouble getting the water out of a boiler, owing to the blow-down valve plug or disk coming off the stem.

BENJAMIN S. HANSON.

Broad Brook, Conn.

Liquid Discharging Device

Mr. Pagett's description of his invention for discharging liquids from barrels looks very much like a device that I made some years ago, to empty oil from barrels to the shop tank, only he has not given a very necessary dimension, that is, the size of the air inlet.

In making my device I figured on using 80 pounds air pressure, but as I did not think a barrel would stand that pressure I reduced the inlet for the air to 0.03 of an inch in diameter, figuring that the oil would run out of the 1-inch exhaust pipe fast enough to keep down the pressure, which it did, and the thing worked fine. I used it in the shop for several months, until one day the helper whose duty it was to look after the oil used it in a barrel of lard oil that was chilled. He put in the device and turned on the air and in just a minute the lard oil was all over the floor and the helper looked as though he was suffering from shock; I know that I was.

I have never seen my device from that day. It may have gone West. I would advise anyone who wants to use Mr. Pagett's invention to see that the inlet hole is something less than 0.03 of an inch in diameter for 80 pounds pressure and that there is a safety valve on the job.

J. J. SEIBERT.

Washington, D. C.

The Expansion Valve

In looking over the October 25 number of POWER, I came across an article by Mr. Reynolds in criticism of an article, in the August 30 number by Mr. Nash, regarding the expansion valve.

In reading the two articles one would conclude either that one of the gentlemen is not posted or that expansion valves differ greatly.

I will not attempt to tell anything about Mr. Nash's expansion valve nor yet about the one operated by Mr. Reynolds, but will tell you about one which I have in connection with an absorption machine which I am operating at present.

The best way of which I know to describe the action of ammonia in the brine cooler is to compare it to the well known action of water in a steam boiler, both under operating conditions. In fact, from a mere verbal description of a brine cooler and steam boiler it would be very difficult to distinguish one from the other.

By way of comparison, I will say that a steam boiler is a cylindrical shell with tubes or pipes extending from end to end and so is a brine cooler, though the pipes in the brine cooler are formed into coils.

The boiler is partly filled with liquid (water) and the remaining space is filled with gas (or steam).

The brine cooler is partly filled with liquid ammonia and the remaining space with ammonia gas. In the steam boiler part of the heat in the flue gases which traverse the tubes is absorbed by the water, a part of which passes into steam.

In the brine cooler part of the heat in the warm brine which traverses the tubes is absorbed by the liquid ammonia, a part of which passes into ammonia gas.

In the boiler the temperature of the flue gases is lowered and the water would soon cease to boil or give off steam if more heat was not supplied by replenishing the fire.

In the brine cooler the temperature of the brine is lowered and the ammonia would soon cease to boil or give off gas if more heat was not supplied in the form of more warm brine.

Water is a great absorber of heat. In fact, it comes pretty near holding the record. Its value as a heat absorber is due to its latent heat, that is, the amount of heat necessary to change it from the liquid to the gaseous state.

Ammonia owes its value as a heat absorber (or as a refrigerating medium) to its latent heat, which is the amount of heat necessary to change it from a liquid to a gaseous state.

A boiler filled with steam would absorb very little heat compared to what it would absorb if partly filled with water, and a brine cooler filled with ammonia gas would absorb only a small per cent. of the heat which it would if partly filled with liquid anhydrous ammonia.

If Mr. Reynolds will fill a test flask about half full of liquid anhydrous ammonia and expose it to the air, he will notice that the flask will frost from the bottom up to the liquid level, which goes to prove that the liquid absorbs the heat. For, if the gas absorbed the heat, it would frost from the liquid level to the top.

Now, to return to my expansion valve: only liquid ammonia ever passes through it, in the form of a coarse spray, and such is the case with all the expansion valves with which I have had any experience (with one exception). The exception was in connection with an air refrigerating machine where the refrigerating agent is not liquefied.

As a matter of fact, I keep my brine cooler two-thirds full of liquid anhydrous ammonia at all times. The expansion valve controls the amount of liquid fed but it has nothing whatever to do with the rate of expansion. That is controlled by the amount of heat supplied or, in other words, by the temperature of the brine, just as the steaming of the boiler is controlled within certain limits by the temperature of the fire and not by the feed pump or injector.

My brine cooler is fitted with gages which enable me to tell to a nicety just how much liquid ammonia I am carrying.

I often shut down with the brine cooler three-fourths full of liquid anhydrous ammonia, and in starting up only open the cold-gas valve between cooler and absorber and run this way until the liquid level in the cooler is somewhat lowered. I have often noticed that when running in this way with the expansion valve closed, the brine cools even faster than after the so called expansion valve is opened.

There has been considerable talk during the past few years about the "flooded system." It seems to me that a brine cooler operated in this way constitutes the important part of an ideal flooded system.

FRANK MIDDLETON.

Sedalia, Mo.

Underground Pipe Covering

Some years ago I was called upon to devise some means of protecting an underground steam pipe similar to that mentioned by W. P. C. in POWER for December 13. The pipe was 4 inches in diameter and carried steam at 90 pounds pressure. The pipe was about 200 feet long and up to the time of my investigation had been laid in a box made of planks and filled with ashes or other material that would form a suitable insulation. Trouble had been experienced and the pipe had to be taken up for repairs about every 3 to 8 months.

At times the trench would nearly fill with water; this caused condensation to take place so rapidly that a very severe water hammer was the result, especially when the steam was shut off, or when first turned on.

After looking the situation over, I selected some old 6-inch wrought-iron pipe with screwed joints. This pipe was connected up and tested with steam at about 20 pounds pressure, which was left on for an hour, so that we could be sure that no leaks existed. We then placed the 4-inch pipe inside the 6-inch and laid it in the box formerly used, packing ashes solidly about the 6-inch pipe. A trench just wide enough to accommodate the box was then made. A space of about 8 inches was left underneath the box, which rested on supports spaced about 10 feet apart.

One end of the 6-inch pipe was closed tightly about the 4-inch and the other end loosely so. This prevented a circulation of the inclosed air and formed a very satisfactory insulation. The entire arrangement proved so effective that I never heard from it afterward.

In many cases of underground steam-pipe work the trench is dug with a pitch toward one or both ends, for the purpose of draining the water into a catch basin, which is arranged with a float to automatically control a siphon or steam pump to remove the water. In some cases the float is connected to a signal which serves to call the attention of the person who has been assigned to the duty of controlling the water in the basin.

H. S. Brown.

New York City.

I noticed on the page of "Inquiries of General Interest," in the December 13 issue, a question by W. P. C. in regard to insulation for underground steam pipe.

It is the general practice among steam-distributing companies to insulate the pipe with a 4-inch thick wood covering, the inside diameter of which is 2 inches larger than that of the pipe.

The inside of the covering is lined with tin, and the outside is given a coat of asphaltum and tar paper to make it waterproof. This is laid on about 6 inches of broken stone in a perfectly drained trench, which is back filled with cinders.

If W. P. C. follows the above suggestions he will have a very satisfactory and efficient job. He will also realize a saving in fuel, for the loss by condensation will be less than with his present arrangement.

Fred. Glass.

Chicago, Ill.

Federal Laws

In the December 6 issue of Power, F. E. Albrecht cites his experience with license laws and adds that "he wishes he had let license laws alone and not bothered his head about them."

I would like to draw Mr. Albrecht's attention to the first-page editorials of Power for November 22 and December 13; they might help some. Also, I wish to point out the fact that engineers in other license districts and towns have had much the same experiences before getting satisfactory results with the license laws.

Apparently, if Mr. Albrecht and his associates had turned their efforts and money to use in getting a Federal license law started or passed, they might have secured some benefit for themselves and their Eastern brothers at the same time.

A good Federal law would do away with all conditions such as those of which Mr. Albrecht complains and, in addition, would place all engineers on an equal footing, both East and West.

There is a law providing for Federal inspection of locomotive boilers, up for consideration by Congress now. What were the various engineers' associations doing when that law was being drafted? Why did they not get busy and have that law extended to cover all stationary boilers within the United States and colonies?

Practically the same men could take care of the inspection work, and I am sure that there is greater need of Federal inspection of stationary boilers than there is of locomotive boilers. The latter are all overhauled and practically rebuilt every year, in the railroad shops, while stationary boilers are kept on operation just as long as they will hold steam and water, and are often operated for months at a time without ever being opened. Yet, there are thousands of lives in danger from explosions in stationary plants for every one in danger from locomotive-boiler explosions, to say nothing of the vast amount of property.

I am not decrying the bill; we need it, but it is only half a bill, only a waste of valuable time and money unless it is extended to include stationary boilers and made a partner to a measure providing for the proper examining and licensing of stationary operating engineers.

Why is it that we do not see or hear more about Federal license laws?

I have been talking and advocating them for five years, trying to get engineers and other men interested in pushing a Federal license law. But, while everyone agrees that it is what we should have, none seem to want to start it going or to help start it. Who started the locomotive boiler-inspection law? Locomotives have been operating in this country almost as long as stationary engines with no law to control them except the railroad rules, while the stationary engine has always been more or less controlled for years.

Wake up, brothers, and get to work; look a little further ahead than your own nose. When you think of a license law do not stop with the boundary line of your State, but reach out; try to help the man out West and down South. In other words, work for the good of all the engineers in this country, not for the few located just in your own town or State.

If every engineer in this country will do his share in this, we can have a Federal law so close on the heels of that locomotive boiler-inspection law that it will scare it. Think it over and act.

A. A. Blanchard.

Boiler and Tube Failures

In reference to the numerous articles on boiler explosions and with especial reference to those on a boiler-tube failure, pages 2128 and 2131, in the issue of November 29, it may be pertinent to inquire whether the reduced thickness from No. 10 gage to nearly 1/32 of an inch at the point of rupture was due to an initial defect in construction, or to internal or external corrosion. If to one or both of the last two, which was the greater inducer, and why? It has been for many years my belief that if we could unite copper with iron and steel after the manner in which gold-plated ware is made on a commercial basis, which I think may be done, the product might be good for boiler shells, tubes, steam and other pipes, etc.

Possibly this might be done to some extent in the manufacture of seamless tubes, and tend to increase the efficiency in economy in steam plants. While the days of the all-copper fire box, staybolts, etc., are doubtlessly past, maybe that copper-plated ones may supersede the ones at present in use. Though much has been said and written by professors and theorists on the forms, construction operation and explosions of boilers and the relative effects of punched, drilled and reamed rivet holes; lap and butt joints, single- double- and triple-riveted, as compared with the initial sheet before being bent and formed, but little has been said of the effects of the strains set up by the forming process. If anything has been said in condemnation of the location of the seams joining the upper to the lower half of the sheets of horizontal boilers, I have yet to learn of it. Why is this seam universally regarded as being the weakest part of the boiler shell situated at a line naturally subjected to the greatest amount of frictional effects by reason of the active elevation of the surface of the water and also the point most susceptible to the effects of corrosion?

Would not these considerations then lead us to the logical conclusion that, if but a single line of joint be used, it should be placed in a position least subject to these effects—at the very bottom of the boiler—even though it would there be subject to strains due to the weight of the water in addition to the pressure to which the upper half of the circumference is subject?

If a diagrammatic chart were constructed of a boiler made practically perfect in all its parts as now constructed and operated; depicting its changes at numerous equidistant points circumferentially and longitudinally; from the first application of heat and at regular points in the increase of the rate of heat absorbed, up to the working pressure desired, when at rest and operating the motor, I think the chart would be curious and, possibly, instructive. If applied also to individual tubes and heads in like manner, probably even still more curious effects would be shown, many parts are fatigued, like overworked men, while others have comparatively easy times.

Overpressure on an Old Boiler

In the Pittsfield boiler explosion is the first instance of an explosion of a boiler which was entirely under the jurisdiction of the Massachusetts district police, and it should not be difficult to place the responsibility for this calamity.

In all of the preceding explosions since the inspection laws of this State went into effect, the boilers have been insured by some commercial inspection and insurance company, and the State inspectors have had little to do with them beyond the examination of reports filed at the State house.

In this instance the boiler was examined by a State official who fixed its operating conditions. A man also examined by a State official was given permission to operate boilers and engines on the supposition that he was duly qualified for such work.

This safe boiler was put in the hands of the qualified man and exploded, on the very first day of its service, snuffing out the lives of twenty human beings.

It is not known what pressure caused the calamity, nor is it possible to approximately estimate it, but it is probable that it was far in excess of that fixed by the inspector. The boiler may have been safe for the pressure allowed, but it is highly probable that the pressure was carried beyond the safe limit by a misunderstanding on the part of the man of the paramount importance of the fact that safety valves and pressure gages should agree.

Profit Sharing Plan of the Brooklyn Edison Company

The recent action of the Brooklyn Edison Company in announcing a profit-sharing and pension system has evoked both favorable and adverse criticism; the optimist regards it as a substantial recognition of the employee's right to share in the profits of labor, while the pessimist can see in it only a scheme to keep the men in a state of virtual serfdom under the guise of pretended benevolence. In spite of whatever grounds these extremists may find for basing their contentions, the plan is to be commended more than condemned.

The avowed purpose of the plan as set forth in the company's announcement to its employees is "a recognition of faithful and efficient service and the encouragement of thrift and investment in the securities of the company." Reading between the lines shows the first part of this statement to be a purely business proposition: the company in return for a bonus expects to receive better service, to make the employees feel a personal interest in the company, thereby eliminating one great source of waste, and to retain their employees for longer periods of time, in this way doing away with the bother and loss in efficiency through continually breaking in new men.

The terms stipulate that those who have been with the company two full years shall receive a percentage of their wages for 1910 equal to one-fourth of the rate of dividends paid on the capital stock of the company during the past year; those who have been with the company three, four and five years shall receive, respectively, one-half, three-fourths and the full rate of dividend. This money, however, cannot be withdrawn by the employee within three years, except in special cases; but instead is deposited to his credit with the Brooklyn Edison Investment Fund, he receiving only the interest upon the dividend. Expressed in dollars and cents this would be as follows:

Assume that a fireman has been in the employ of the company for three years. His wages amount to $910 per year and if the rate of interest on the capital stock is eight per cent. (a fair estimate based upon the figures of past years), his share of the profits would be $36.40, but as this is turned over to the Investment Fund, he would receive only the interest which, at five per cent., would amount to $1.82 one year from this January. A watch engineer under the same length of service would have $58.24 placed to his credit and would receive $2.91. At the expiration of six years of service the fireman would be entitled to withdraw $163.80 and still have $72.80 to his credit, which latter sum he would receive annually thereafter. This would be equivalent to an increase in weekly wages of $1.40.

Although these figures may appear insignificant, their fairness, after five years of service, cannot be questioned. If a man's labor be considered as part of the working capital of the company, and providing he receives equitable wages, his share in the profits is obviously a percentage of his yearly wages equal to the rate of dividend paid on the capital stock of the company.

Flywheel Rims

It may not be too late to suggest that there is still room for improvement in the design and construction of the rims of large flywheels. That there has been progress in the past ten years is generally admitted, but there still seems to be a lack of knowledge on the part of some builders, of the essential weakness of the old-fashioned joint for wheel rims.

That this weakness is not confined to flange joints is evidenced by the sample of a large wheel on the engine of a plate mill which was examined some years ago and found to have a safety factor of only two. That is, an increase in speed of about 40 per cent. would have wrecked the wheel. This engine and its flywheel were built by a firm of national reputation and were in other respects of a high standard of workmanship, but the keyed joints of the wheel rim had only a small fraction of the strength of the rim itself.

In order to clear up any misunderstanding on this important feature of engine design, it may be well to state a few facts which have been determined partly by calculation but largely by direct experiment on smaller wheels.

A thin, comparatively wide, cast-iron rim such as is used on belt wheels, is subjected when in motion to tension along its circumference caused by the centrifugal force, just as a boiler shell is subjected to tension due to the internal pressure.

If the rim is unrestrained by the arms, as is the case in some wheels having the arms free to slip in the rim sockets, this tension in pounds per square inch of rim section will be expressed very nearly by the fraction, $v^2 \div 10$, for cast iron, where v is the rim velocity in feet per second.

Assuming the tensile strength of soft, gray iron to be 16,000 pounds per square inch, $v^2 \div 10$ would equal 16,000, and v would equal 400 feet per second, the bursting velocity.

Numerous experiments have verified this conclusion and have further shown that in wheels with whole rims, as ordinarily designed, the influence of the arms is negligible. The effect of arms which rigidly connect hub and rim is to restrain the rim from expanding, cause it to assume a wavy outline and to induce contrary bending moments at the arms and at points midway between the arms. This action causes stresses of tension, compression and shear which combine with the tension already existing to produce complicated resultant stresses. These are further complicated by the stretch of the arms themselves and by the initial stresses due to cooling strains. An ordinary cast-iron pulley having six or more arms will, however, burst at about the speed above indicated.

The introduction of rim joints changes all this, especially if the joints are between the arms. The addition of flanges or bosses and the introduction of heavy bolts or links for fastenings very much increase the local centrifugal force and therefore increase the bending moment at that point.

It is as if we had a plate girder, spanning a gap between two abutments and designed to carry a certain uniform load, and should proceed to cut it in two at the center, fasten it together by bolts located near the top flange and then put a large concentrated load at the point of weakness. We would naturally expect failure.

To illustrate the enormous force sometimes exerted by concentrated weights, we may consider a wheel twenty feet in diameter running at two hundred revolutions per minute or about one-half its bursting speed. The centrifugal force of a one-pound bolt in the rim at this speed would be about one hundred and forty pounds. A cast-iron double flange on such a wheel might weigh two or three hundred pounds and would exert a pressure of fifteen or twenty tons tending to rupture the joint.

For the same reason, balance weights inside the rims of high-speed pulleys are always a source of danger.

Experiments have shown that wheels having flange joints between the arms sometimes burst at less than half the speed attained by whole-rim wheels.

Now, whatever factor of safety is adopted in determining the safe speed of such wheels, this fact must be remembered:

A flywheel requires a certain interval of time to attain a dangerous speed and the larger this interval, the better for all parties concerned.

The racing of a flywheel is usually due to temporary disarrangement of the governor and depends upon the difference between the full energy of the steam and the load which the engine happens to be carrying at the time. If the flywheel is so designed that the bursting speed is three times the normal, there will ordinarily be ample time to close the throttle and prevent an accident.

Furthermore, it is known that air resistance and friction are considerable at high speeds and exert a marked retarding effect. If a wheel has radial ribs upon the faces of arms or rim the air resistances may be sufficient to prevent the attainment of dangerous speed.

Granted that any wheel will burst at some speed, it must be admitted that the wider the margin between the normal and the bursting speeds, the less the danger of accident.

It requires less courage to close the throttle when the engineer knows there is a respectable factor of safety in his flywheel.

Graft

The frank expression of such opinions as that of Amos Skeg in our issue of December 20, to the effect that "sales people and not the engineer or the employer are the ones to benefit by a too critical view of what constitutes a bribe," is not calculated to accelerate the movement for the abolition of graft. The picture of an employer conspiring with his engineer to get more out of the seller of supplies than the face of the bill calls for is not flattering to the employer and is degrading to the employee, who, to put it in its most charitable light, has received his master's permission to accept tips like any menial.

Where are the high ideals of the professional engineer?

No Boiler Explosions in Montana

Although last year was one of the most disastrous in the matter of boiler explosions, Montana's record shines out bright and clear, for during the entire twelve months not a single boiler explosion occurred. J. H. Bailey, State boiler inspector, is proud of this record. During the year three inspectors traveled 23,306 miles to examine internally and externally 2021 boilers.

In those inspections 2382 defects were noted, 1819 of which were considered dangerous, and suitable repairs were ordered made. Eleven boilers and seven mud drums were condemned as unfit for further service and pressure was reduced on 43 boilers.

The man who mistakes a mark on the gage glass for the water line, can be classed with the man who knocked the milk pitcher off the table, mistaking it for the cat, or tried to hang his coat on a nail only to find that it was a housefly.

The average man refuses to buy a clay pipe with a piece broken off the stem, but breaks off the stem to suit himself. This seems to be the case with the engineer who buys nicely finished brass unions and mars them all up with a stilson wrench.

Do not be hasty in prophesying failure, as things are sometimes practical that do not look so. It is often easier to make a thing work than to try to convince your boss to the contrary.

The engineer gets into trouble with two kinds of appliances: one is imperfect, and sticks; the other is too perfect, and sticks.

Reliability of both men and machines consists in their working when your back is turned.

Boiler Explosion in Pittsfield, Mass.

By F. L. Johnson

An incorrect steam gage leads to screwing down on the safety valve, causing an overpressure, which blew the boiler into more than fifty pieces, some of them no bigger than a man's hand, and threw pieces of boiler and engine weighing hundreds of pounds an eighth of a mile.

The Morewood Ice Company's plant at Pittsfield, Mass., was the scene of a disastrous boiler explosion at 9:45 on the morning of December 29, when 12 men were instantly killed and 20 or more injured, 5 of whom died later. The boiler was of the locomotive type surmounted by a 10x18-inch slide-valve engine which was scattered with parts of the boiler in all directions.

The barrel of the boiler was 36 inches in diameter, built in two courses of [illegible]-inch charcoal-iron plates, and was 7 feet between the heads, in which there were fifty-three 2[illegible]-inch tubes. Both the longitudinal and round-about seams were double riveted. The fire box, water leg and crown sheet were slightly over 5/16 inch thick. The crown sheet was supported by crown bars and the sides were supported by [illegible]-inch staybolts, pitched 4[illegible] inches.

During its many years of service, the fire-box portion had been subjected to a varied course of repairs, one being a strip of [illegible]-inch steel plate going around three sides.

As near as can be learned, the boiler was approximately 40 years old and had been in intermittent service in various parts of the State from Holyoke to Pittsfield. It was picked up at a bargain four years ago at Springfield, near where it had passed several years doing duty in a small sawmill and had carried a working pressure of 125 pounds. During the ice harvest the boiler was used from 10 days to two weeks and lay idle the rest of the year. There were in the boiler house when the explosion took place about 20 men, not one of whom is alive to give any information of what was going on immediately before the failure. It is reported that the boiler was inspected last March by one of the Massachusetts State inspectors who ordered some minor repairs and fixed the working pressure at 70 pounds, and ordered the purchase of a new steam gage and safety valve.

Fig. 1. Main Part of Fire Box

In accordance with the orders of the State inspector the repairs and changes suggested when the boiler was inspected in March were made before the boiler was put under steam. These consisted of a new water glass, a [illegible]-inch steam-gage connection conforming to the rules of the Board of Boiler Rules, a new steam gage and a new safety valve. Also a thorough cleaning of all bricks, dirt and ashes from inside and around the fire box.

Steam was raised for the first time this season on the day before the explosion, and the safety valve blew when the steam gage indicated a pressure of only 35 pounds. The tension on the valve spring was increased and the gage taken to a local plumber for testing and repairs, after which it was replaced on the boiler.

One man who had left the boiler house just before the failure reported that the gage showed a pressure of 40 pounds when he left and that steam was blowing from several places about the boiler.

Fig. 2. Cylinder of Engine

It was not a lap-seam failure and with the exception of the single riveted joint at the smoke-box end, nearly all of the ruptures tore through solid metal. It was not a case of tearing along the lines of least resistance but more as if the explosion was caused by a charge of dynamite.

Some slight idea of the force expended may be gathered from a study of the direction of and the distance to which various parts of the boiler and engine were thrown. The fire box was torn from the barrel and, like a pasteboard box, crushed and hurled backward against a corner of one of the ice houses, while the engine cylinder sailed off to one side, landing about 200 yards away on the hill side, dropping the piston and slide valve on the way. One side of the fire box and a part of the head landed diagonally about 100 feet away. The middle course, with rags of iron torn from the fire box, went nearly 500 feet in a direction opposite to that taken by the engine cylinder, cutting off the tops of several trees on its way.

About 50 feet in front of the boiler were two trees growing closely together, between which the flywheel end of the crank shaft dropped on its course southward. The other end of the shaft, with the connecting rod and the crosshead from which the piston rod had been pulled, shearing the 2[illegible]-inch taper key, fell about 25 feet to one side. The front course was torn from the head and fell in several pieces quite near, while the front head went fully 100 feet directly forward.

The safety valve, which was found about 50 feet away, was taken by the chief of police to one of the plants of the Pittsfield Electric Company, where it was

FIG. 3. MIDDLE COURSE THROWN 500 FEET

FIG. 4. PART OF MIDDLE COURSE WITH PART OF WATER LEG

subjected to a pressure of 154 pounds per square inch, which failed to open it. No additional pressure was put on the valve at this time. Later it was taken to the laboratory of the Stanley works, where it was subjected to a dead-weight test of 161 pounds without opening. It was finally forced open by the application of a water pressure of 225 pounds after which it popped repeatedly at pressures ranging from 210 to 220 pounds.

While the failure was almost instantaneous in all parts of the boiler, it is probable that the initial rupture started in one of the water-leg sheets where the feed-water pipe entered, as near this point the metal was eaten away to about one-third of its original thickness. There was no evidence of low water and the fusible plug taken from the crown sheet is in good condition. It was a case of overpressure caused by an incorrect steam gage which led to the screwing down on the spring of the safety valve.

Proportion of Nitrogen in Flue Gas

BY JULIAN C. SMALLWOOD

In view of the occasional publication of improbable, if not impossible, results from flue-gas analyses as made from apparatus such as the Orsat, it seems worth while to call attention to the significance of the proportion of nitrogen. The amount of this constituent of flue gas, in the case of coal combustion, is always nearly 80 per cent. if the accompanying results are valid. The reasons for this are as follows:

The proportion, by volume, of the oxygen to the nitrogen in the atmosphere is approximately 21 to 79. If pure carbon were used in the furnace, no matter how much air were admitted, these same proportions of oxygen to nitrogen would be found in the flue gas. For example: if just enough air for complete combustion were used and if, under these circumstances, the combustion were complete, the reaction would be

$$79\ N_2 + 21\ O_2 + 21\ C = 21\ CO_2 + 79\ N_2,$$

the right-hand member representing the flue gas, in which there are twenty-one molecules (that is, volumes) of oxygen, in the CO_2, as in the air.

The effect of the nitrogen, oxygen and hydrogen in the coal actually burned is to alter the proportion of oxygen to nitrogen originally existent in the air. But the amounts of these elements in the coal are small; therefore, the proportion of 21 to 79 is approximately realized in actual flue gas. If anthracite coal is

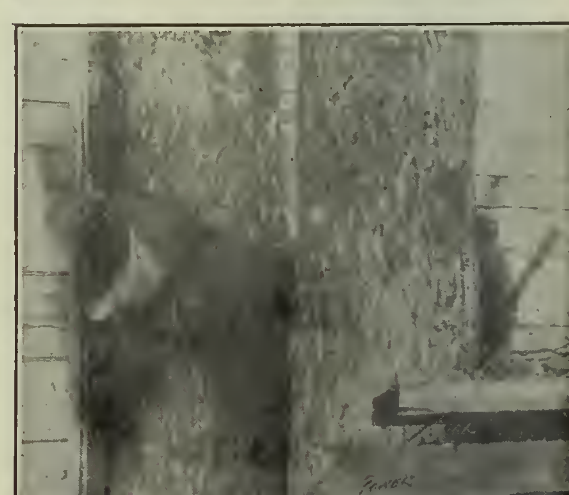

FIG. 5. PART OF CRANK SHAFT IN TREE CROTCH

used, the effect of its constituents in altering the proportion is slight; but with bituminous or semi-bituminous coals it is more marked, on account of the comparatively large amounts of hydrogen and oxygen. Part of the hydrogen may be considered to combine with the oxygen of the coal to form water, which does not appear in the flue-gas analysis. What is left of the hydrogen combines with oxygen from the air, and this tends to reduce the proportion of oxygen apparent in the flue gas. The nitrogen in the coal also has this effect, since it increases the total nitrogen, but not so much as would superficially appear. Coal containing 2 per cent. by weight of nitrogen would add to the flue gas a very much smaller percentage by volume, nitrogen being a heavy gas. Furthermore, the flue gas is formed by the combination of several pounds of air with each pound of coal; the proportions of the coal's ingredients when in the flue gas are less than when in the coal.

Since the ratio of oxygen to nitrogen remains the same and since the oxygen appearing in CO occupies the same volume as free oxygen, it follows that the percentage of nitrogen as shown by the analysis will be approximately the same as in air; namely, 79. If CO is present, the percentage of nitrogen will be reduced, because this gas occupies twice the volume of the free oxygen entering into its composition. But as the CO is usually only a fraction of 1 per cent., if present at all, its effect to lessen the percentage of nitrogen is not marked. Free hydrogen, on the other hand, is measured as nitrogen and tends to increase its apparent volume, but it, too, is likely to be present in very small quantities.

The foregoing facts may be demonstrated by calculating the reactions for various combustions of a coal high in hydrogen and nitrogen and comparatively low in oxygen, to show the resulting percentage of nitrogen in an extreme case. Such a coal is represented by the following analysis:

Carbon, Per Cent	Hydrogen, Per Cent	Nitrogen, Per Cent	Oxygen, Per Cent	Sulphur, Per Cent
[illegible]	[illegible]	2	[illegible]	1

Following is the flue-gas analysis which theoretically would result from such a coal. The calculations for the reactions neglect the SO from the sulphur and complete combustion of hydrogen is assumed.

	CO_2, Per Cent	O_2, Per Cent	CO, Per Cent	N, Per Cent
With [illegible] per cent. excess air	12.5	[illegible]	0	[illegible]
With no excess air (complete combustion assumed)	[illegible]	0	0	[illegible]
With [illegible] excess air (incomplete combustion assumed)	[illegible]	[illegible]	[illegible]	[illegible]

These results show, as would be expected, that the greater the excess air the more nearly does the percentage of nitrogen approximate to 79. Also, it may be observed that, although the CO decreases the percentage of nitrogen, the ratio of total oxygen to nitrogen is the same as in the case of complete combustion with the same amount of air. When anthracite coal is used, the percentage of nitrogen is between 79 and 80. It is not likely to exceed 81.2 even in the case of bituminous coals, and every excess of this figure renders the results questionable.

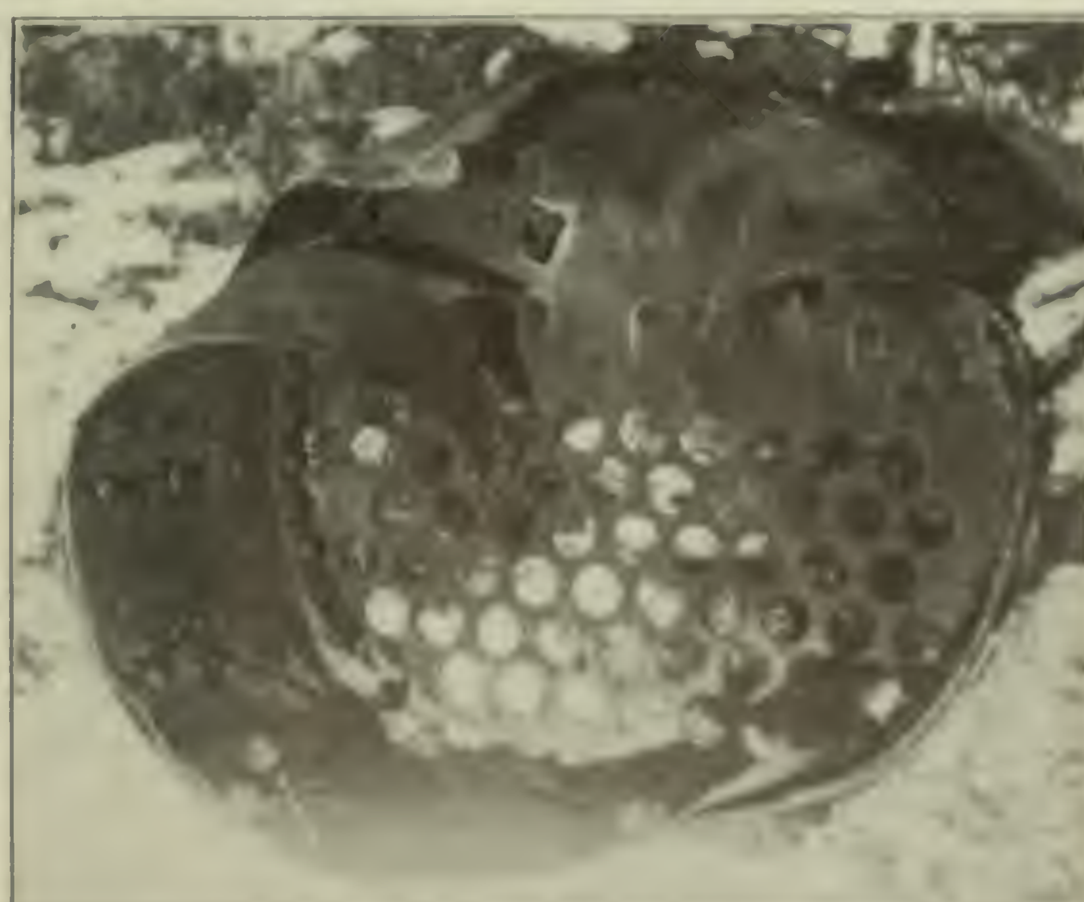

FIG. 8. FRONT AND REAR VIEWS OF FRONT HEAD AND SMOKE BOX

Inquiries of General Interest

Questions are not answered unless accompanied by the name and address of the inquirer. This page is for you when stuck—use it

Compound Gage

What is a compound gage, and for what purpose is it used?

A. C. G.

In a compound gage the dial is graduated to indicate pressures both above and below that of the atmosphere. From the zero mark the numbers read on one side the pressure in pounds above the atmosphere and on the other inches of mercury or pounds pressure below the atmosphere or vacuum. It is used wherever the pressure is liable to be either above or below that of the atmosphere, as is the case of the pressure in the receivers of compound engines.

Most Economical Vacuum

With a compound-condensing engine, how can I tell whether a 25- or a 27-inch vacuum is the more economical?

V. M. E.

By noting the hight at which the governor revolves. Other things being equal, the engine is using the least steam when the governor is highest.

Low Water

What should be done in a case of low water in a boiler carrying 100 pounds pressure?

C. L. W.

Smother the fire immediately with green coal. Close the ashpit doors. Open the damper, allowing cool air to draw through the furnace and tubes. Leave the engine running until pressure is reduced to the lowest possible point. If the feed pump is running let it run as long as it will. When the pressure will no longer run the engine or pump, it may be still further reduced by opening the gage cocks and the water-column drain valve. When the pressure has been reduced to near the atmosphere, water may be let in to the usual hight, and a search made for leaks or signs of overheating. If none appear, the fire may be started and the boiler put into service.

Incrustation and Corrosion

What is the difference between the corrosion and incrustation of steam boilers?

C. A. I.

Corrosion is the rusting or eating away of the iron or steel of the boiler, either internally or externally. It may be caused by air, water, acid, sulphur, etc. Incrustation is the covering of the surface with the solid matter left behind when the water passes away as steam and occurs only on the inside of the boiler.

Initial Condensation

What is initial condensation?

I. E. C.

When steam enters the cylinder at the beginning of the stroke it comes in contact with the piston, cylinder head and wall, which are cooler than the entering steam and as steam cannot exist in contact with anything cooler than itself, a part of it is condensed. Initial means at the beginning and as the steam is condensed at the beginning of the stroke, it is called initial condensation.

Rotary Engine

What is a rotary engine?

R. E.

A rotary engine is one having no reciprocating parts, the force of the steam being expended directly in producing rotation without the intervention of piston, connecting rod or crank.

Vacuum Breaker

What is a vacuum breaker, and for what purpose is it used?

C. V. D.

A vacuum breaker is an appliance attached to a jet condenser which automatically admits air to the exhaust pipe or condensing chamber of a condensing engine when water rises above a predeterminated hight in the system, destroying the vacuum and preventing water from entering the cylinder.

Complete Combustion

What conditions will cause practically complete combustion in a boiler furnace?

C. F. C.

There must be a high-furnace temperature, sufficient air intimately mixed with the fuel and distilled gases and room enough for the gases to burn without the flame coming in contact with the heating surfaces.

Loop in Steam Gage Pipe

Why is there always a loop in the pipe connecting a steam gage to its boiler?

L. S. G.

It is placed there to form a trap for water so that steam may not come in contact with the spring and by its heat affect its temper.

Lead Joints in Water Pipe

How are the lead joints in cast-iron water pipe made?

J. W. P.

The lengths of pipe are laid in position with the small or spigot end of one length accurately centered in the large or bell end of the next and held central by blocks of wood underneath and at the sides.

The annular space between the bell and spigot is then filled with tarred rope yarn which is calked in until the bell end is filled to within a half inch of the end.

A dam is made around the joint, usually a strip of tuck packing held by a clamp and melted lead poured into the space between the dam and the packing. Afterward, the lead is solidly calked. The packing makes a water-tight joint and the lead holds the packing in place as would a gland.

Compound Engine Cylinder Ratio

How can the proper cylinder ratio in a compound engine be found when the steam pressure, vacuum and load are known?

C. E. R.

The proper cylinder ratio in compound engines is a debatable question. A ratio which will give an equal number of expansions in each cylinder is found by assuming the probable initial pressure in the high-pressure cylinder and the terminal pressure in the low; then divide the initial pressure by the terminal and the square root of the quotient will be the proper cylinder ratio.

The life of the rubber hose of the flue blower can often be doubled by arranging the steam pipes so as to avoid short bends of the hose, also by remembering to turn on the steam before uncoiling the hose, as it is stiff and brittle when cold.

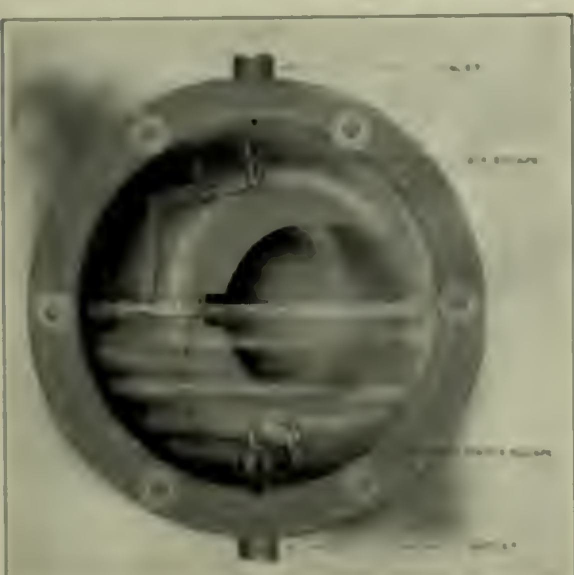
New Power House Equipment

What the inventor and the manufacturer are doing to save time and money in the engine room and power house. Engine room news

Combination Air and Water Trap

This trap is designed to handle both water and air from steam pipes, radiators, separators, etc. The trap does away with air cocks and air valves, and the escape of air is automatically taken care of. The accompanying illustration shows the interior construction of the trap, which consists of a casing, two needle valves, a float and lever connection.

The trap operates as follows: The trap being attached and the connection opened, the float is at the bottom of the chamber with the air escape open and the water escape closed. The pressure will then rise in the trap, and should the system be air bound the air will escape through the air valve. The steam will follow, and with it the water, which will



Sectional View through Trap

accumulate in the bottom of the float chamber, raise the float and gradually close the air escape. Further raising of the float after the air escape is closed will open the water escape and water will be discharged.

To compel the operation of the trap at the neutral point when both valves are closed, the bottom valve and its seat are not ground to a tight fit, thus permitting enough water to escape to insure continuous action of the trap when but very little steam is being condensed in the piping or other apparatus to which the trap is attached. The capacity of this trap is large, and it will successfully pass quantities of dirt and scale, due to the construction of the water valve, which is without wings or guides, and the seat, which has but small bearing surface and is removable.

This trap is made by the Atkins Brothers Company, Springfield, Mass.

Rolin Adjustable Interchangeable Grate Bar

This grate is so designed that four different air spaces can be obtained with

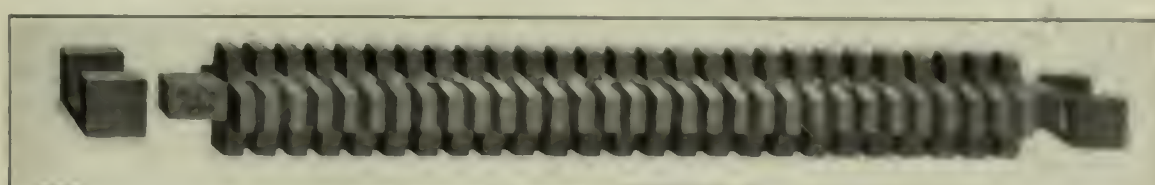


Fig. 1. Section of Bearing Bar

the same set of bars. It consists of three revolving bearing bars, one of which is shown in Fig. 1. This bar is made with

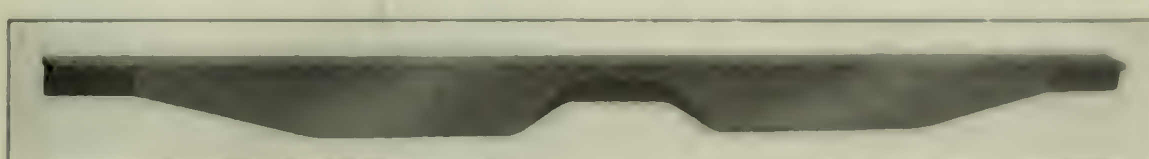

Fig. 2. Section of Grate Bar

four sets of projections, each set being differently spaced. On these revolving bars, the surface bars, Fig. 2, are placed and as the end and central bearing surfaces are made tapering, the surface bar will fit into the slope of the revolving bar to a greater or less degree according to the spacing of the projections. Fig. 4 shows how this is done.

Whenever it is found desirable to change the size of coal and to decrease or increase the width of the air space between the bars, it is only necessary to lift the grate bars from the grooves they are resting in, and turn the bearing bars until the desired groups are on top, when the grate bars are replaced. By this means a [illegible]-inch air space can be obtained for barley or rice coal; [illegible]-inch air space for pea or stove coal; [illegible]-inch for nut coal, and [illegible]-inch, [illegible]-inch and [illegible]-inch for all grades of bituminous coal.

Fig. 3 shows the grate in position under a boiler.

The surface bars are the only part that

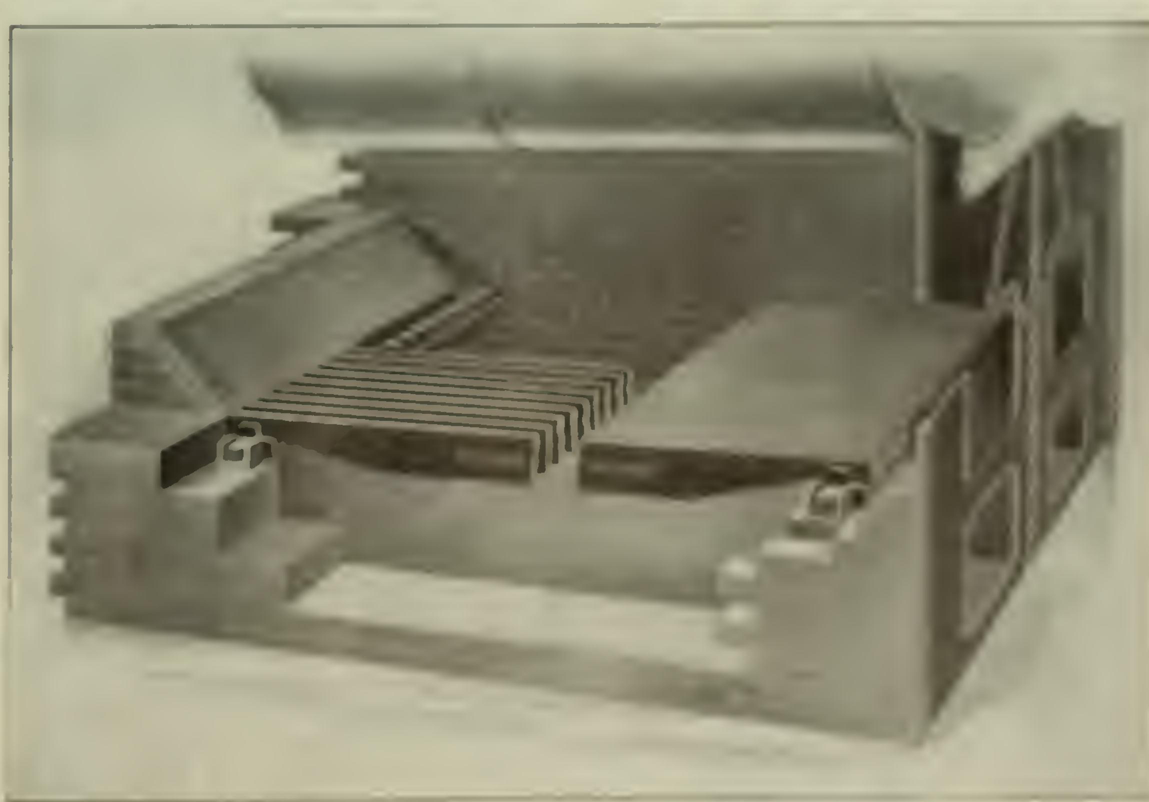

Fig. 3. Grate Bars in Position Under a Boiler

will require renewal, as the bearing bars should last the life of the boiler. This grate is made by the Standard Grate Company, 1213 Filbert street, Philadelphia, Penn.

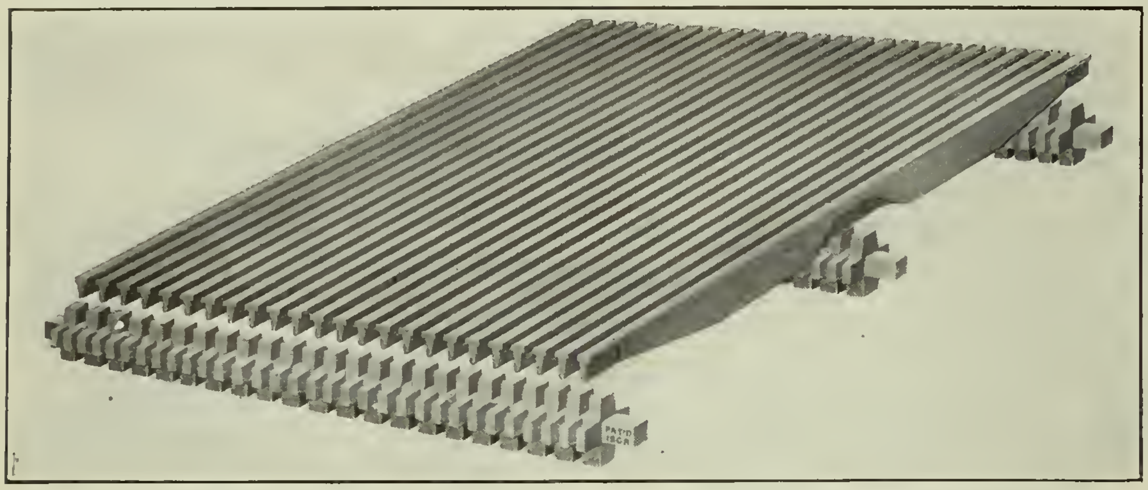

FIG. 4. SURFACE BARS AS SPACED BY THE BEARING BARS

OBITUARY

With Geheimen Kommerzienrat Dr. Ing. h.c. Rudolf Ernst Wolf, of Madgeburg, passed away on November 20, 1910, one of the most important and sympathetic personalities in German industry.

He was born July 26, 1831, the son of Wilhelm Wolf, professor in the Madgeburg Gymnasium. His father intended to give him a university education, but this did not suit the boy's inclinations, and his proficiency in ancient languages left so much to be desired that his father came to doubt whether he was able to study at all. "I don't want to," the lad replied, "I wish to become a machinist." Such a desire was then unheard of in educated circles, since the "black trade" was not considered respectable. But after he had delivered his mind, the parental opposition was soon overcome, and Wolf entered, April 12, 1847, the Maschinenfabrik Buckau as a simple apprentice. After two and a half years of practical instruction in this old-time shop which has given their rudinentary knowledge to so many able engineers, he attended, from October, 1850, to October, 1852, the provincial trade school at Halberstadt. After that he found a place in the Wöhiertschen Maschinenfabrik, of Berlin, where, under the leadership of H. Gruson, the then director of the firm and later founder of the celebrated Grusonwerk in Madgeburg, he was occupied especially in building locomotives. In 1855 he entered the factory of G. Kuhn in Stuttgart-Berg, where at the youthful age of 24 years he filled the office of chief engineer. Here for six years he was engaged in various kinds of work, till he decided to start a factory for himself, since he felt that he had sufficient force and experience to stand on his own feet. On June 15, 1862, he began work in the machine and boiler shop which he had erected at Buckau, and from the beginning constructed his locomobiles (portable steam engines), whose fundamental principles of construction were original with him. They contained removable tubular boilers with cylindrical fire boxes; the working cylinders were live-steam jacketed and connected with the steam dome itself. Thus he was the founder of modern German locomobile construction and developed the engine to its present important position. Among the radical improvements which he introduced were

RUDOLF ERNST WOLF

the method of compounding and the use of highly superheated steam.

R. Wolf had early recognized the importance of specialization in machine construction, and had therefore made his shop a special one for locomobiles and locomobile boilers. The greatest possible simplicity of organization and working methods, with concentration of all mental, manual and machine forces upon a single object, enabled him soon to turn out engines of high economic and constructive perfection. Already at the locomobile competitions at Madgeburg in 1880 and at Berlin in 1883, those of Wolf surpassed others, including the English ones. Today Wolf locomobiles show as good economy as eight pounds of coal per effective horsepower-hour.

Among the various products that, during its long existence, have been turned out by the Wolf shop, are rotary pumps and screw propellers, known as Buckau screws and intended for river steamers. The line of threshing-machine locomobiles has been supplemented by threshers themselves.

With Wolf appliances there have been drilled the deepest bore holes in the earth, those of Schladebach in the Saxon province, and of Paruschowitz in upper Silesia, which are 1748.4 and 2002 meters deep. Wolf has also been building stationary boilers and engines and machinery for a variety of industrial purposes.

In 1862, Wolf began with six workmen, and three officials, and built an 8-horsepower locomobile of six atmospheres working pressure, which did forty years' good service and now stands in the technical museum at Munich. Today the Wolf Works employ 3300 officials and workmen, turning out a large number of locomobiles, various in form and size, up to more than 800 effective horsepower and as high as 15 atmospheres working pressure. Beside the old works in Buckau, a new plant has been erected at Madgeburg-Salbke.

Wolf was not only a fine engineer, but a good salesman and a competent organizer. He understood the work of the shop from his own experience and could direct its details with great sagacity. He was popular with his men and solicitous for their welfare. In respect to pensions and various other means of social benefit among them, he far exceeded the requirements of the paternal German laws and long anticipated them. He was a man of public spirit and activity, and received official honors.

Edwin Ford, engineer of the Harlem hospital in Brooklyn, recently passed away. Mr. Ford was past financial secretary of Robert Fulton Association No. 57, National Association of Stationary Engineers, also member of the Municipal Engineers Local No. 319, International Union of Steam Engineers, and past senior warden of Washington Lodge No. 1, Free and Accepted Masons. He was a hard worker for the engineer and seemed to take great pleasure in doing anything within his power to aid the cause.

PERSONAL

John I. Rogers announces that having resigned one year ago from the Midvale Steel Company, of Philadelphia, to take up professional practice, he has since that time engaged in consultation and design, and has now opened a New York office at 165 Broadway. He will make a specialty of the design and operation of the most modern plants, furnaces and machinery for steam hammer, hydraulic press and drop forging; tire, wheel and other special rolling; hot- and cold-metal working; machine shops and power plants, iron and steel manufacture.

As a result of a Civil Service rule recently inaugurated in Kansas City, E. H. Lane was appointed a member of the board of examining engineers.

NEW PUBLICATIONS

Next best to knowing a thing one's self is to know where to find it. Next best to being able to retain in one's memory all the data and information which come to one's attention is to put it where it can be found. Many engineers keep card indexes of such data, and Edward Wray has conceived the idea of compiling such information as is likely to be of value to engineers and issuing it upon leaves of the standard 3x5 size, printed upon one side only, for filing in a standard index card set. He has associated with him a dozen editors expert in different lines, and issues the sets monthly in a little cover under the name of *Data*. The publication office is at 92 La Salle street, Chicago.

Will Hold Convention Soon

The Institute of Operating Engineers has created a renewed interest in its work by the issuing of the prospectus containing the proposed plan and scope of its work. Several branches are now in process of formation throughout the country and the work has already been adopted in the extension courses at Teachers College, Columbia University. A working agreement has been entered into between the Institute and the Williamson Free Trade School, whereby the graduates of the latter will receive a certificate of the journeyman grade in the Institute of Operating Engineers. Employers are also getting interested in the institute to such an extent that over seven desirable positions have been offered its members. Prominent educators who are interested in industrial education are taking great interest in the work of the Institute of Operating Engineers and are lending their aid and counsel in its formation. It is expected that the first convention will be announced in the very near future.

An industrial exposition to commemorate the fiftieth anniversary of the kingdom of Italy will be opened at Turin in April of next year. It is situated on the outskirts of the city on both sides of the River Po and includes an area of a million square meters, of which 280 square meters will be covered by buildings, making it one of the largest expositions yet held.

NEW INVENTIONS

Printed copies of patents are furnished by the Patent Office at 5c. each. Address the Commissioner of Patents, Washington, D. C.

PRIME MOVERS

GASOLENE ENGINE. George [illegible], Bakersfield, Cal. [illegible]

EXPLOSION ENGINE. Guy E. Price, Detroit, Mich. [illegible]

INTERNAL COMBUSTION ENGINE. [illegible], Boston, Mass. [illegible]

TWO-CYCLE EXPLOSION ENGINE. [illegible], Iowa. [illegible]

SINUSOIDAL WAVE CURRENT APPARATUS. [illegible], Hammond, Ind., assignor of one-half to Frank S. Betz, Hammond, Ind. [illegible]

FOUR-CYCLE INTERNAL COMBUSTION ENGINE. Robert Miller, New York, N. Y. [illegible]

WIND MOTOR. John [illegible], Chicago, Ill. [illegible]

ROTARY ENGINE. [illegible], Boston, Mass., assignor of one-half to [illegible], Boston, Mass. [illegible]

CURRENT MOTOR. [illegible] and [illegible], [illegible]. [illegible]

PRIME MOVER. Frank J. [illegible], Detroit, Mich., assignor to [illegible] Engineering Company, Detroit, Mich., a corporation of Michigan. [illegible]

INTERNAL COMBUSTION ENGINE. [illegible], Warren, Penn. [illegible]

BOILERS, FURNACES AND GAS PRODUCERS

STEAM BOILER. John A. [illegible], Roanoke, Va. [illegible]

STEAM GENERATOR. Robert L. Thompson, Elgin, Ill. [illegible]

POWER-PLANT AUXILIARIES AND APPLIANCES

BOILER CLEANER. [illegible], St. Louis, Mo. [illegible]

GAGE. Frederick C. Blanchard, Bridgeport, Conn., assignor to the Ashcroft Manufacturing Company, Bridgeport, Conn., a corporation of Connecticut. [illegible]

STEAM TRAP. John M. [illegible], N. Y., assignor of one-half to [illegible], Chicago, Ill. [illegible]

HYDROCARBON BURNER. William [illegible]. [illegible]

FLEXIBLE PIPE JOINT. Warren A. [illegible], [illegible] Highlands, Mass., assignor to the [illegible] Manufacturing Company, Boston, Mass., a corporation of Maine. [illegible]

PIPE HANGER. William H. [illegible], New York, N. Y. [illegible]

FURNACE ARCH. William [illegible], Scranton, Penn., assignor to McClave-Brooks Company, Scranton, Penn., a corporation of Pennsylvania. [illegible]

VALVE. Edward O'Malley, Jackson, Tenn., assignor, by direct and mesne assignments, to O'Malley-Beare Valve Company, Chicago, Ill., a corporation of Delaware. [illegible]

Moments with the Ad. Editor

A department for subscribers edited by the advertising service department of Power

When you were a small boy did you ever go swimming with the other "kids" in some fresh-water pond and, when emerging, find a big, black, ugly looking leech fastened onto you?

"Blood-suckers" we used to call them and we remember that they were about as repulsive a worm as ever made a small boy shiver.

Compared with them a mosquito is a respectable sort of parasite. He, at least, comes at you in a business way. You know which is head and which is tail, and that is more than can be said of your leech.

There are leeches in the business world and, after their fashion, they are quite as ugly and quite as repulsive and, when allowed to get busy, quite as destructive as the old original "blood-sucker."

Their first business in life is to remain unnoticed. Nature seems to have provided them with the instinct that makes them efface themselves as much as possible.

Their next business is to find some big and conspicuous concern manufacturing some conspicuously good article and to fasten onto them for reputation.

Their third business is to find the "easy marks" who will provide their nourishment.

These leeches of the business world are better known to you and us as "substitutors."

Do you know that there are large manufacturing concerns in this country whose whole business is to turn out substitutes for well known, trade-marked brands of goods?

Imagine it—big, wide-open *counterfeiting* factories!

Can you think of anything more crooked and despicable than that?

Yet these industries are made possible because there are enough dishonest dealers in the country to take their goods and enough indiscriminating buyers to accept the counterfeits.

Take it right in your own business, for instance—say some-engine room supply such as grease, oil or packing.

The fake manufacturer's agent says to the dealer, "Here, Mr. Man, you are selling so many pounds of Smith's Packing (mentioning a well known, old established, thoroughly advertised brand), and you are getting about 20 per cent. profit on it. Now, look at this stuff. Same trade-mark, nearly, isn't it? Same kind of a box; same stuff to all intents and purposes, what? Well, I'll sell you this so that you can clean up 35 per cent. on it and nobody will be the wiser."

The dealer can't resist the temptation or doesn't want to. Next time you send for Smith's Packing you get the substitute, and because you don't investigate the name and trade-mark closely enough you accept it as the real thing.

You use it and the next thing you know you find the stuffing box leaking badly. Out comes the offending packing and from that day on Smith's Packing is on your black list.

Unless he hears of your particular case Smith has no come-back—no chance to "show" you—no square deal.

Unconsciously, you are a party to the fraud.

Moreover, in the long run, you are the victim. You put up your good money or recommend that your concern put it up, and you get an inferior article, one which doesn't give the results you expected or one which actually works harm.

These business leeches have no reputation to live up to. They create nothing, they build up nothing. They are destroyers. Their whole function in life is to sustain themselves on a big manufacturer's reputation and a buyer's credulity, through a dealer's avariciousness.

The manufacturer who is everlastingly printing his claims—advertising—must live up to them, deliver the goods, or fail.

Your safeguard in buying is the trade-marked, advertised article.

But, when you buy, *get what you ask for.*

In your hands lies the remedy for the whole rotten practice.

Exercise your prerogative *every time.*

POWER

NEW YORK, JANUARY 17, 1911

Do you recollect the first time someone took you to a circus? You were a boy then, but the memory of the event will always be bright.

Some events in life are difficult to forget, and some are remembered with the keenest pleasure.

A truth known the wide world over is that the man who helps another gets more out of the act than the one helped. There is nothing to compare with that satisfied, full, "under the belt" feeling that creeps over a man when he has helped another to do something worth while, and the act of giving a helping hand to another has often resulted in the formation of a life-long friendship.

And the other fellow—well, he can't do much or say much, but he does a whole lot of thinking, and with him you are "IT."

There is some satisfaction in being appreciated, even if it is by the man who is running the little forty-horsepower plant.

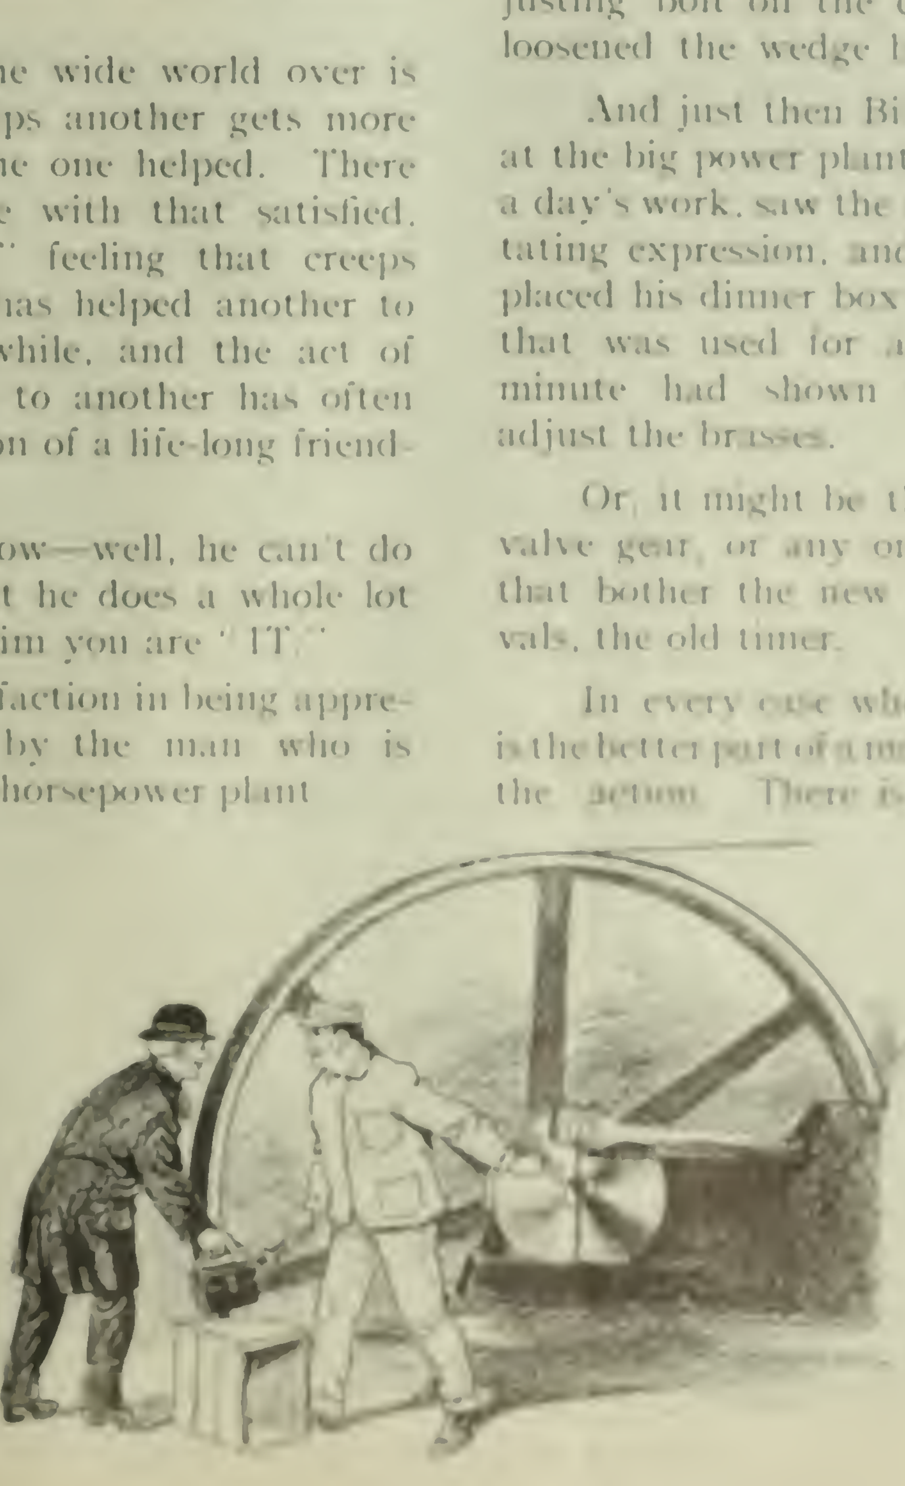
There are thousands of engineers, many holding "high up" positions, who are not above giving a lift to the little fellow—glad to give him the boost that is just necessary to enable him to get on his feet and toddle along alone.

Some engineers may recollect the time when they were new to the game, when they didn't know whether they were playing hide and seek or blind man's buff, and sometimes felt as if both games were on at once. They didn't know whether the top or bottom adjusting bolt on the crank rod tightened or loosened the wedge back of the brasses.

And just then Bill Somebody from down at the big power plant, on his way home after a day's work, saw the puzzled, undecided, hesitating expression, and, guessing the trouble, placed his dinner box on the old wooden box that was used for a tool chest, and in a minute had shown the way to properly adjust the brasses.

Or, it might be the crosshead shoes, the valve gear, or any one of a thousand other that bother the new beginner and at intervals, the old timer.

In every case where assistance is given it is the better part of a man's nature that prompts the action. There is no expectation of obtaining anything in return and nothing is wanted. It is one of the characteristics that go to make up the average engineer—and it pays, sometimes, in dollars and cents, but most often in the knowledge that a fellow man has been helped to help himself.



Hudson Manhattan Power Station

By F. R. Low

Boiler-room practice in a plant which produces current at less than 0.42 of a cent per kilowatt-hour and makes a thousand pounds of steam with 12.5 cents worth of coal. It is enabled to do this by the use of No. 3 buckwheat. The article describes the furnace and methods by which this is successfully done, notwithstanding the varying load.

The station at Jersey City which furnishes power for the operation of the trains in the McAdoo tunnels under the Hudson river is called upon to supply a load fluctuating momentarily from 8000 to 16,000 kilowatts and swinging from 1500 kilowatts in the early morning hours to 13,000 on the morning and evening peaks. Current is supplied by two 6000- and two 3000-kilowatt generators, driven by Curtis turbines to supply steam for which eight Babcock & Wilcox boilers of 900 rated horsepower each have been installed. Some of the dimensions and proportions pertinent to this article are as follows:

Water-heating surface per boiler, sq.ft.	9,128
Grate surface per boiler, sq.ft.	190
Water-heating surface per square foot grate surface, sq.ft.	48.05
Total rated boiler horsepower	7,200
Total rated capacity of generators, kw.	18,000
Maximum sustained capacity of generators, kw.	28,000
Boiler horsepower per kilowatt, rated	0.40
Boiler horsepower per kilowatt, maximum	0.26
Water-heating surface per kilowatt, rated, sq.ft.	4.06
Water-heating surface per kilowatt, maximum, sq.ft.	2.61
Grate surface per kilowatt, rated, sq.ft.	0.084
Grate surface per kilowatt, maximum, sq.ft.	0.054

While this is a generous amount of boiler and especially of grate surface for the present demands upon the station, the character of the service is such that no interruption is admissible and no chances could be taken of being found short of steam-generating capacity. Furthermore, it was believed by John Van Vleck, its designer, that a station thus of necessity liberally supplied with grate surface could be run upon No. 3 buckwheat, although none of the large power stations in this vicinity are being so run today and it is doubtful if it is being done elsewhere by a plant carrying a load of this magnitude and with this degree of variation.

Some difficulty was at first experienced in doing this, but a proposition was submitted by the McClave-Brooks Company, of Scranton, Penn., in which they agreed to burn No. 3 buckwheat, without the formation of clinker, to keep the boilers running at the required capacity, with a low per cent. of carbon in the ash, and to burn 35 pounds of this coal per hour per square foot of grate surface with not over 2.5 inches water pressure of air in the ashpit.

In accordance with this agreement the

Fig. 1. Turbine Room of Hudson-Manhattan Plant

furnaces were reconstructed, as shown in Fig. 6. Each furnace has three arches, so spaced that the area between them is sufficient to allow the products of combustion to pass through under slight compression, and placed sufficiently high above the fire to allow the complete combustion of the gases before they are discharged through the openings between the arches upon the cold tubes.

The grate used is what is known as the McClave No. 4. It is arranged in front and rear sections, both of which dump toward the middle, so that the ashes, clinkers, etc., fall naturally into the center of the hopper, into which the ashpit is extended; see Fig. 3. This grate has been especially designed for the burning of small grades of anthracite, allowing the necessarily strong undergrate draft to be used without disarranging the fuel and throwing it about in ridges and mounds all over the surface of the fire bed. To this end it has a uniform mesh of [illegible] of an inch not only on the surface of each bar but also on the surface of the bars adjacent to the sides of the longitudinal carrying bars which span the space from the edge of the dead plate to the bridgewall.

The grate bars are made with sectional removable tops or caps, having [illegible]-inch air space arranged as in Fig. 3. Into the shanks of these caps are cast soft-steel lugs which are bent under the bottom of the carrying bar, thus preventing any change in the location of the cap and insuring a uniform mesh all over the grate surface. The body portion of the bars is over 2 inches below the top level of the caps and is, therefore, not likely to warp or burn out from the fire on top of the grate. The bars overlap at their ends, as shown in Fig. 3, necessitating the use of the center tie *A* when the front and back of the grate dump in opposite directions. They may be brought into contact where they then overlap, or an opening may be left between them, by placing stops in front to arrest the throw of the stub levers at

Fig. 2. Front of Boilers Which Are Hand Fired

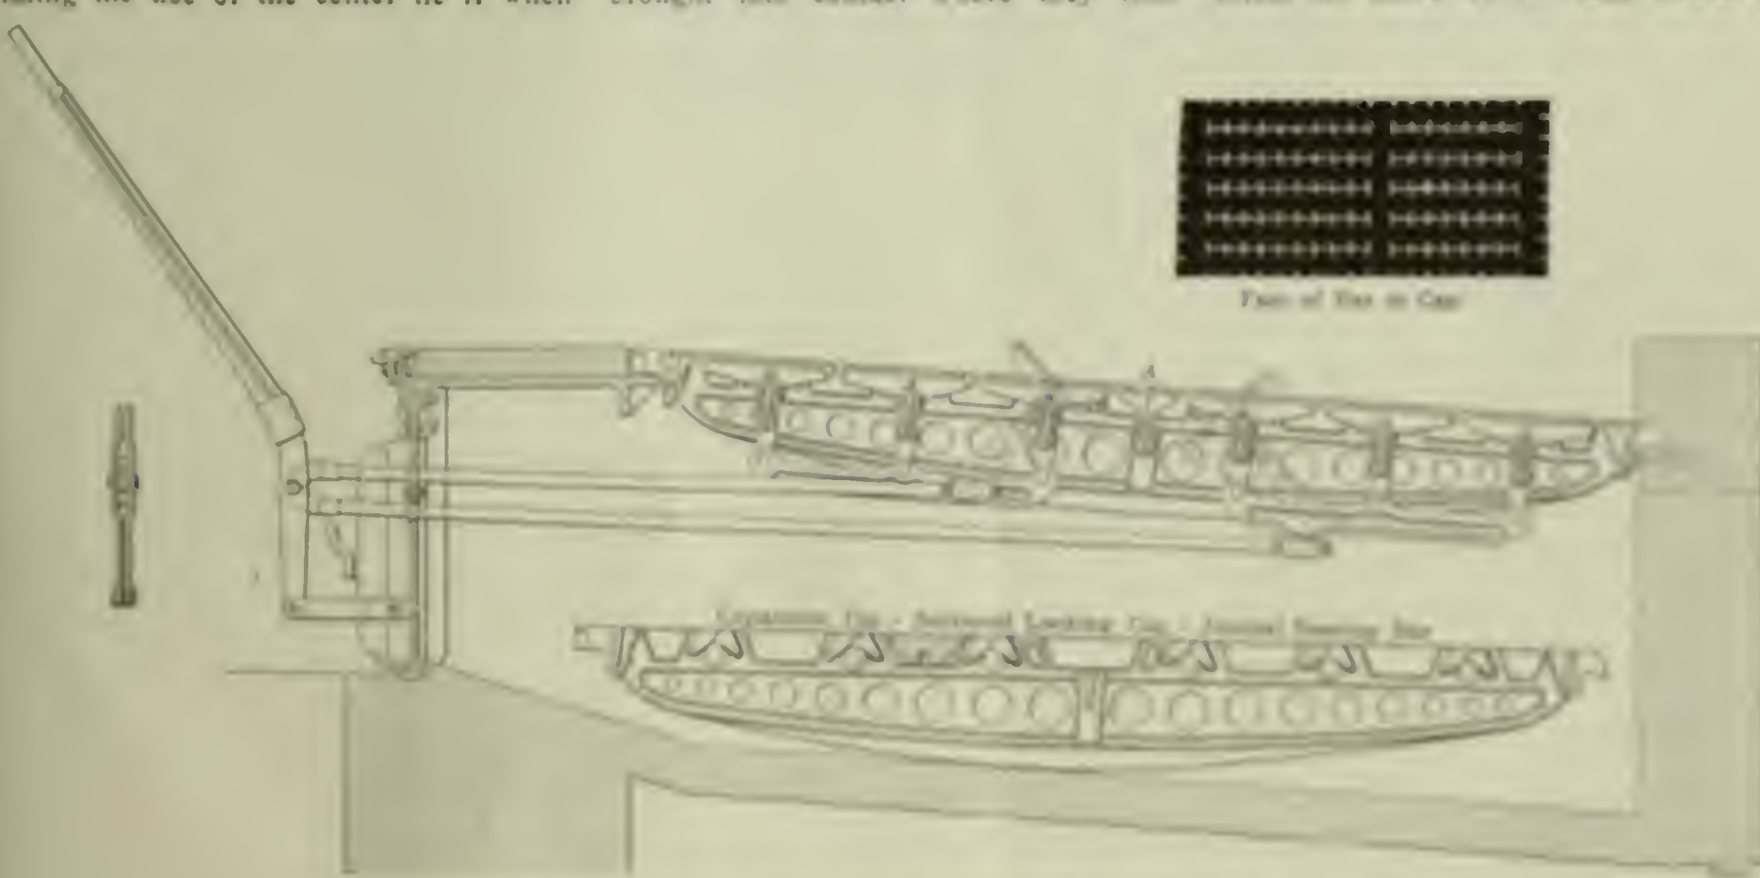


Fig. 3. The McClave No. 4 Grate Installed under the Boilers

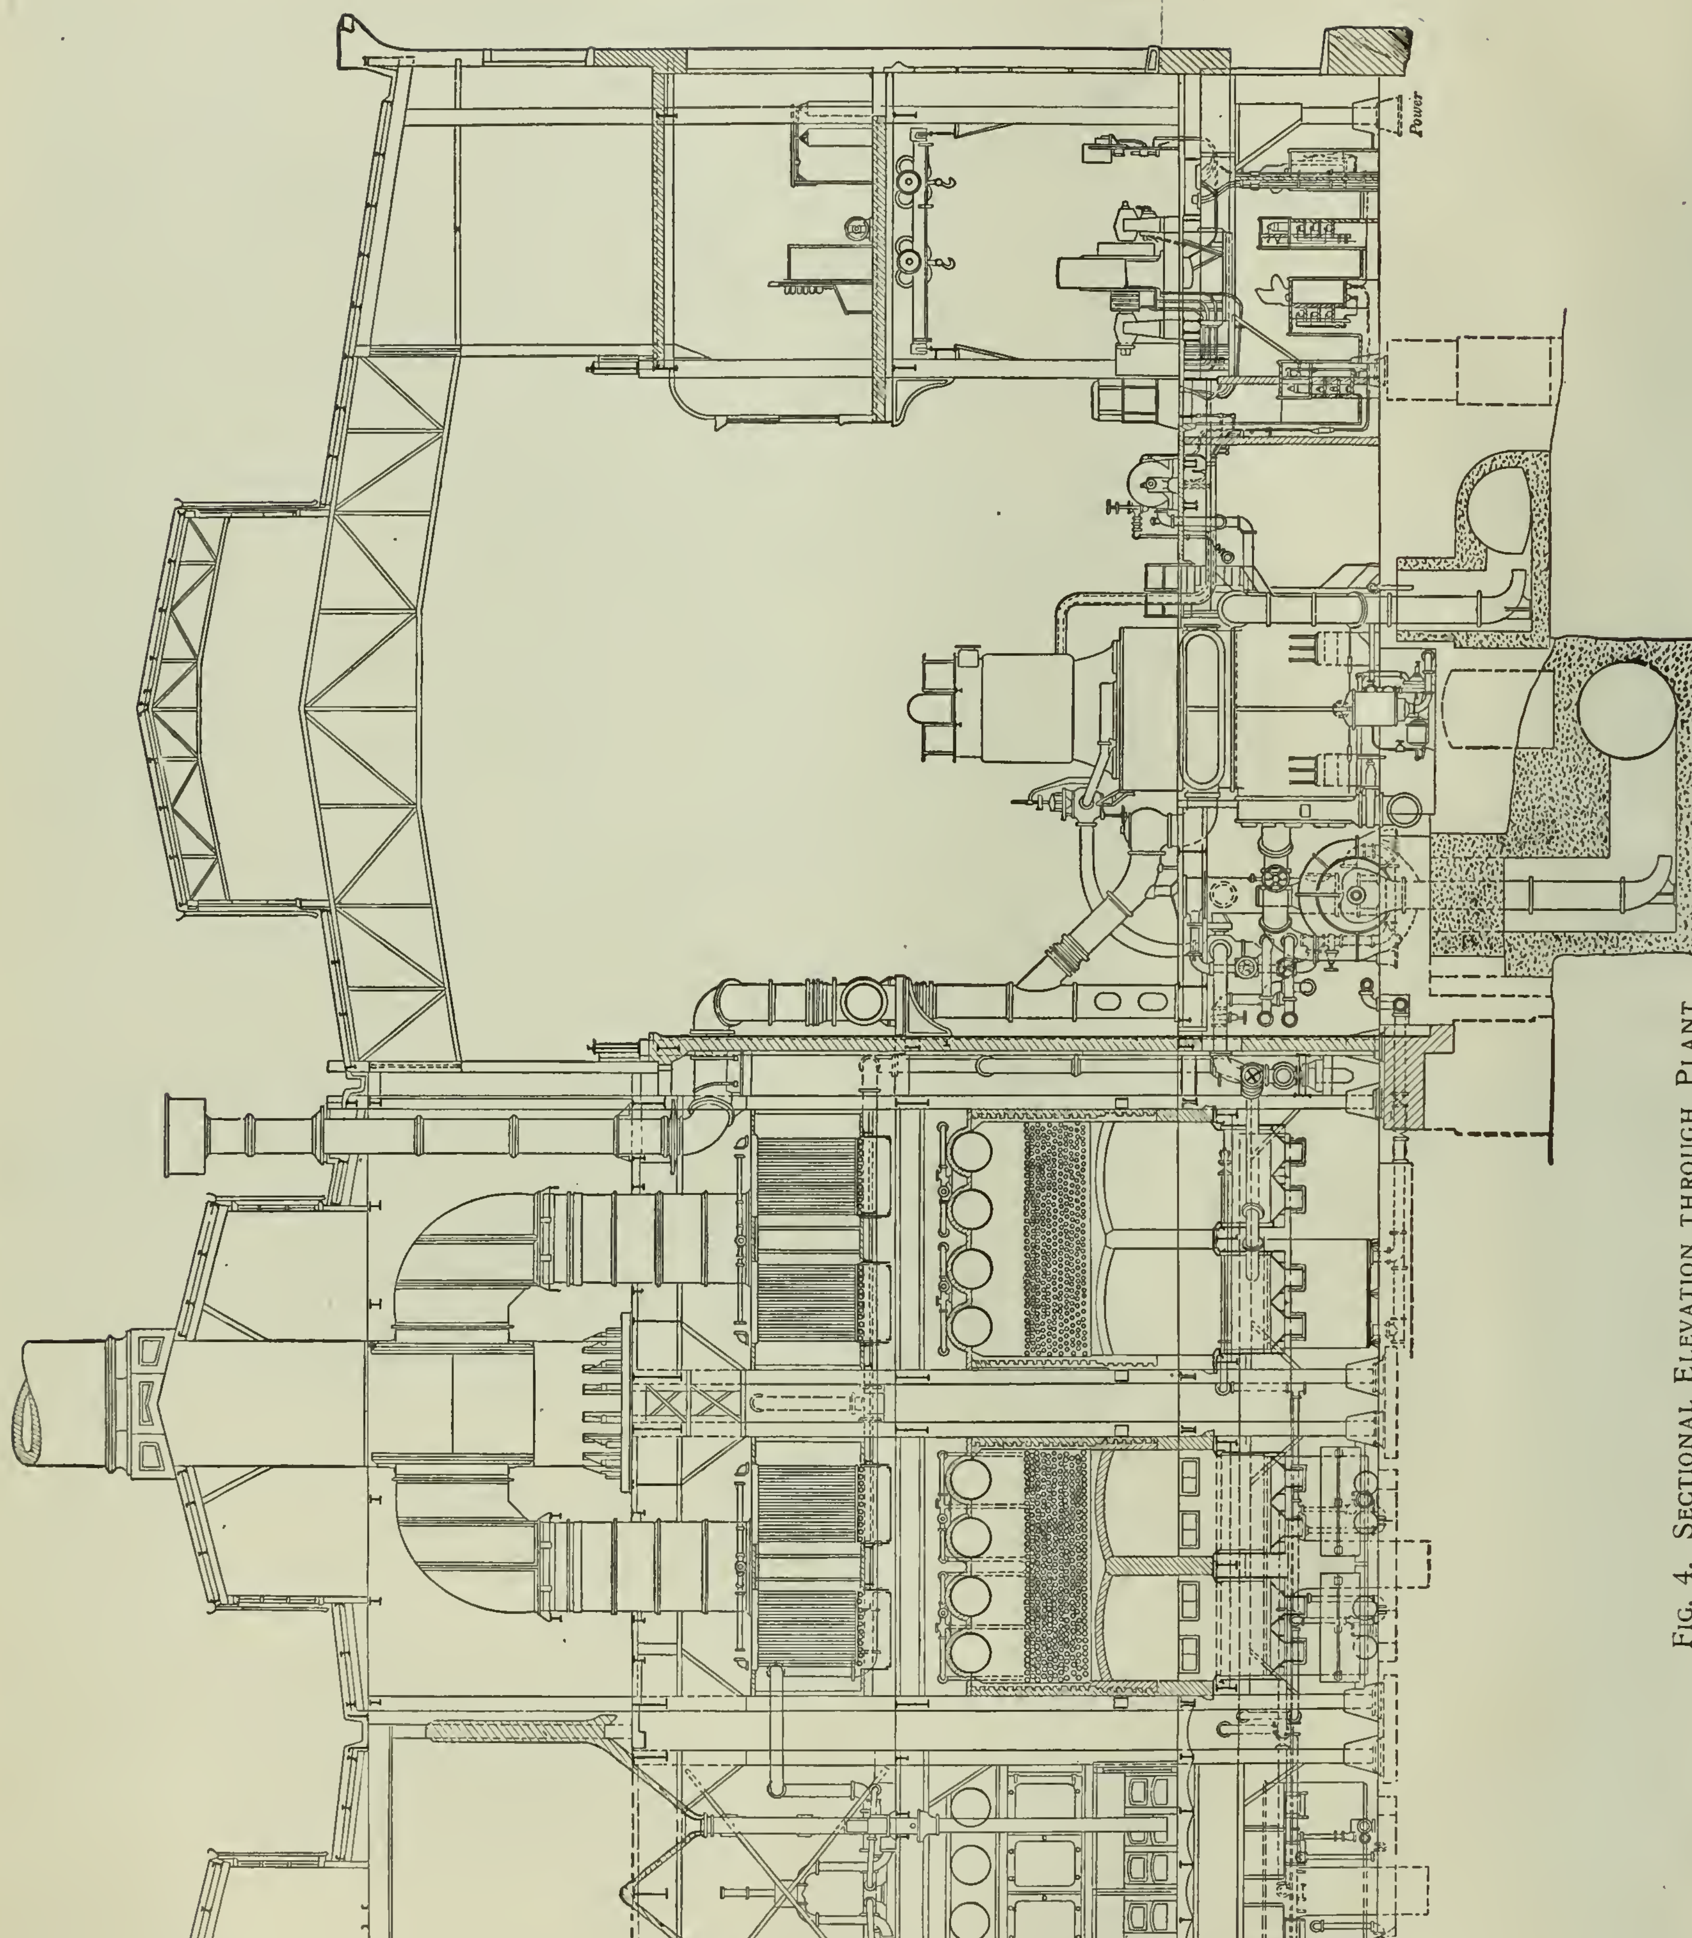

Fig. 4. Sectional Elevation through Plant

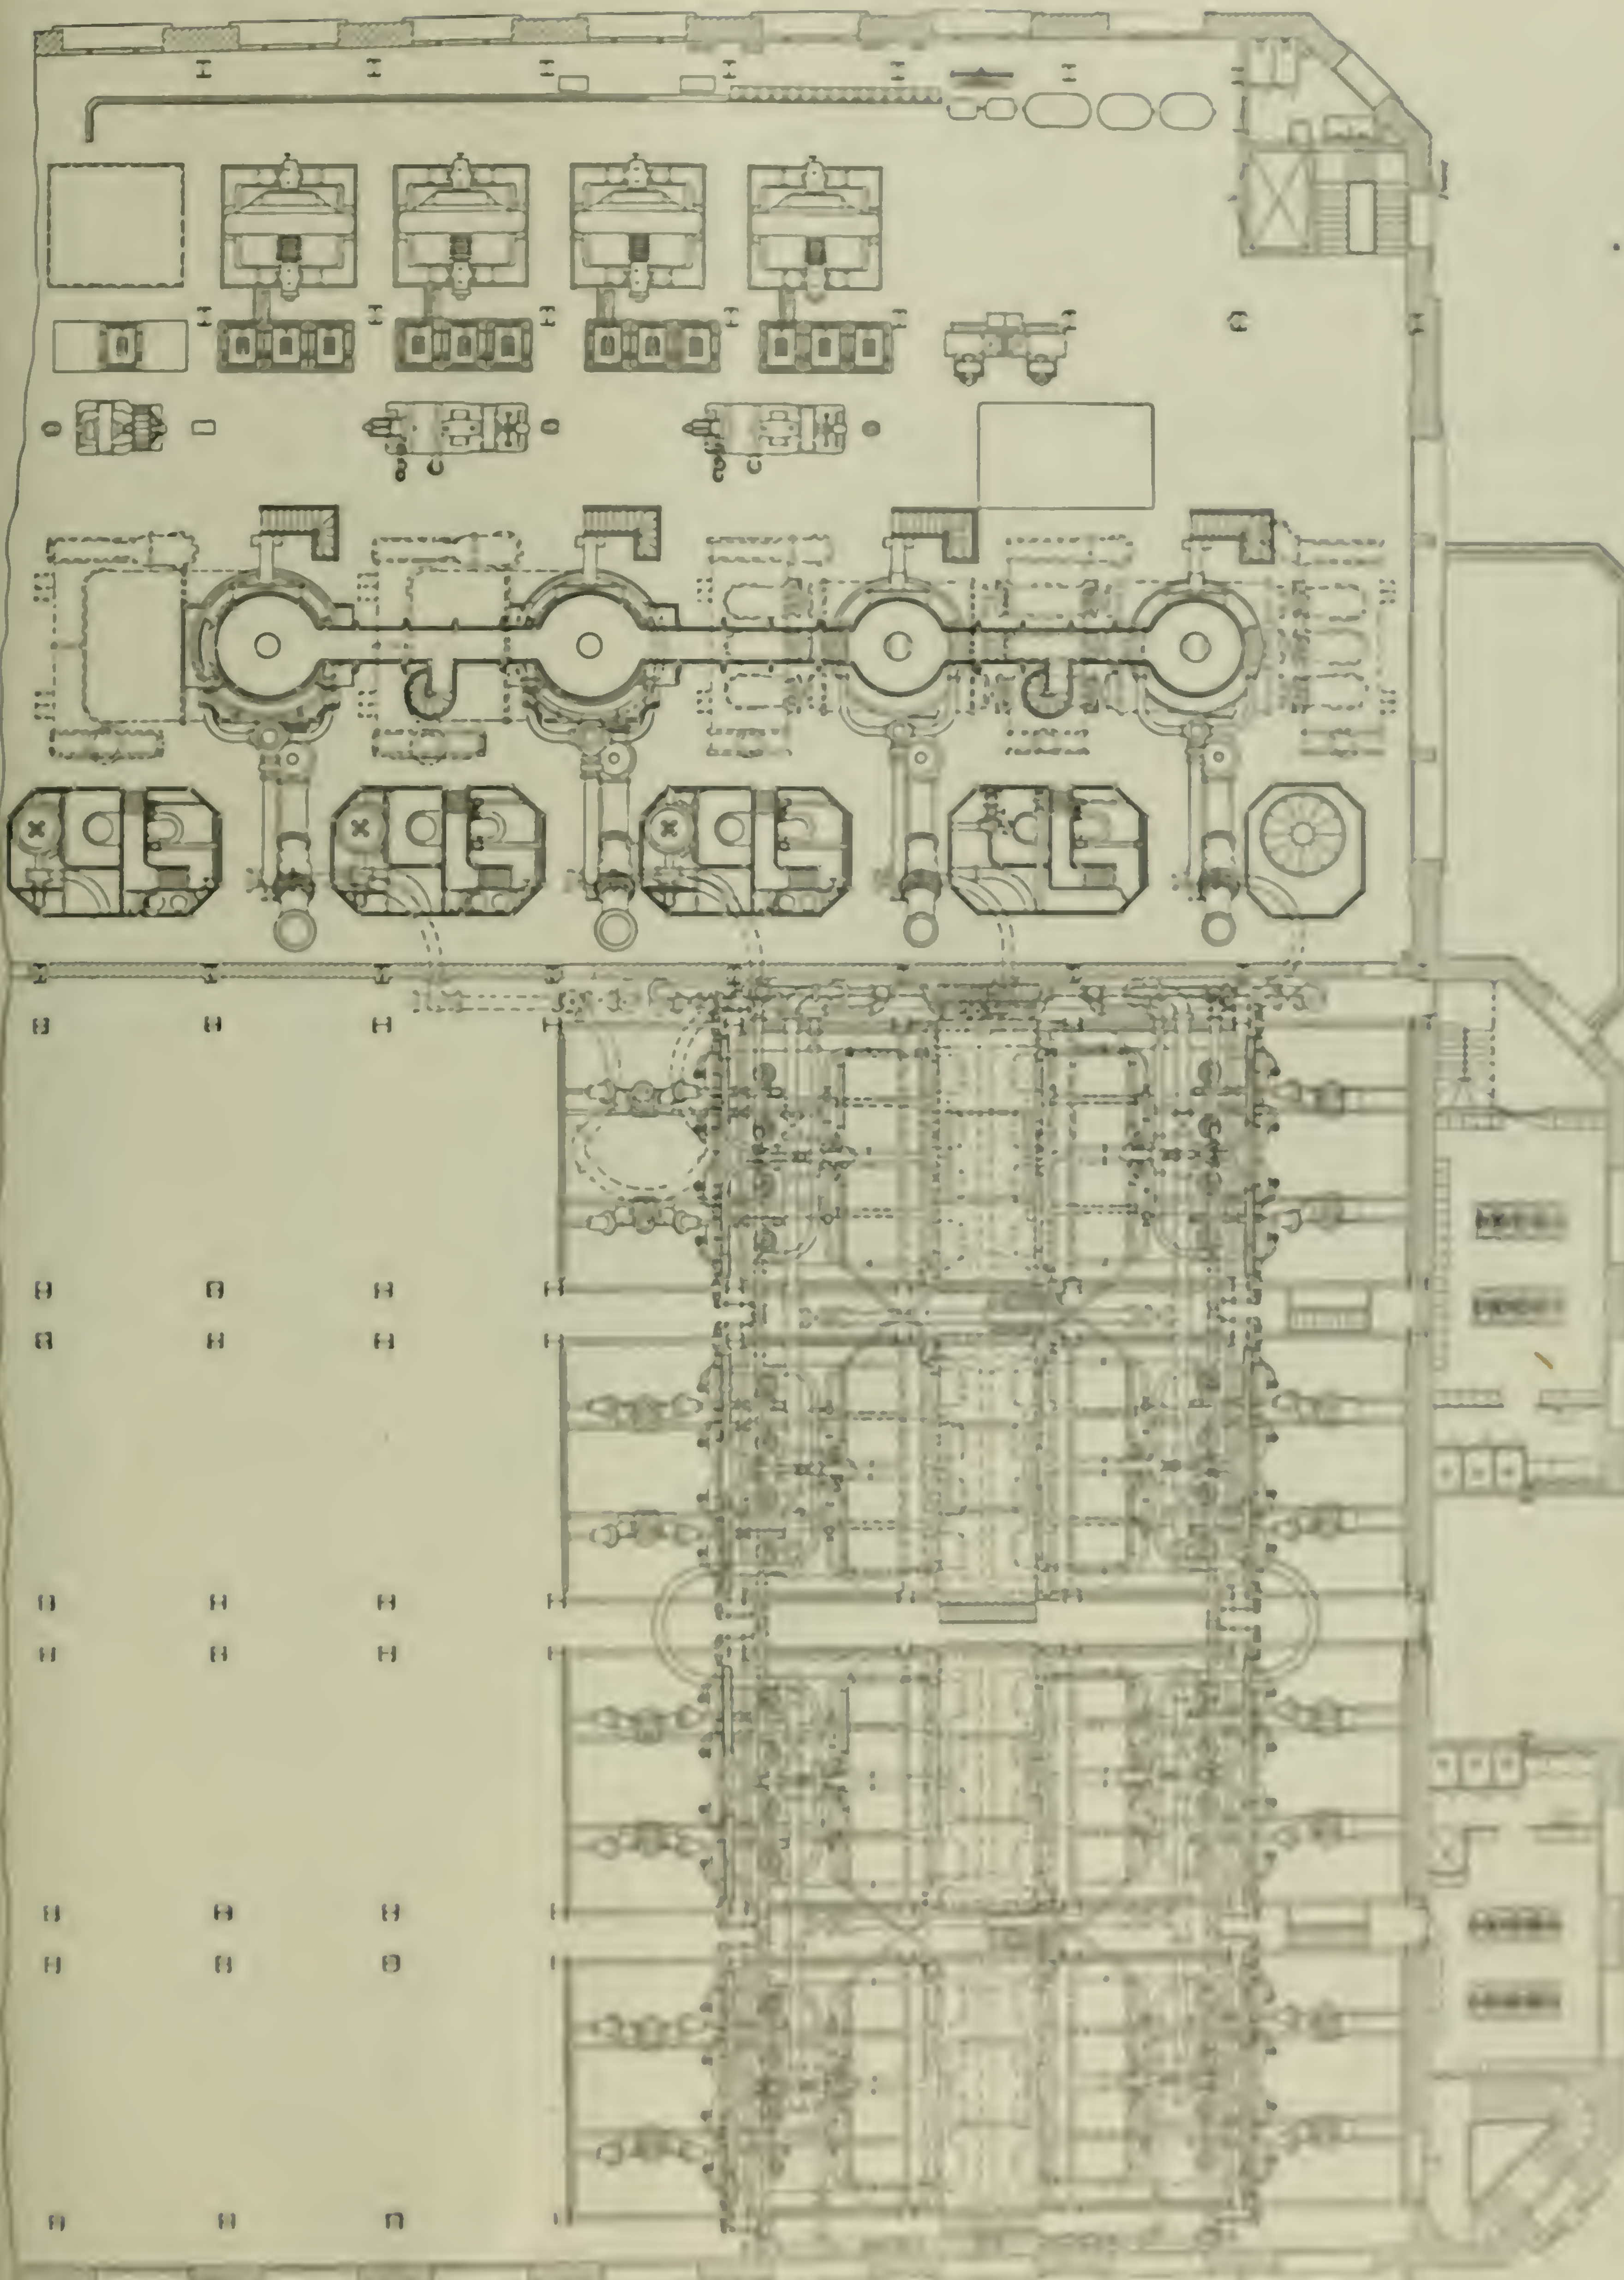

Fig. 5. Plan View of Plant, Showing Arrangement of Boilers and Turbine-room Equipment

the right point to secure whatever space is desired.

The dead plate is protected with firebrick. The ledge on which the front edge of the grate rests is dropped several inches below the general level so that there may be always a considerable depth of fire at the front edge of the grate to resist the too liberal admission of air in the clear and having three sections of grates and three fire doors, as shown in Fig. 4.

When the fire is to be cleaned, the unconsumed fuel is pushed back onto the back half of the grate and the front half is dumped, after which the live coal is pulled forward onto the clean part and the rear section dumped. All of the untop part live coal. The cleaning is done between the peaks. The air pressure used is from ½ to ⅝ inch of water in the ashpit with a light load, and with ⅛ inch suction in the furnace. After the fire gets to be 4 or 5 inches thick it is blown with about 2 inches of pressure in the ashpit, which gives a balanced condition in the furnace. When the fire is

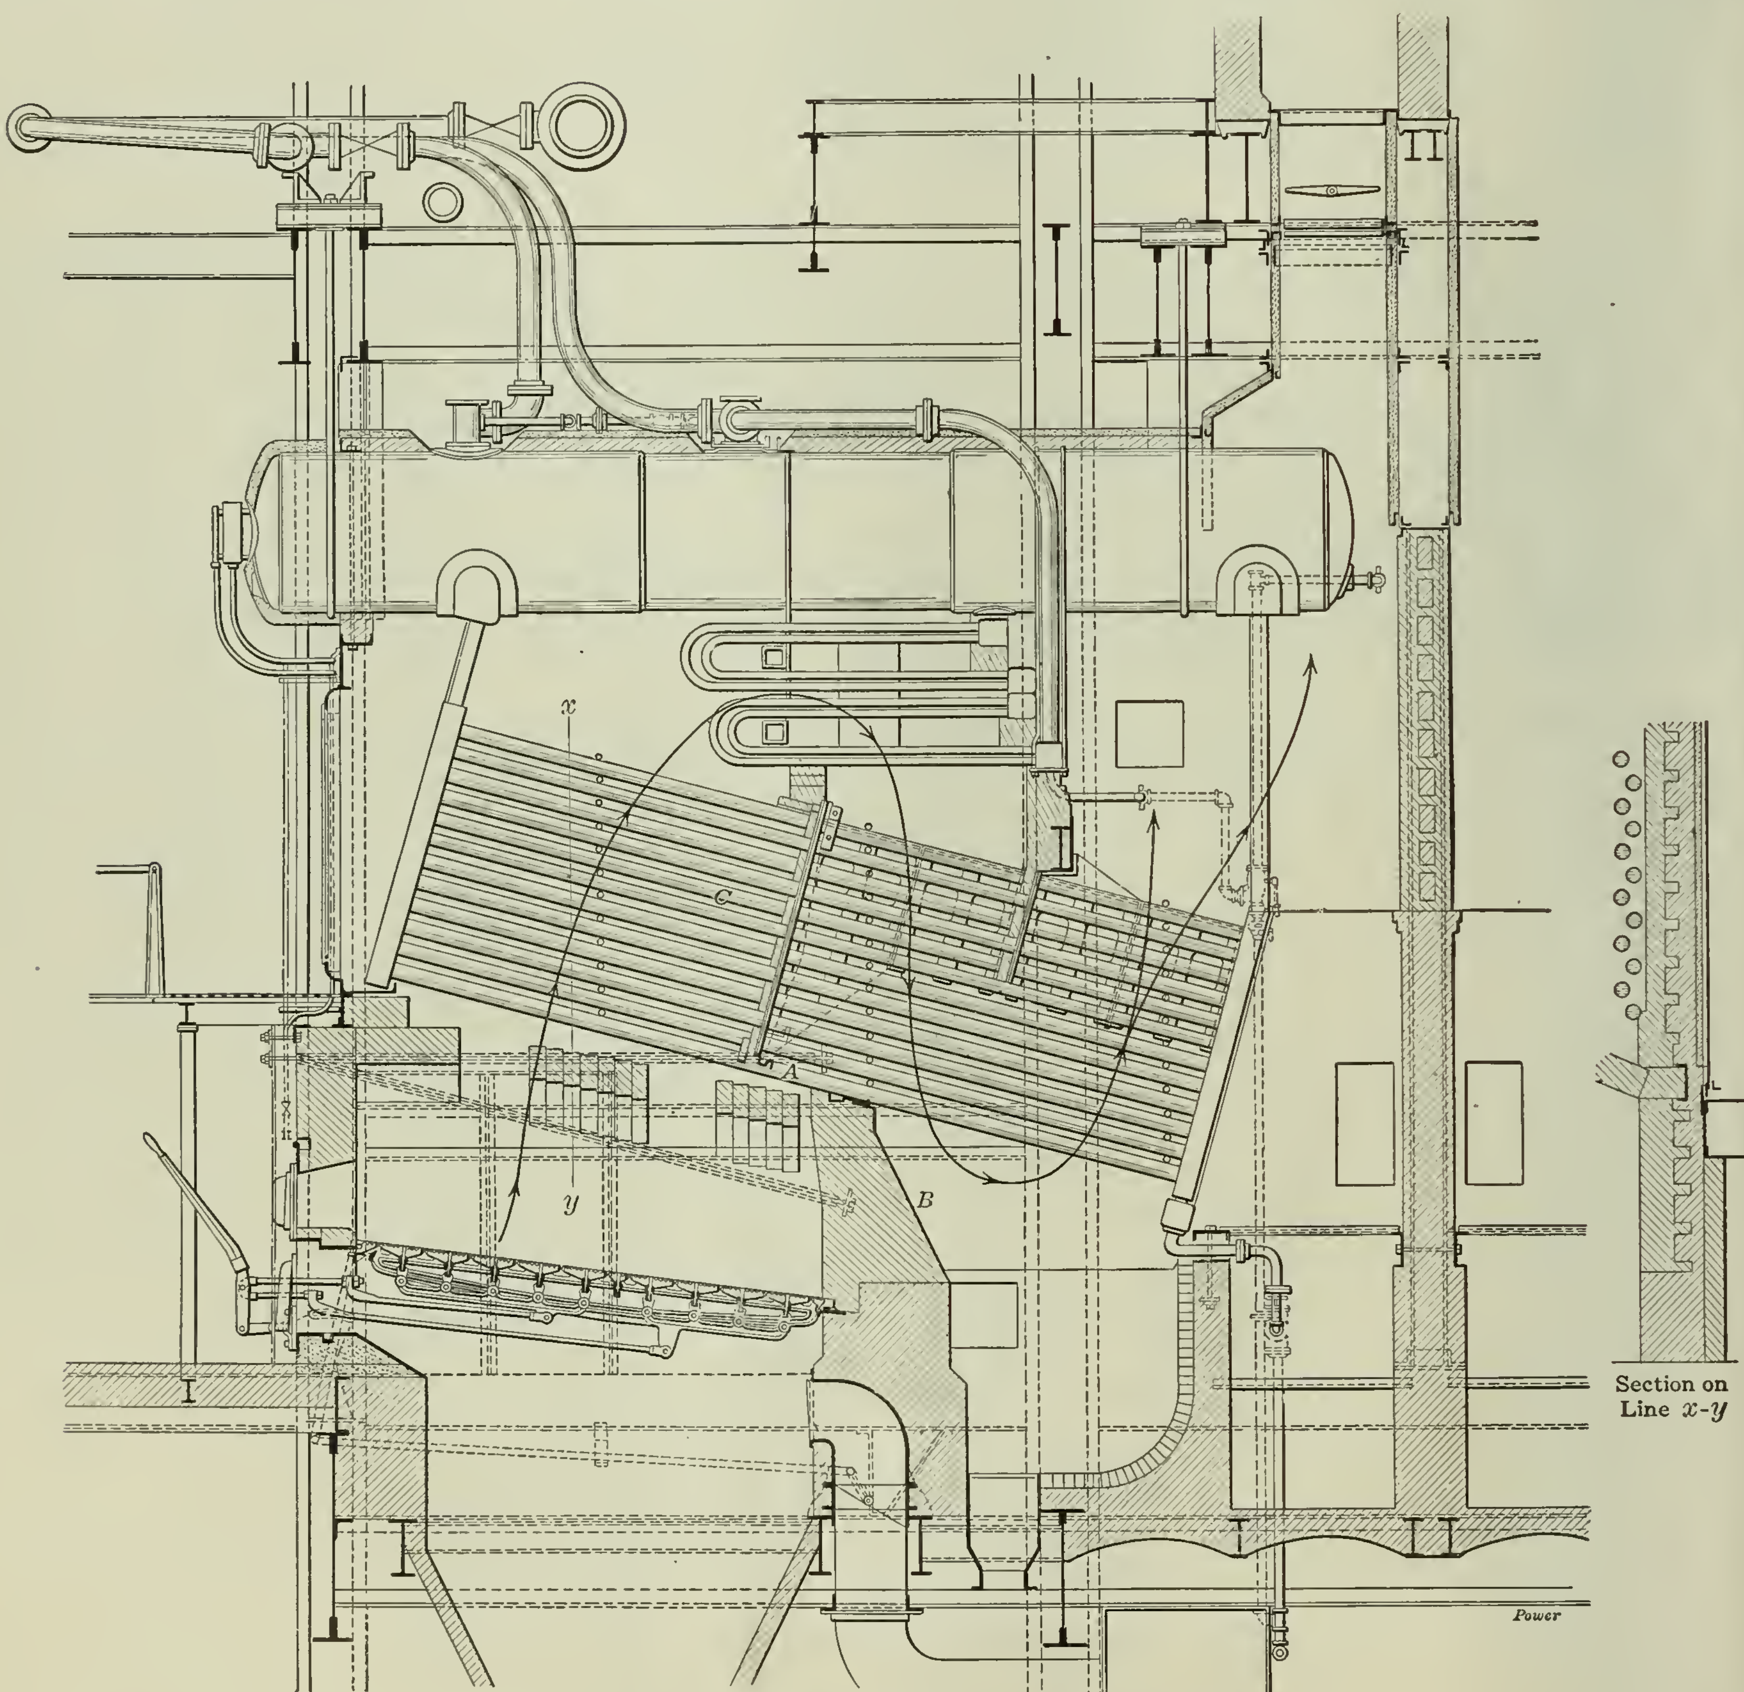

Fig. 6. Vertical Section through Boiler Setting

at this point without allowing the fuel to pile back into the doorways.

The grate is 10 feet in depth from the dead plate to the face of the bridgewall, made up as shown in Fig. 6 of five rows of bars dumping backward, the center tie and four rows of bars dumping forward. Each boiler is served by two furnaces separated by a division wall supporting the arches; each furnace being 10 feet deep by 9 feet 6 inches wide

consumed fuel is then distributed over the entire grate and fresh fuel added, all of which may be accomplished in less than two minutes. This is done separately for each furnace. Starting with this, perhaps 2 inches of live coal, the fires are allowed to build up until in the course of six to seven hours they will have attained a thickness of some 12 or 14 inches, two-thirds of which will be ash and only the at its thickest a blast of 2½ inches is used. The average rate of combustion is 25 pounds per square foot of grate and the maximum 36 pounds. At this average rate of combustion they are able to carry the load with five boilers in active operation with one banked in reserve for emergency.

In the report of the Committee on Power Generation presented at the recent meeting of the American Interurban Railway Engineering Association, C. E. Roehl mentioned the fact that practice is tending toward the reduction of the number of square feet of grate surface served by one fireman, and in turn increasing the rate of combustion which is expected of this fireman. In order to maintain a reasonable economy in the operation of a plant in which the hourly peak load is approximately two and a half times the average day load, it is absolutely necessary that the number of boilers in operation be kept down, so that the normal rating of the boilers will be approached during the light load of the middle day and night. Experience in this station shows that it is possible, roughly speaking, to obtain 1200 kilowatts from a fireman for a period not exceeding two and a half hours, and that the average fireman is as able to do this when shoveling this coal upon, say, 200 feet of grate surface as when shoveling the same amount of coal upon 100 square feet. It would, therefore, seem quite feasible to operate a boiler containing 200 square feet of grate surface with one man during the period of light loads, during which that man will develop, say, 700 kilowatts, and continue the same boiler in operation through the peak loads served by two firemen. During the peak load each of these men would have to work harder than the one alone during the light loads, as more than twice the light load output would be obtained by the two men, or 2400 kilowatts. At present, this practice is approached as nearly as operating conditions will permit and has proved quite effective, those of the surplus hands that it is nec-

essary to keep on during the periods of light load being used in cleaning fires and doing the odd jobs that can best be done at that time. In this way the services of the firemen are used at their utmost efficiency and, as the load increases, an extra fireman can be put on who will simply work the hours of peak loads, receiving extra compensation in return for his split watch. This will probably give a lower operating cost for the boiler room than having the extra fireman stay during the entire watch at his normal rate of wage, as he can waste more coal in the hours when his services are not needed than the extra compensation given him for his split watch.

The pressure carried is from 180 to 185 pounds with 125 degrees of superheat. Each boiler has a separate Green economizer which heats the feed water to 240 or 250 degrees. The water is passed first through closed heaters, supplied with steam from the auxiliaries, and there is also an open heater at work in the construction plant for which the station also supplies power from which a considerable quantity of hot water is returned.

In addition to the railroad load there are nine air compressors taking steam equivalent to about 1000 kilowatts. The turbines require 13.5 pounds of steam per kilowatt-hour of themselves, and 17.5 including the auxiliaries.

The cost of operation has been running down steadily since the plant was started, as shown by the chart in Fig. 7, and has reached the remarkably low figure of less than 0.42 of a cent per kilowatt-hour for current at the switchboard, including the cost of water, supplies, wages and coal. The No. 3 buckwheat costs about 43 per cent. less at the conveyer siding of the station than No. 1 buckwheat coal. One of the units is fitted with a Venturi meter, Richardson coal scales, Westover CO_2 recorder, etc., and produced upon test the results in the accompanying table, the test being made with No. 3 buckwheat and with the alternate method of starting and stopping, as recommended by the Boiler Testing Code Committee of the American Society of Mechanical Engineers.

For the data and information contained in this article we are indebted to E. T. Munger, general manager of the Hudson & Manhattan Railroad Company.

Vacuum for Reciprocating Engines

In a recent paper upon the economical working of reciprocating marine engines, Mr. Morison contends that it is advantageous to run at as high a vacuum as possible. Mr. Weir takes issue with this assertion and places the maximum economical vacuum at 25 inches with triple- and quadruple-expansion marine engines.

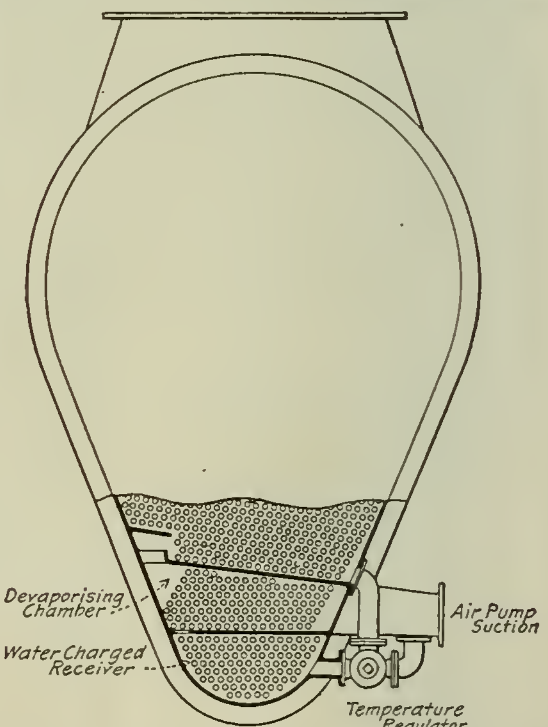
In a paper read before the Northeast Coast Institution of Engineers and Shipbuilders on November 25, D. B. Morison, whose words upon the subject of condensers have come to have more than ordinary importance, attributed the usual practice of carrying a low vacuum with triple- and quadruple-expansion marine engines to the fact that it produced a high temperature of air-pump discharge water. This practice is associated with the assumption that any vacuum above 25 inches in the condenser is a source of waste, while a few inches less works no difference as the feed water becomes just so much hotter.

In support of the contention that the power increases and the steam consumption per brake horsepower decreases with approximate uniformity up to the highest vacuum that can be reasonably carried on a steamship, Mr. Morison quoted the result of some investigations by Mr. Willans which showed that with a central-valve compound engine, the consumption per brake horsepower decreased with an increase of vacuum, at the rate of 1 per cent. per inch up to 27 inches vacuum. Referring to land practice, tests by Messrs. Belliss and Morcom showed that in a triple-expansion high-speed engine, the increase in steam consumption per brake horsepower was at the rate of 1.77 per cent. per inch of decrease in vacuum, from 28 inches down to 21.5 inches.

It was pointed out that the first essential in any condenser is a disposition of the surfaces such as will result in the greatest over-all efficiency; but the mere fact that a condenser has a large surface per horsepower is no criterion of its condensing capacity, because much of this may be ineffective. It is the treatment of the air in a condenser which is so vital to its efficiency, and from this point of view that condenser is the best which provides the air pump with air at maximum density.

Air-pump efficiency is a governing factor in any condensing plant, and in ordinary reciprocating engines the quantity of air leaking into the system is considerable. Tropical sea water also has a highly prejudicial effect on air-pump capacity by reason of the smaller difference in temperature of the water flowing through the tubes and that of the aërated vapor outside the tubes in the lower part of the condenser. This fact is largely responsible for the great fall in vacuum that invariably takes place in the tropics. Marine engineers accept its evil consequences as inevitable; but they are by no means inevitable, and can be overcome in an extremely simple manner. Many steamships trading in the tropics cannot carry more than 20 to 22 inches vacuum; but if the condensers were designed to carry 27 inches vacuum in the tropics and the engines were properly proportioned, together with adequate arrangements for feed-water heating, the saving would amount to about 10 per cent.

The air-withdrawing capacity of any reciprocating air pump depends upon the difference between the vacuum that can be produced in the pump barrel on its suction stroke and the vacuum in the condenser. It would obviously boil as soon as the pump buckets commenced the suction stroke, and the resultant vapor would impair the inflow of air from the condenser. Therefore, an air pump can be rendered flexible in air-withdrawing capacity by regulating the temperature.



SECTION OF CONDENSER, SHOWING WATER RECEIVER AND DIAPHRAGM

There are several devices on the market for accomplishing this. The condenser herein illustrated contains a divided receiver in its base, which is always completely filled with water of condensation. At a distance above this water receiver is a diaphragm which catches the water of condensation formed in the condensing chamber above it. There is a pipe connecting the top of the water-collecting diaphragm and water receiver, and in the pipe there is inserted a two-way cock; one way leads to the air-pump suction pipe and the other to the water receiver. If there is a clear way between the water-collecting diaphragm and the water receiver, all the water of condensation passes through the receiver and is reduced in temperature before it passes into the air pump. If, on the other hand, there is a clear way between the collecting diaphragm and the pump, all the water of condensation passes at a maximum temperature into the pump. The temperature of the pump and, therefore, its air-withdrawing capacity, is under complete control by the partial or full use of the temperature regulator. An extended experience has demonstrated that this simple apparatus will raise the vacuum in the tropics from 1½ to 3 inches, and often more, depending upon the amount of air prevailing; at the same time the air-pump discharge water is kept at the highest temperature consistent with the maintenance of the highest available vacuum in the condenser.

The air pump will withdraw air in maximum quantity only when the condenser delivers that air to it as free as possible from water vapor; therefore the interdependence of an air pump and condenser is obvious. The action of the one so influences the action of the other that both must be correctly designed if the available results must be realized.

Feed water in any steamship can be heated to the pumping limit by the available auxiliary exhaust steam, so that to ignore the economical possibilities of a high vacuum in the main engine and to work at a low vacuum in the condenser, with the sole object of obtaining a high temperature of air-pump discharge water, and then to throw away heat by deliberately discharging exhaust steam into the condenser because the feed water is already too hot to absorb it, is a system that involves considerable loss to the ship owner throughout the life of a ship.

Mr. Weir's Reply

In the December 9 number of *Engineering*, W. Weir takes issue with Mr. Morison, stating that after a careful perusal of the results of Mr. Willans' investigation he was unable to find any evidence that in a marine engine the steam consumption per brake horsepower decreases at the rate of 1 per cent. per inch of vacuum over 25 inches. Furthermore, Messrs. Belliss and Morcoms' figures show that from 21.5 to 25 inches the total economy was 1.3 pounds, or 2.8 per cent. per inch, while from 25 to 27.0 inches, the total economy was 0.3 pound, equivalent to 0.78 per cent. per inch—a very notable difference. He also charges an important omission in considering these latter figures in the fact that the reader is left to assume that the figures given represent the actual difference in economy, whereas they must be corrected for the cost of obtaining the relatively high degree of vacuum.

As regards the power required for the air pump, this can be omitted, as it will be practically the same for a 25-inch vacuum as for 28 inches, but for the latter condition, twice as much circulating water must be pumped as for the former. Figures are quoted to show that with the best type of high-speed engine for utilizing low terminal pressures, the actual saving in water consumption with vacuums over 25 inches may be 1.47 per cent. as a maximum. This, however, is more than counterbalanced by the extra power required for circulating water, together with the thermal loss due to the low hotwell temperature. A hotwell temperature of 124 degrees associated with a vacuum of 25 inches easily prevents the absorption by the feed water of all the steam from the auxiliary apparatus in the plant.

Features of Plant at Kodak Park Works

By A. R. Maujer

The features of the plant at Kodak Park works which are of more than ordinary interest are tallest chimney in New York State, motor driven boiler-feed pumps and a system of oil storage which reduces the waste of oil to the minimum.

The large steam-power plant which serves the great manufactory, Kodak Park Works, of the Eastman Kodak Company, located at Rochester, N. Y., where photographic film, paper and dry plates are manufactured, possesses some features of more than passing interest.

Chimney

Perhaps the most conspicuous object about any steam-power plant is the chimney. In this instance the chimney is especially conspicuous due to its great hight and fine design. It is 366 feet high, the tallest chimney in New York State. The object in making the chimney so high was, not so much to secure a strong draft as to carry off the acid fumes from the plate-coating departments and discharge them into the atmosphere at such a hight that they become well diffused before they can sink back to the ground level. The chimney is built of radial brick and contains an acid-proof brick lining throughout its entire hight. The inside diameter of the chimney is 9 feet. The present boiler capacity is approximately 5000 horsepower. Owing to an enlargement of the works an addition of about 3000 horsepower is to be made to the boiler equipment. To take care of this additional boiler capacity another chimney of the same hight but having an inside diameter of 13 feet has just been completed. This increases the capacity by 125 per cent. Both chimneys were erected by the Alphons Custodis Chimney Construction Company.

Electrically Driven Boiler-feed Pumps

Another interesting feature is the two electrically driven boiler-feed pumps. The pumps are of the Deming triplex single-acting type. The larger one is 9x10 inches in size and the smaller one, 7x8 inches. The speed at which they can vary is from 20 to 40 revolutions per minute; under normal conditions they operate at speeds of 25 and 30 revolutions per minute respectively. The larger pump is driven by a 35-horsepower Three Rivers Electric Company motor, the smaller one is driven by a 10-horsepower Rochester Electric Company motor. The pumps are designed with a double gear-and-pinion drive which tends to make the torsion in the crank shaft uniform and cause the pumps to run smoothly and efficiently. The motors have field control for varying the speed. The ratio of variation is 2 to 1. The pumps are provided with relief valves on the discharge pipes having outlets to the floor. When a rise in pressure causes the relief valves to open and thus indicate that there is trouble somewhere in the system, the discharge of water onto the boiler-room floor quickly attracts attention and the pumps are slowed down. The pumps have just been fitted with automatic pressure-regulated electric controllers so that the speed of the motors will be regulated according to the pressure. A set of steam pumps having the same capacity as the electrically driven pumps is maintained as an emergency equipment.

The smaller of the electrically driven pumps has been in continuous service for three and one-half years and the larger one for two. During these periods neither has gone out of service through accident or sudden failure. The average temperature of the water handled by the pumps is 210 degrees Fahrenheit; the boiler pressure against which they pump is 140 pounds. After passing through the pumps, the feed water goes through economizers and thence to the boilers. The larger of these pumps was illustrated in the September 27, 1910, issue of POWER.

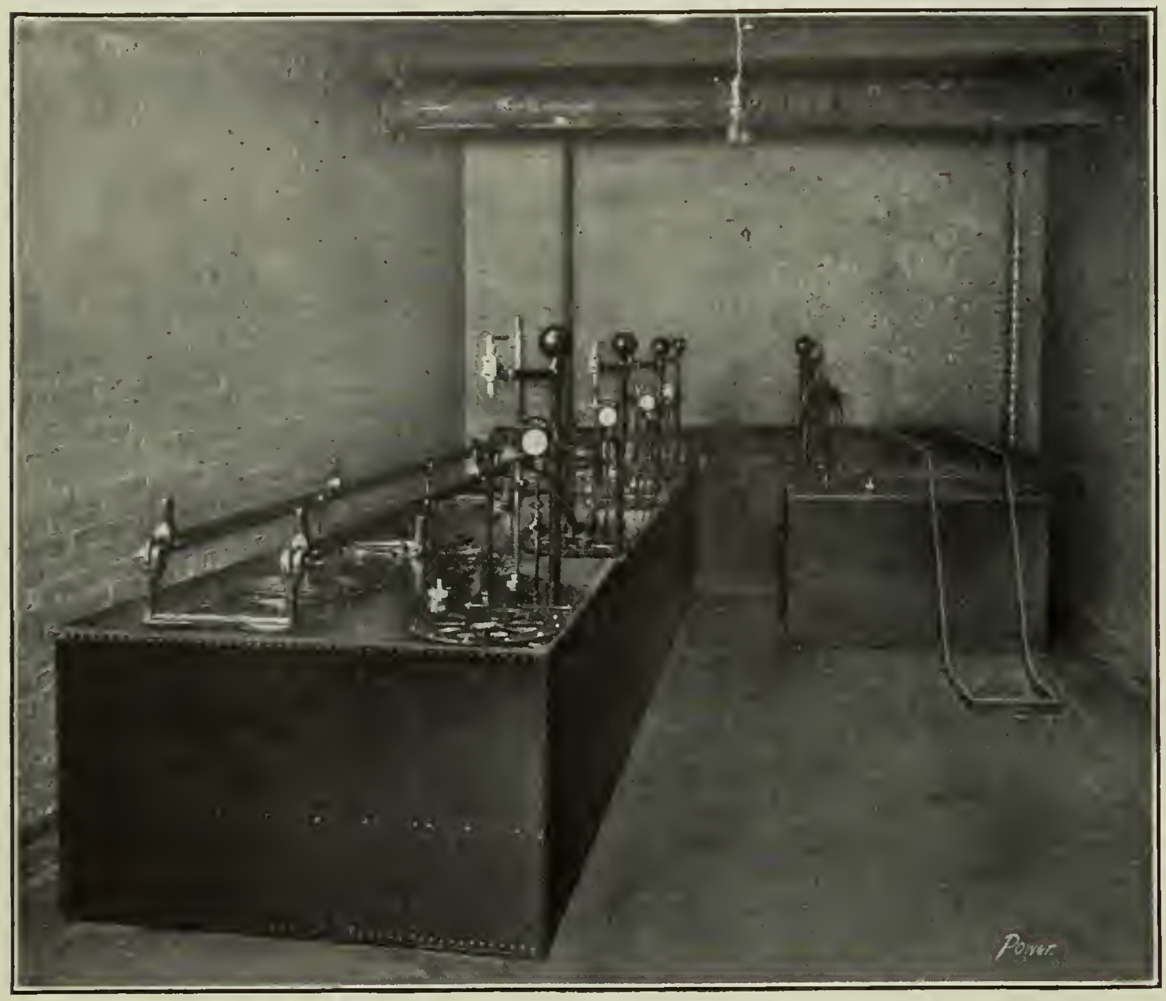


FIG. 1. OIL-STORAGE VAULT

OIL-STORAGE SYSTEM

Opening into the engine room is a brick and tile-lined vault which contains six self-measuring oil tanks manufactured by S. F. Bowser & Co. A view of the interior of the vault is given in Fig. 1. The vault is kept locked and oil may be obtained only by presenting a written order from the head of a department. Some such arrangement is highly desirable in a plant of this size and type where there are numerous departments in which various oils are used. If a rather close check were not maintained, the yearly expense for oil would undoubtedly be far above what it reasonably should be.

Each month a report is made out on a card of the form shown herewith. Thus the consumption of each department for

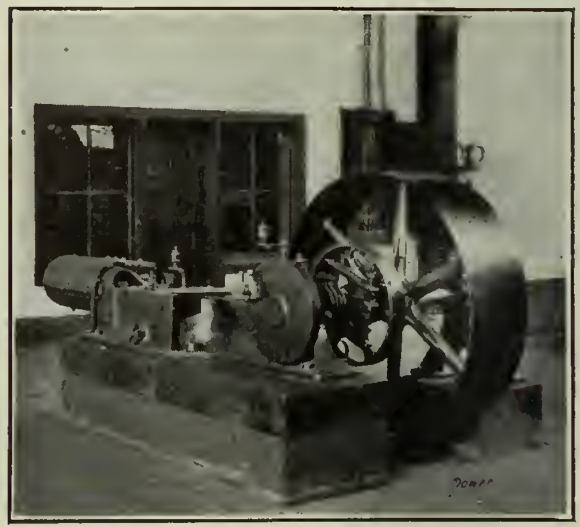

FIG. 3. THE ORIGINAL EQUIPMENT

each montn is placed on record in a convenient manner.

The arrangement of the tanks in the storage vault is convenient for filling the tanks and drawing the supplies. A barrel is rolled onto the cradle which is hinged to the barrel track. A tackle suspended from the ceiling is attached to the ring in the cradle, the end of the cradle is hoisted up and the barrel rolled off onto the track and around to the proper tank into which it is emptied through the manhole.

Oil is drawn from the tank by a plunger hand pump. One full stroke of the plunger discharges one gallon from the spout. A rod alongside of the plunger rod carries a number of adjustable stops. By turning this rod so that when the plunger is lifted, a projection on the

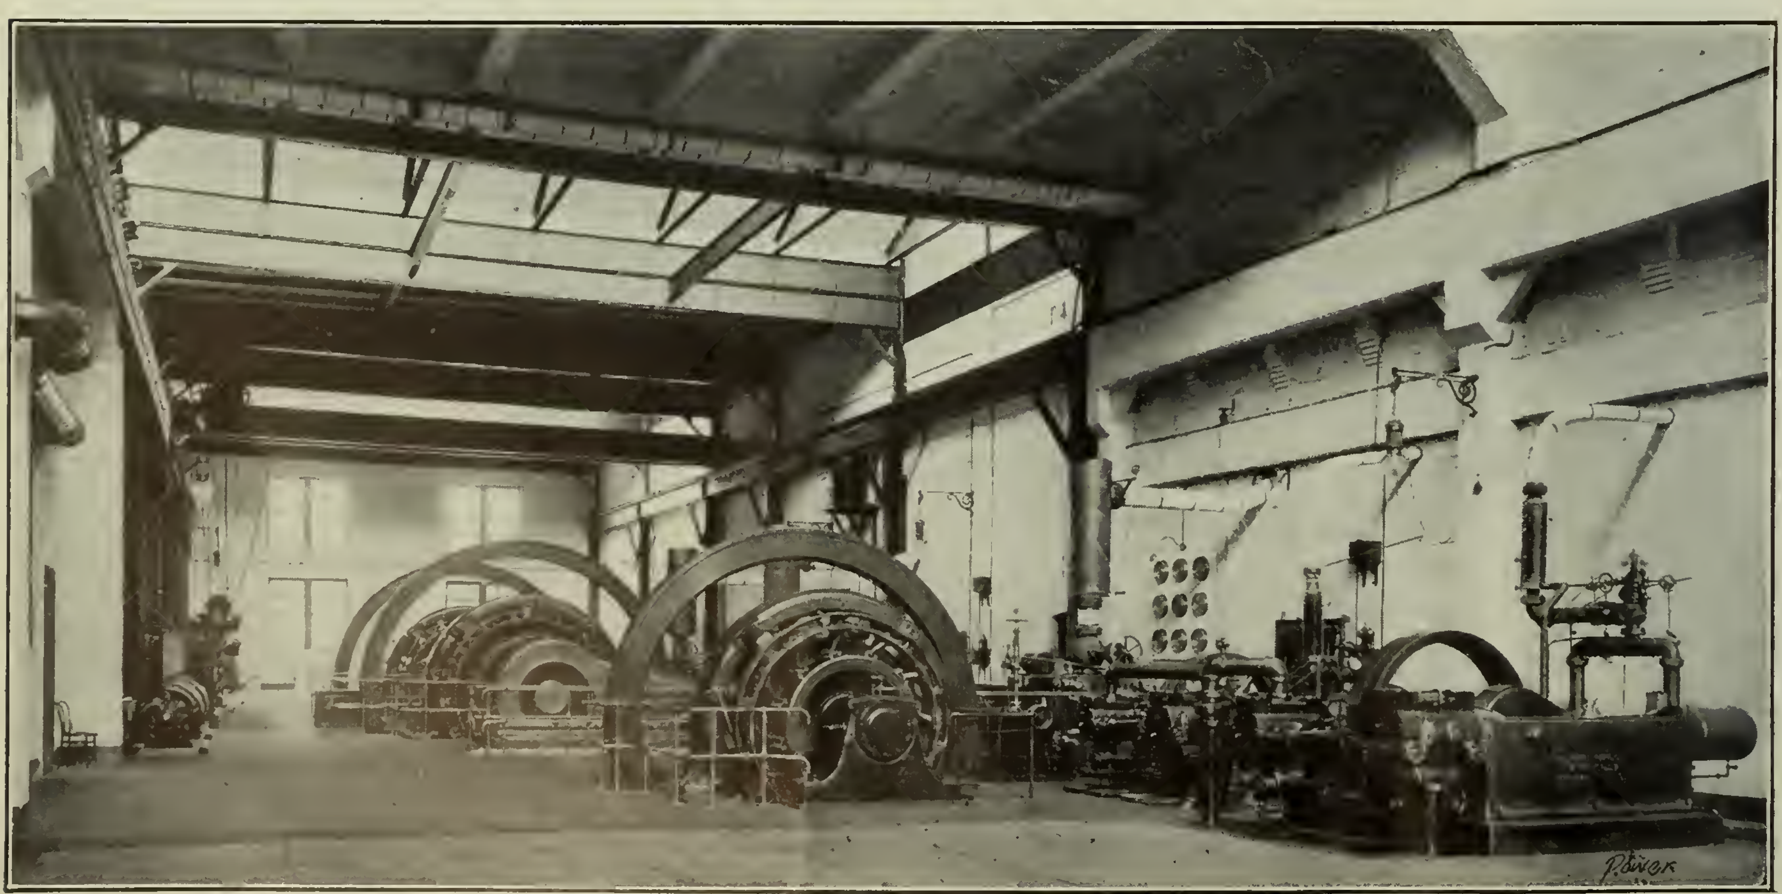

FIG. 2. VIEW OF GENERATING ROOM, SHOWING PRESENT EQUIPMENT

plunger-rod comes in contact with a given stop, the stroke of the plunger is limited and only a given fraction of a gallon is discharged. A registering device at the side of the pumping mechanism records the number of gallons successfully drawn.

A marked metal gage rod is provided in each tank so that the amount of oil still remaining in the tank can easily be ascertained at any time. Each tank has a capacity of 280 gallons. Two tanks contain cylinder oil, two contain engine oil, one contains kerosene and one, oil for the ice machines.

Original and Present Equipment

A general view of the engine room is shown in Fig. 2. The present equipment consists of two 500-kilowatt Crocker-Wheeler generators direct connected to Rice & Sargent Corliss engines, one generator of the same make but of 300 kilowatts capacity driven by an Allis-Chalmers Reliance engine and two Ingersoll-Rand duplex two-stage air compressors, one having a capacity of 530 cubic feet of free air per minute, the other, 710 cubic feet.

Because of the increase in the amount of power required, the capacity of the present equipment will be increased by the installation of a 1000-kilowatt generating unit, built by the Crocker-Wheeler Company. This unit will be driven by a 31 and 48 by 48-inch horizontal cross-compound noncondensing Corliss engine built by the Robert Wetherill Company.

In a separate building there are two York compression and six Isbell-Porter absorption ice machines of a combined capacity of 1020 tons per 24 hours. The refrigerating equipment will be increased by the installation of one 400-ton York compression machine, furnished by the York Manufacturing Company.

A relic of the small beginnings from which the present vast plant has grown is present in the engine room in the shape of the first steam engine used by George Eastman in the manufacture of cameras and supplies. The engine is shown in Fig. 3. It is 8 by 14 inches in size and ran at 275 revolutions per minute. The engine was built by the Buckeye Engine Company about 1885. It was used continuously until two or three years ago.

Some Testimonial Letters

More or less importance is credited to testimonial letters, according to the knowledge the reader has of how they were procured. Usually the party desiring a letter of this sort makes the request from several users of the device in question, and naturally selects the best for publication.

Some of these letters are indeed humorous when the literal meaning is taken. For instance, a certain water-purifying company recently sent out carbon copies of letters from satisfied users of their filter.

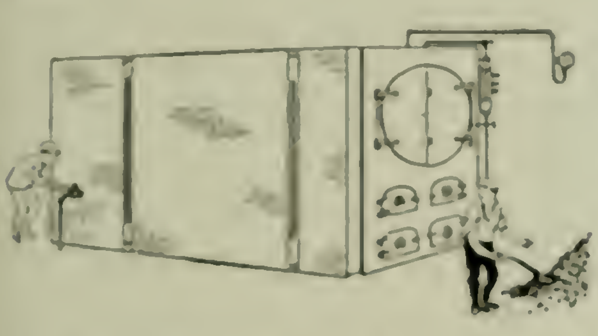

Fig. 1. Loose Scale Did Stunts in the Blowoff Pipe

One engineer writes in part as follows:

"No compound has been put in the boilers since water from the filter was turned on. The boilers were blown off twice a day as required and we could hear the scale rattling out the blowoff pipe."

It certainly looks as if the boiler had better be opened and cleaned, for if there is enough free scale in it to attract the engineer's attention as it passes through the blowoff pipe, it is about time the scale was removed by other methods.

Another engineer, since using the filtered water, states that "The boilers steam now in nine and a quarter against forty-five minutes before."

Getting up steam in forty-five minutes is going some, but generating steam in nine and a quarter minutes is a record and certainly speaks well for the filter.

> *Be careful how you read them. Don't jump at conclusions. The literal translation is frequently absurd.*

How about the boiler seams and tube heads?

Further on the same engineer says, "The purifier has accomplished everything claimed by them. It works automatically and requires no attention. We are now using water for drinking and washing purposes in our office and plant."

It is difficult to determine just what is meant by the above. Whether it is the purifier or the manufacturer that makes the claims, is not quite clear. The letter says it's the filter, but it must be a kind of filtered testimony.

The third sentence is enough to overcome the equilibrium of most readers,

Fig. 2. Used Real Water for Drinking and Washing Purposes

and cause them to wonder what liquid was used for drinking and washing purposes before the filter was installed. Most of us know that in breweries, Milwaukee and Cincinnati, water for drinking purposes is almost an unknown quantity, but it is not generally known that washing is performed with any other liquid than water. Oh, well, everyone to his own taste.

Still another engineer makes the following wonderful statement as to the results obtained from using filtered water:

"Never before had I seen the tubes of my boilers and shell as clean. Just nine and a quarter minutes after lighting the fire this boiler blew the safety valve off."

Nothing is said as to where the valve landed or how far it was blown. Truly these testimonials are most remarkable and convincing.

If there was anything under the sun which seemed to defy the old trite saying that there is a use for everything if you can only find it, it was the sudd of the Nile, that dense vegetable growth which is the continual bugbear of the Nile engineer and navigator. But now all that is to be changed; sudd is to become a commodity instead of a nuisance, and in time to come we may see its price rising in the market just as that of petroleum refuse rose when means of using it profitably as a fuel were found. What is to happen to the sudd is that it is to be conveyed to suitable machinery in which it will be dried, disintegrated and compressed into briquets suitable for consumption in steam boilers, in which it is expected to give an evaporation of about 4½ pounds of water per pound of briquet. When it is recalled that the present price of coal in Khartum is about $13 a ton, the possibilities of the new fuel are apparent. Experiments on a comparatively small scale have so far only been made, but there seems little doubt that in a short time sudd-briquet factories will be established on the banks of the Nile, and that the 20,000 square miles of sudd will become an Egyptian asset instead of an unmitigated nuisance.—Exchange.

Engine and Compressor Power Charts

By T. M. Chance

A graphic method of quickly determining the required dimensions for a given power, or vice versa, of a steam engine, gas engine or air compressor.

One of the most frequent calculations made by mechanical engineers is the horsepower of engines and compressors. When rough estimates of the power delivered by an engine of certain dimensions are hurriedly made, errors often occur from the improper use of the formulas or quantities under consideration. For example, it often happens that the number of revolutions is used as the value of the quantity N in the formula

$$\frac{PLAN}{33{,}000}$$

instead of the number of strokes per minute, and in a double-acting engine this gives a result only one-half as large as

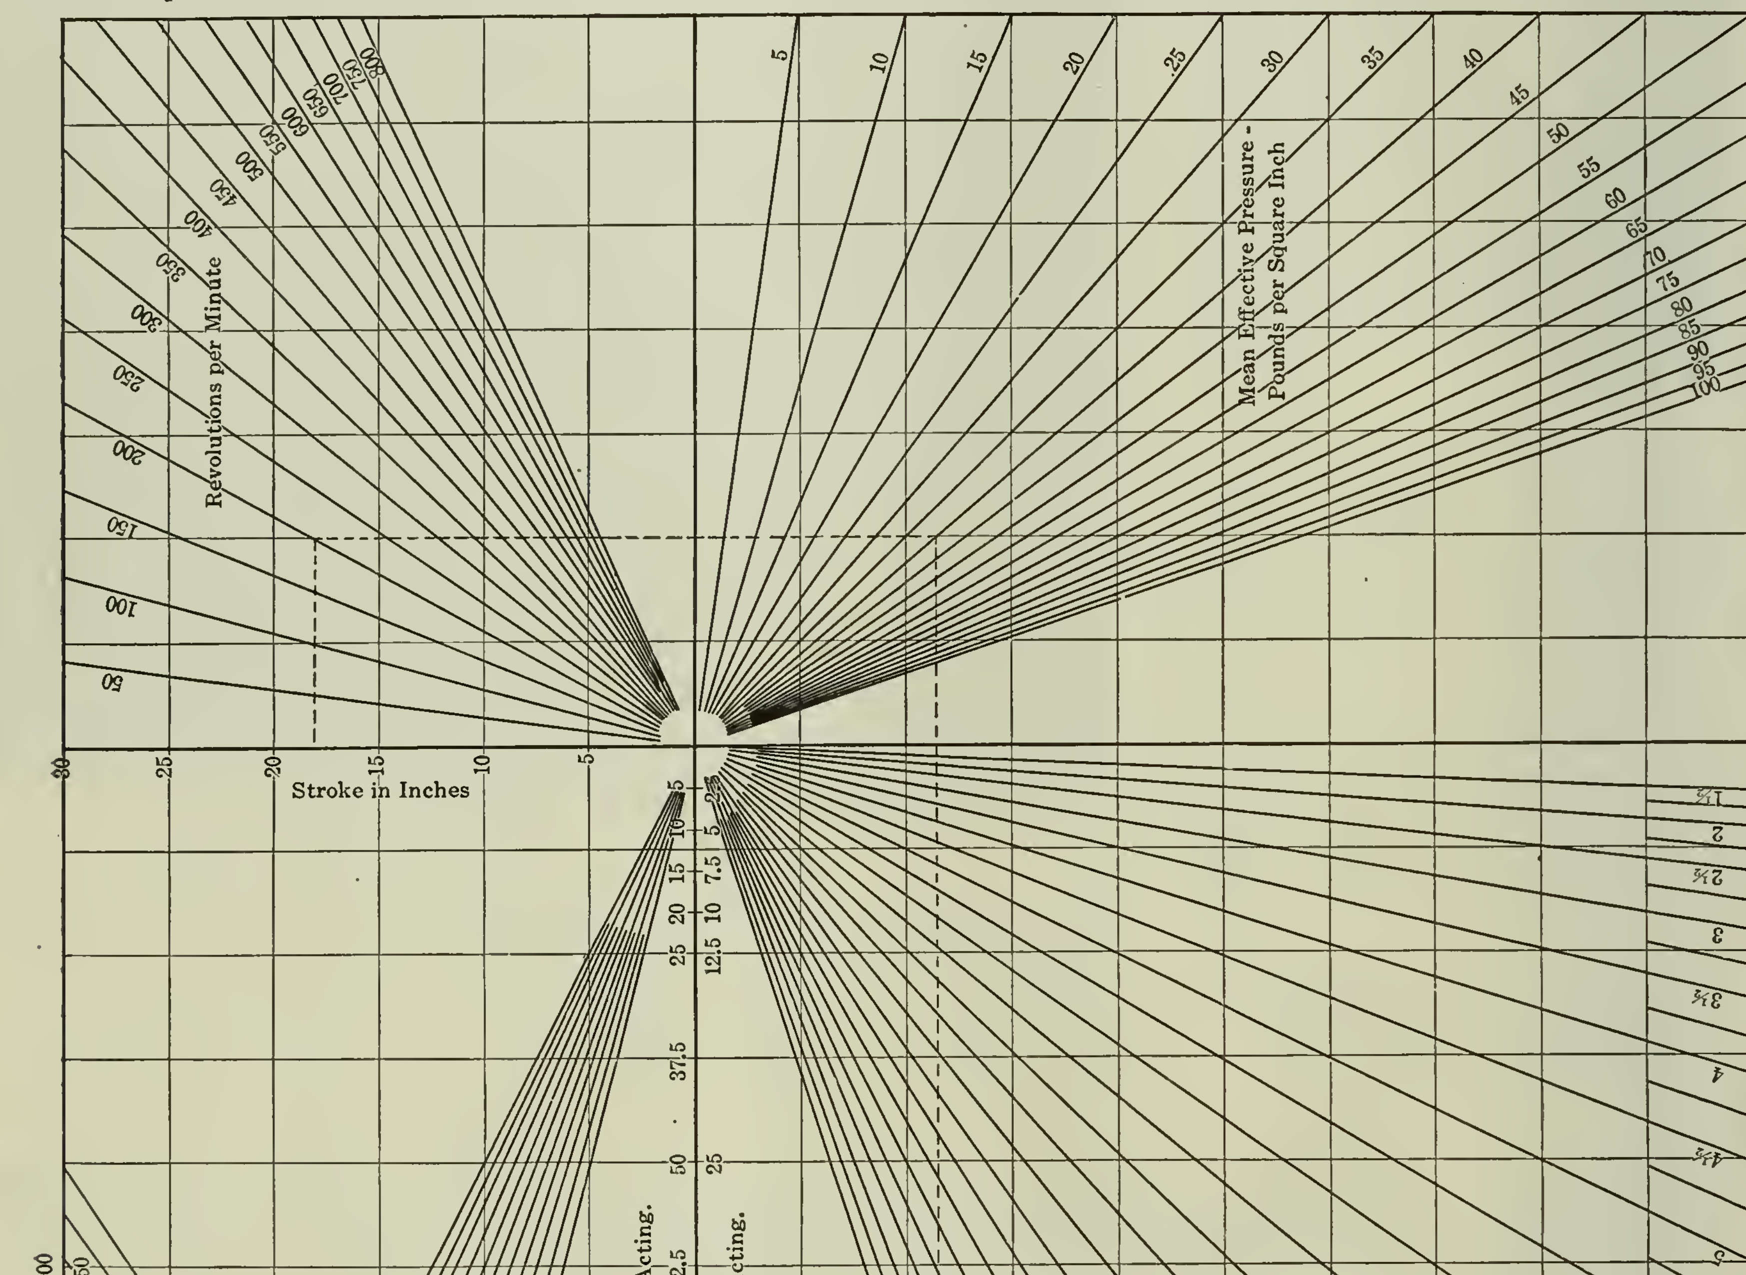

FIG. 1. HORSEPOWERS OF ENGINES UP TO 12½x30-INCH SIZES

that which should be obtained. Similar errors, as well as arithmetical inaccuracies not due to ignorance, are of common occurrence and may lead to large discrepancies in the subsequent result. It occurred to the writer that if a curve, or a series of curves, could be devised which would show at a glance the indicated brake and electrical output of an engine of any size, stroke, mean effective pressure and revolutions per minute, it would be exceedingly convenient and useful to engineers.

In the accompanying diagrams the horsepower rating is based upon the formula

$$\frac{PLAN}{33{,}000} = I.h.p.$$

Where,

P = Mean effective pressure in pounds per square inch;

L = Stroke in feet;

A = Area of the piston in square inches;

N = Number of strokes per minute (twice the number of revolutions).

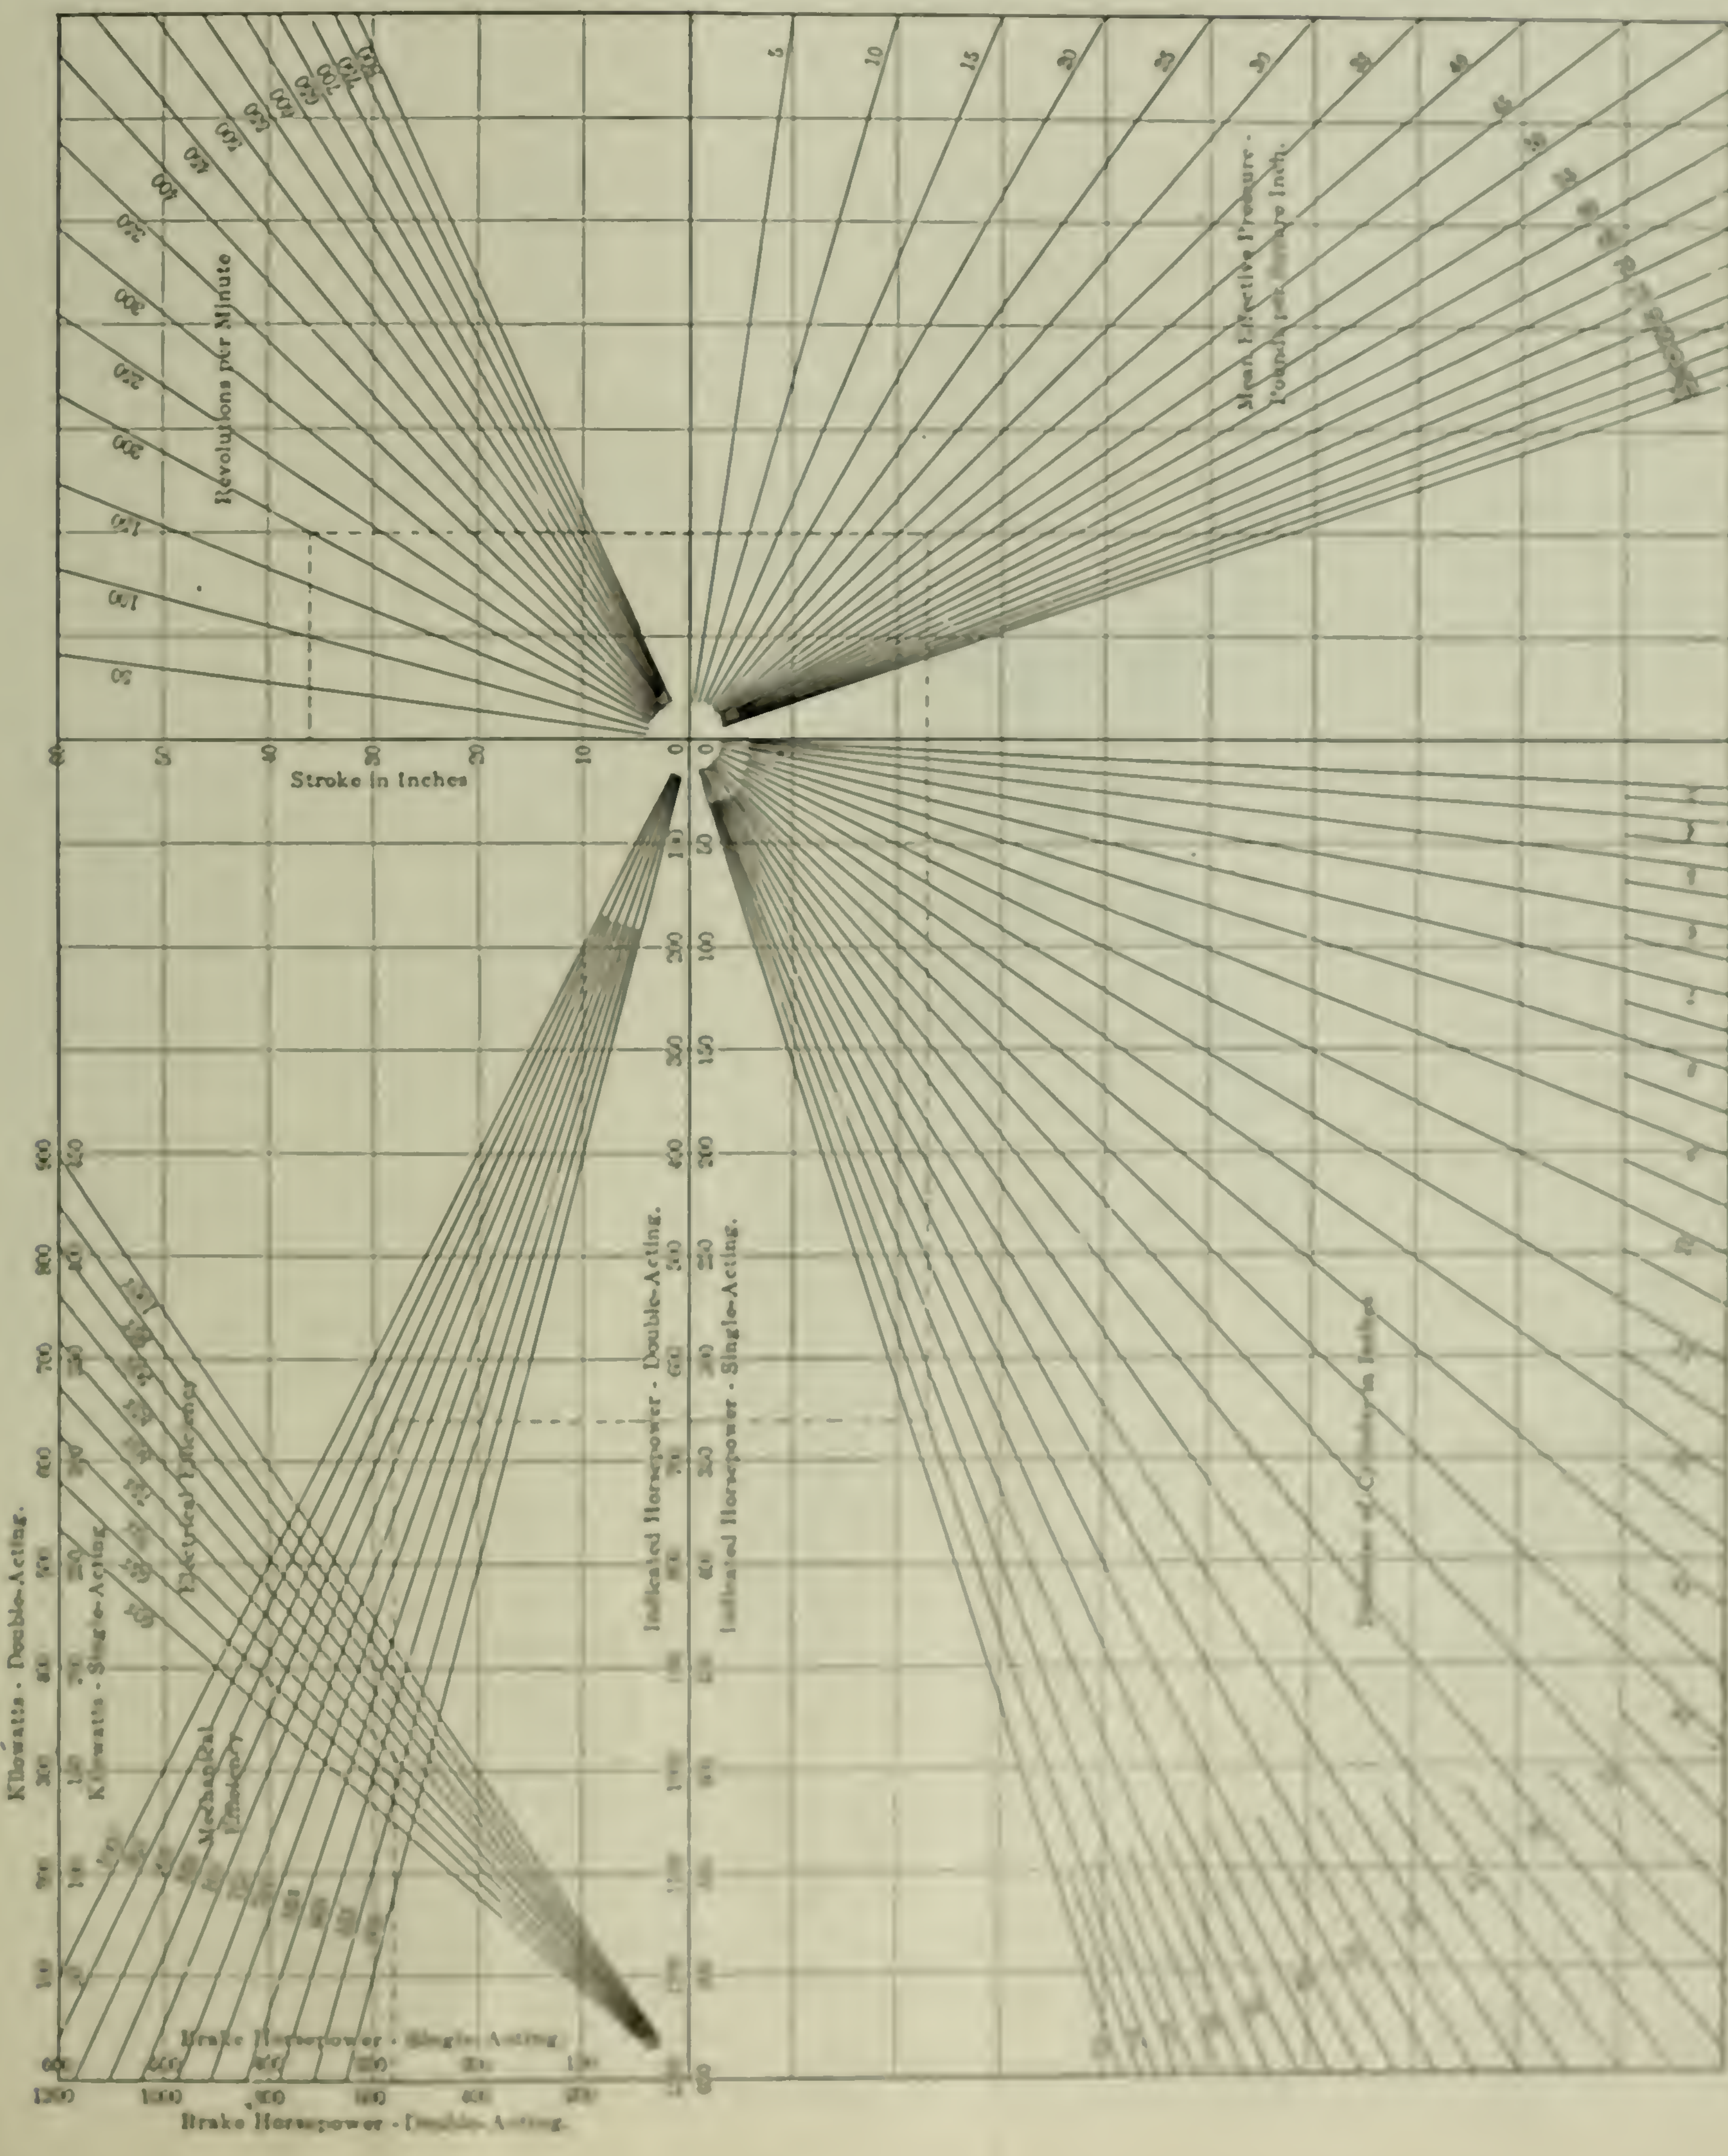

Fig. 2. Horsepower of Engines up to 25x60-inch Size

and,

I.h.p. $\times m =$ Brake horsepower;

B.h.p. $\times e =$ Kilowatt rating;

where,

$m =$ Mechanical efficiency of the engine,

$e =$ Total efficiency of the generator.

In the diagrams the stroke of the engine is laid off in inches instead of feet, and the diameter is similarly measured, the inch being the most convenient unit for this purpose. It should be noted that the horsepower varies directly with the area of the cylinder, that is, as the square of the diameter; hence, the diameters must be spaced proportionately to their squares, since they graphically represent the areas of the cylinders.

For the sake of accuracy in the smaller powers, the diagram has been prepared on three scales; Fig. 1 is to be used for engines up to 12½ inches cylinder diameter and 30-inch stroke; Fig. 2 includes engines up to 25 inches cylinder diameter and 60-inch stroke, and Fig. 3 deals with engines up to 50 inches cylinder diameter.

Referring to Fig. 1, suppose it is required to compute the horsepower of a 12x18-inch engine working under 40 pounds mean effective pressure and run-

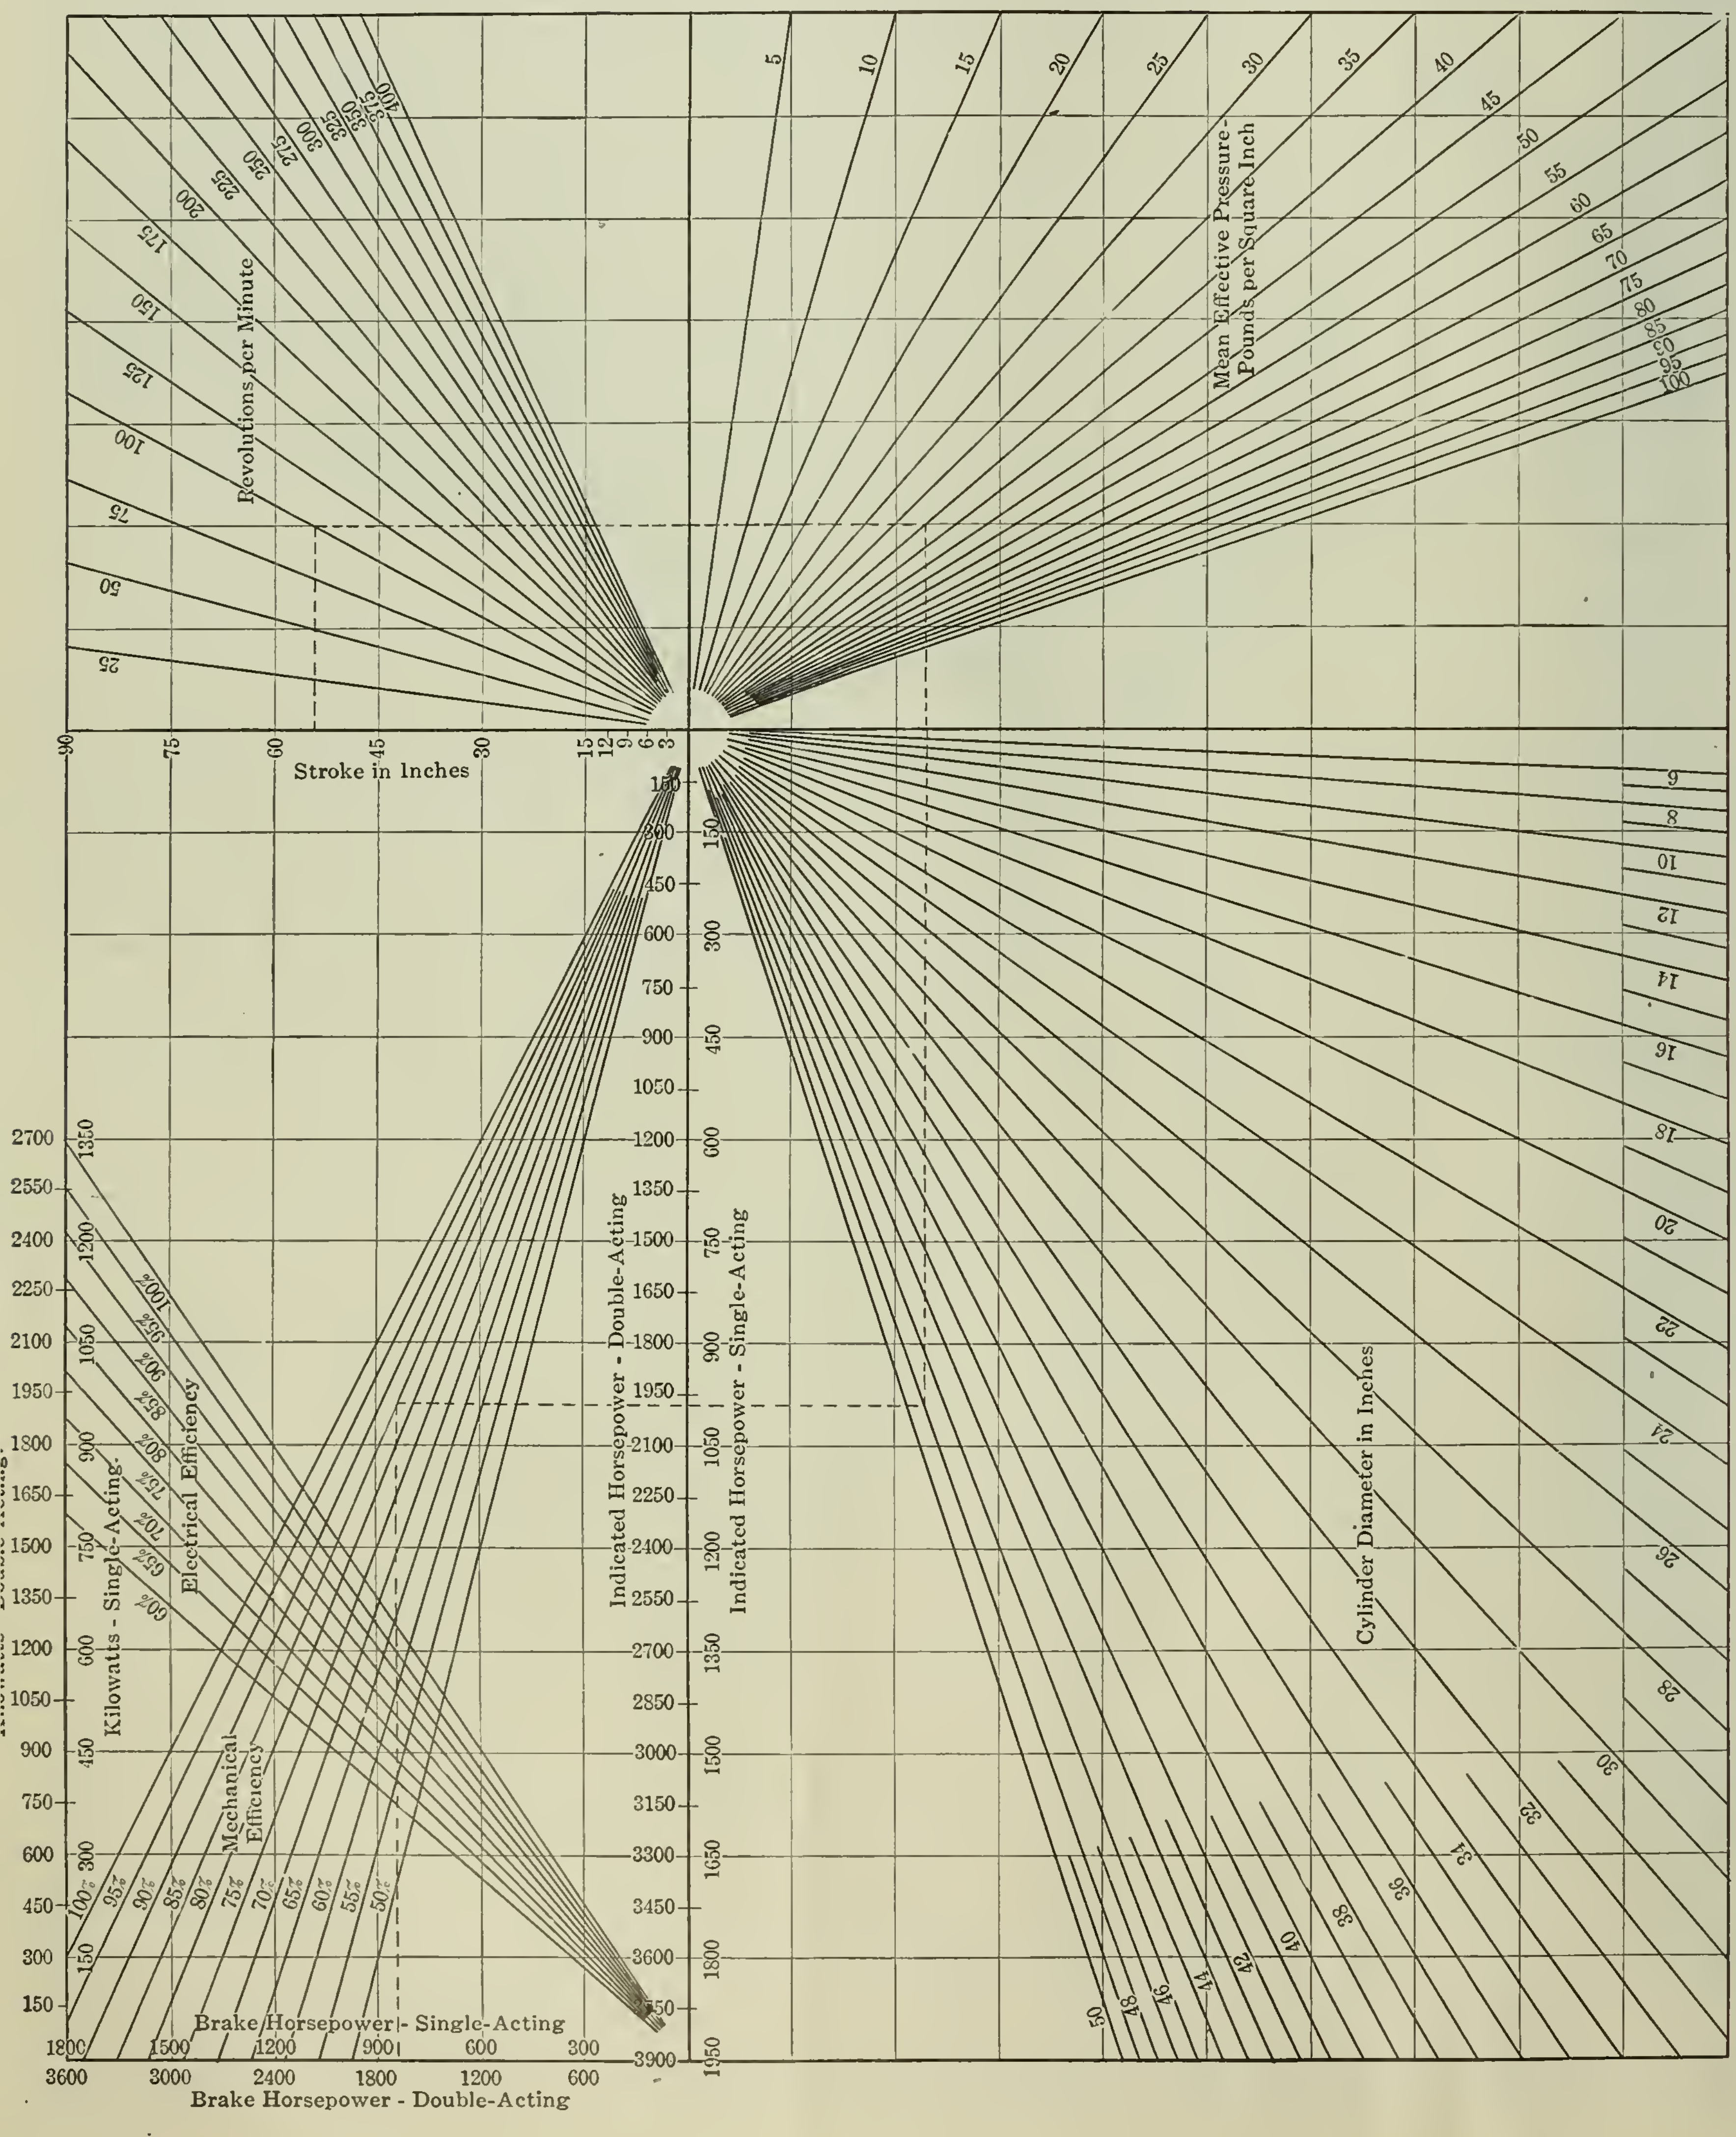

Fig. 3. Horsepowers of Engines up to 50-inch Cylinder Diameter

ning at 200 revolutions per minute, the dotted line indicates the steps taken in the solution of the problem. Reading up the scale of "Stroke in Inches" to 18 inches, follow horizontally across to the intersection of this line with the diagonal line marked 200 on the scale of "Revolutions per Minute"; from this intersection drop vertically downward until the diagonal line marked 40 on the scale of "Mean Effective Pressures" is crossed; follow horizontally across from this point to the line marked 12 inches on the "Diameter in Inches" scale and, running vertically upward from this intersection to the scale of "Indicated Horsepower, Double Acting," the result is found to be 82.5 indicated horsepower. If it is desired to find the horsepower of the engine running single acting, it will be found to read 41.25 indicated horsepower on the lower scale of "Indicated Horsepower, Single Acting."

If the brake horsepower and kilowatt capacity of the engine is desired, assuming 85 per cent. mechanical efficiency and 95 per cent. generator efficiency, read vertically upward along the 82.5 indicated horsepower line to its intersection with the diagonal line marked 85 per cent. on the scale of "Mechanical Efficiency"; the horizontal line passing through this point shows the brake horsepower to be 70 on the scale marked "Brake Horsepower, Double Acting." To determine the electrical output, follow vertically upward from the intersection of this horizontal line with the line passing through 95 per cent. on the scale of "Electrical Efficiency" and read 50 kilowatts on the scale marked "Kilowatts, Double Acting." The same use may be made of the single-acting scales for the brake horsepower and kilowatts output as was done in the case of the indicated horsepower.

Where refinement in the calculations is desired, the decrease in power due to the reduction in effective area of the piston on account of the piston rod and tail rod, if the latter is used, must be computed. This is easily done with these diagrams by considering the piston rod and tail rod as two single-acting engines having a cylinder diameter equal to that of the rods and working in opposition to the engine. When the piston rod and tail rod are of the same diameter they may be considered as one engine, running double acting. Therefore, if the decrease in power caused by the piston rod of a 100-brake horsepower engine amounted to 2 brake horsepower, the actual brake horsepower delivered by the engine would be 98.

The diagrams are also useful in calculating compressor dimensions. For example, a compressor is to be installed to develop 600 indicated horsepower; the stroke of the compressor is 30 inches, the mean effective pressure 40 pounds and the diameter of the cylinder 24 inches; find the number of revolutions. The dotted line in Fig. 2 indicates the steps taken in the solution of this problem. Starting with 600 on the scale of "Indicated Horsepower, Double Acting," drop vertically downward to the diagonal line marked 24 on the scale of "Cylinder Diameter in Inches." From this intersection follow horizontally across to the diagonal line marked 40 on the scale of "Mean Effective Pressures" and from this point run vertically upward to the intersection with the horizontal line passing through 30 inches on the scale of "Stroke in Inches." A diagonal line passing through this intersection and the common center of all the diagonal lines gives the number of revolutions, on the scale of "Revolutions per Minute," which in this case is 200.

The diagram may also be used to directly calculate the dimensions and power of gas or oil engines, if of the two-stroke type, as the horsepower of engines of this type is computed by the same formula as that used in steam-engine calculations; hence,

$$I.h.p. = \frac{PLAN}{33000}, \text{ for double-acting engines}$$

$$I.h.p. = \frac{PLAN}{33000 \times 2} \text{ for single-acting engines}$$

In the case of four-stroke engines the result obtained by the use of the diagram must be divided by two, as the four-stroke engine receives but half as many impulses as the two-stroke machine, during the same number of revolutions; that is,

$$I.h.p. = \frac{PLAN}{33000 \times 2} \text{ for double-acting engines}$$

$$I.h.p. = \frac{PLAN}{33000 \times 4} \text{ for single-acting engines}$$

When determining the dimensions of a four-stroke engine it should be remembered that the principal dimensions of a four-stroke engine and those of a two-stroke engine of twice the power are identical; hence, read twice the power of the machine under consideration on the horsepower or kilowatt scales and proceed as if the dimensions of a two-stroke engine of that power were being computed. The dotted line in Fig. 3 represent the procedure in the calculation of the dimensions or power of both a two-stroke engine of 1000 horsepower and a four-stroke engine of 500 horsepower.

Weighing Small Parts Accurately

By S. Kirlin

In machine shops, as well as in many other places, it is frequently desired to ascertain the exact weight of small pieces of castings, etc., and with the ordinary kind of platform scales generally used in those places it is impossible to weigh anything less than 5 or 10 pounds with any degree of accuracy. In machine shops especially, where the scales are used for weighing pig iron, heavy castings and subjected to the rough treatment usually given to them, it is practically impossible to weigh anything less than five pounds accurately.

Here is a method by which small parts weighing from a fraction of a pound up to several pounds may be weighed with extreme accuracy on almost any size of scales.

Slide the weight on the scale beam back to 0 and remove the weights from the beam in the same manner as when "balancing" them. Now, hang the small piece that is to be weighed on the end of the beam from which the weights were removed; next pile enough iron, or any other heavy material, on the platform until it just balances the small piece on the end of the beam. Now remove the small piece from the end of the beam and weigh the iron on the platform in the usual manner; divide this weight by the "ratio" of the scale and the product will be the exact weight of the small piece.

The "ratio" of the ordinary small platform scales is usually 100 to 1, that is, a weight of one pound on the end of the scale beam will just be balanced by a weight of 100 pounds on the platform. This ratio on larger scales may be 200 to 1 or greater.

Example: Suppose there is a small piece to be weighed; first remove the weights from the end of the scale beam, slide the weight on the beam scale back to 0 and see that the scales "balance." Now hang the small piece on the end of the beam from which the weights were removed and pile enough scrap iron on the platform to just balance the small piece. If the iron on the platform is found to weigh 175 pounds and the ratio of the scales is 100 to 1, then divide this 175 pounds by 100 and obtain 1.75 as the weight of the small piece. If the ratio of the scale was 200 to 1 it is obvious that it would have been necessary to place double the weight on the platform to balance the small piece. In this case there would have been a weight of 350 pounds, which divided by 200 gives 1.75 as the weight of the small part. This is extremely accurate even though the scales may be far from accurate in weighing anything less than 10 pounds in the ordinary manner.

I hear someone ask how you would go about it to find the ratio of the scales in case you did not know what it was.

This is easy. If you live east of the Missouri river, just lay your pound plug of "terbacker" on the end of the beam and see whether it required 100 or 200 pounds on the platform to balance it. Or if you are west of the above mentioned stream, where everybody carries a "Colt 45" (except when they go to church), you can use it for a test weight, as everyone knows that the regulation Colt "peacemaker" weighs exactly two pounds.

New Wave Motor of the Float Type

By A. R. Maujer
and Franklin Van Winkle

With this motor, by means of an ingeniously devised system of levers, power can be derived from every motion of the waves. Motor is governed by varying amount of submergence of floats, this being accomplished by compressed air which serves to force water out of a float to any extent desired.

The United States Wave Power Company is demonstrating on Young's "Million-dollar" pier, Atlantic City, N. J., the latest thing in wave motors. The ideas underlying this motor are most ingenious. By means of a system of levers and ratchet wheels advantage is taken of every motion of the water in sidewise and slantwise directions as well as in the vertical.

Fig. 1 is a general view of the upper part of the motor. Fig. 2 is a view under the pier, showing three of the floats which operate the machine. The motion and energy of the waves are imparted to the shaft *A*, Fig. 3, by means of mechanism which is the same for all floats; hence, a motor is divided into a given number of unit sections each composed of a float and the apparatus for converting the assorted motions of the waves into a rotary motion of the driving shaft.

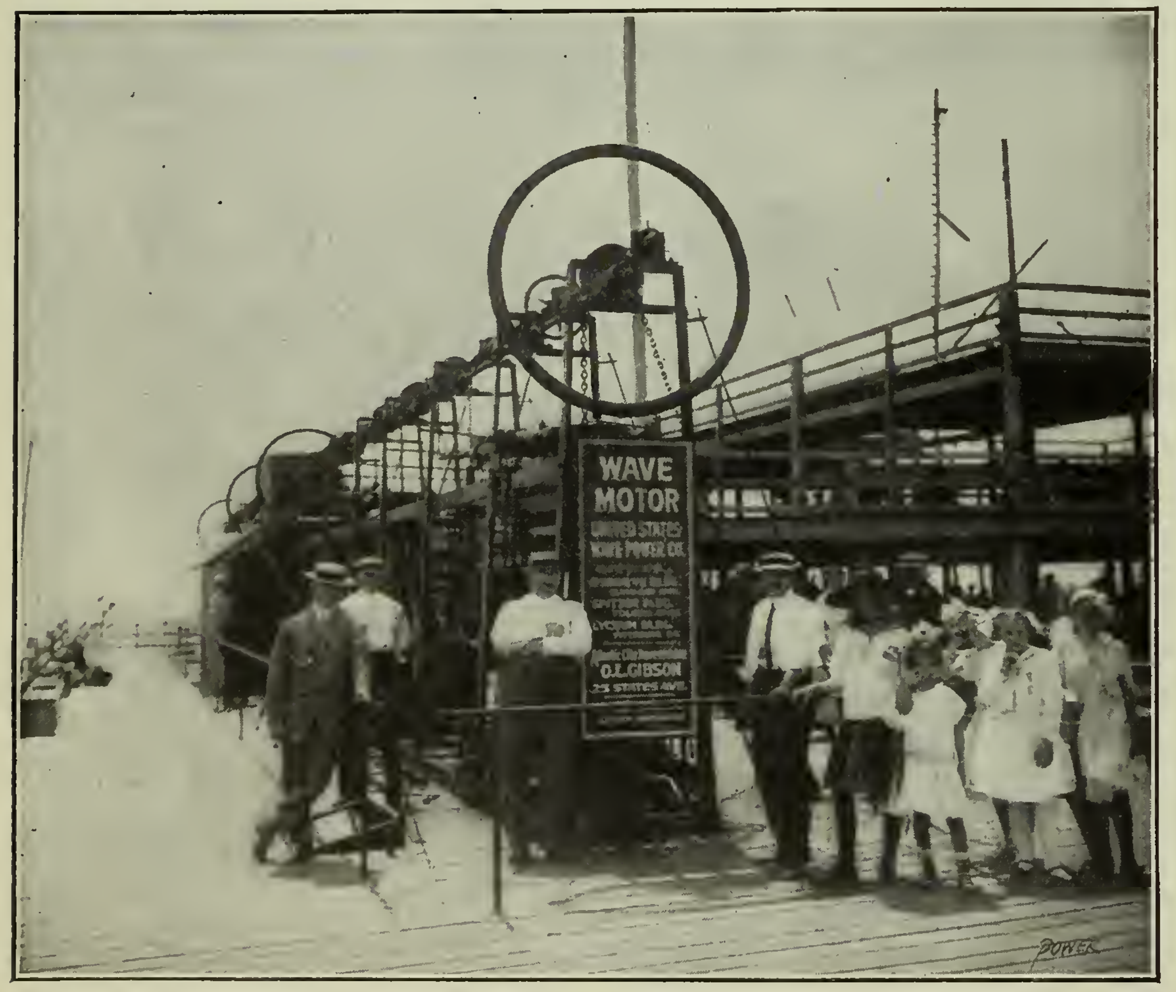

Fig. 1. View of the Entire Superstructure of the Wave Motor

The action of the machine may readily be understood by referring to Fig. 3. The float is free to slide up and down on the hollow rod *C* which has an open slot in one side. A lug at the top and one at the bottom of the float project through this slot into the core of the rod. To these lugs two chains are attached. The chain which is fastened to the upper lug passes up through the rod and over the ratchet wheel *D* and terminates with the weight *F*. When the float slides down on the rod, the chain causes the ratchet wheel to engage teeth on the shaft *B*, which is thereby caused to rotate with the wheel in a counterclockwise direction. When the float rises, the weight *F* makes the ratchet wheel rotate in the opposite direction; the ratchet then simply slides over the teeth.

The chain attached to the lower lug passes down through the shaft, over the pulley, then up again and over the ratchet wheel *E*, terminating with the weight *H*. When the float rises the chain causes the ratchet wheel *E* to turn the shaft counterclockwise, and when the float falls the wheel slides free. Thus, a vertical motion of the float either up or down tends to cause the rotation of the shaft *B*.

The upper end *I* of the rod *C* forms a ball and socket joint with the yoke *J*. The flanged disk piece *K* is integral with the ball *I* and the base ring *L* of the frame *M* rests on this disk. When a wave gives a sidewise motion to the float the disk *K* is thrown out of level and the frame *M* rides up on the high side of the disk. The lever *N*, which has its fulcrum at *O*, is fastened to the frame *M* at *P* by a compound hinge joint. As the end *P* of the lever is pushed upward the opposite end *Q* swings downward and the chain fastened thereto causes the ratchet wheel *R* to rotate the shaft *B*. Due to the large ratio between the lengths of the arms of the lever *N*, even a slight lateral movement of the float produces a considerable movement of the end *Q*. The counterweight *R* performs the same function as do weights *F* and *H*; namely, of keeping the chain taut on the ratchet wheel and causing the wheel to rotate in the reverse direction when the pull due to a wave is finished.

The power which the shaft *B* receives is transmitted through gear wheels of suitable ratio to the shaft *A*, which carries as many flywheels of proper size as are needed to steady the rotation; the number required depends, of course, on the size of the motor, that is to say, on the number of float units employed.

Method of Governing

The speed and the amount of power which the motor develops are regulated by means of compressed air. The floats, which are made of steel, are hollow and air tight except for four holes in the bottom, which are sealed by the water. Each float is connected by means of a flexible hose to a compressed-air tank which is located on the pier and in which a pressure of about 15 pounds is maintained. Thus, by admitting air the float can be entirely emptied or by releasing the air the float can be completely filled with water.

However little work there is upon the motor, it cannot run away, for, if the wheels upon which the pawls work were to run faster than the floats actuate the pawls they would receive no acceleration while such conditions existed. As there is always some resistance to the movement of the shaft its speed never gets beyond that at which a ratchet can exert a pull on its ratchet wheel fastened on the shaft. The energy taken up from the succeeding pulls of the ratchets is absorbed and distributed by flywheels on the main shaft which are of sufficient weight to do this efficiently.

Size and Capacity

The size and capacity of a motor are determined by the number and size of the floats. The demonstration motor at Atlantic City is composed of six floats and the necessary transforming mechanism. The floats are 4 feet in diameter, 4 feet long and have a displacement of about 50 cubic feet. It is said by the officers of the company that the machine is capable of developing between 100 and 125 horsepower, although no records of any authenticated test are available. A commercial plant would have not less than 32 floats.

Theoretical Estimate of Capacity

An estimate of the power derivable from the wave motions of a body of water by the employment of mechanism should be based upon a rational assumption of the forces and motions that are incident to water when agitated in the form of waves. When the crest of a wave is observed sweeping over the surface of an expanse of water, the eye naturally follows the moving crest and an impression is received that the same surface particles of the water remain on the crest of the wave, partaking of the same horizontal movement as the crest. As a matter of fact, visible wave motions consist, for the most part, of only a change of the form of the surface which rises up and down over the same place, much the same as a carpet on a floor would be disturbed by moving a rod sidewise over the floor under the carpet. The surface motions of waves are clearly comprehended when the effect of wave motion imparted to a body of water covered with irregular-sized floating bodies is observed, as a field of broken ice. The floating masses appear, from the action of the waves, to have the motion of rising and falling very nearly over the same spot, combined with an oscillation forward as they rise, and an oscillation backward as they fall, being left slightly advanced in the direction of the motion of the wave's crest. This lateral motion is illustrated in the swaying of a spile loosely held in the bottom when swept over by the waves. The net horizontal displacement of the water may be very small from the passage of a single wave over the surface of a placid body of water; but when the surface is disturbed by a succession of waves, each accompanied by greater energy in the direction of the wave movement over the whole surface, the effect is to drag along the whole body of water with accumulating velocity in the direction of the main surface-wave motion.

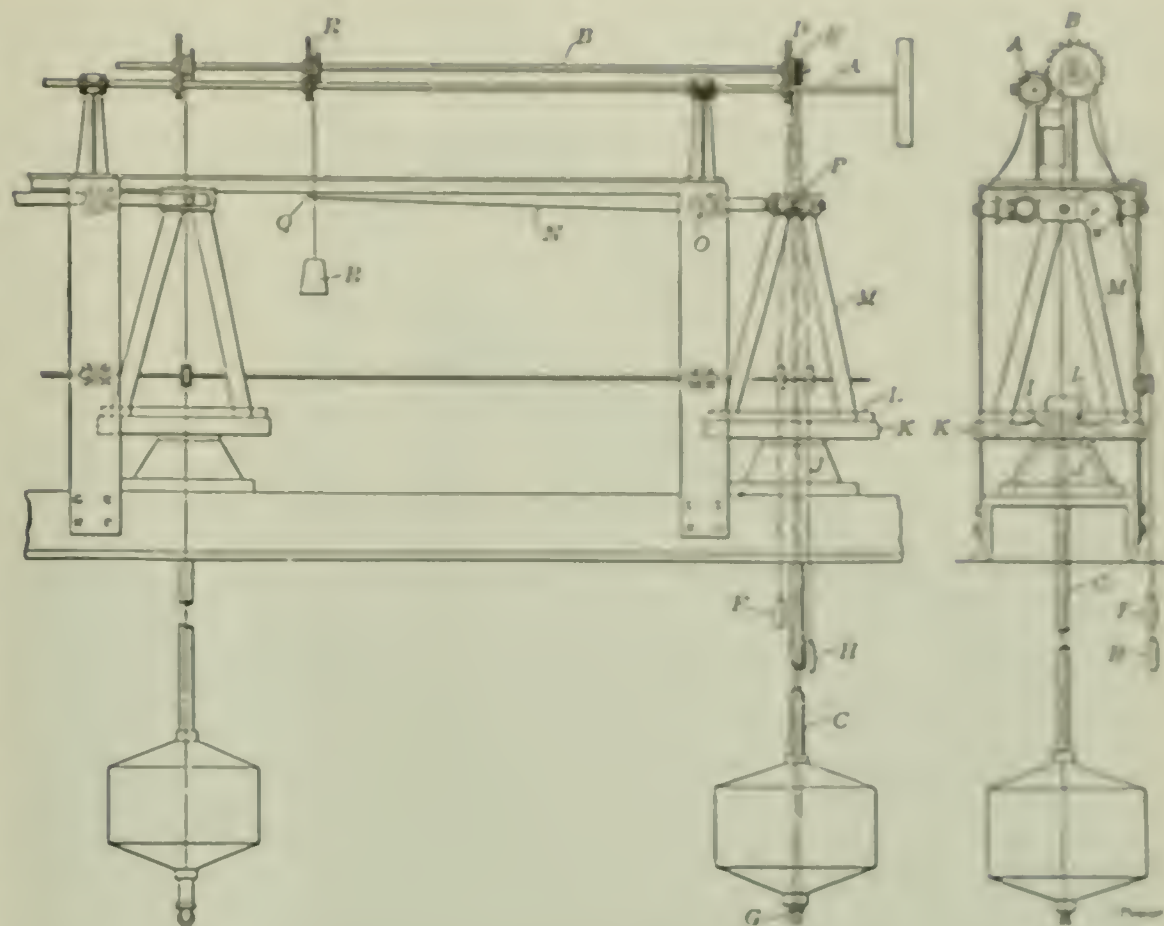

Fig. 3. Diagrammatic Arrangement of the Mechanism

Fig. 2. Three of the Floats Which Actuate the Motor

The wave motor herein described is intended to gather energy both from the horizontal and from the vertical motion of the particles of the water in which it may be immersed.

Wind, weather and other conditions which affect the height, speed and frequency of ocean waves are all so variable that any assumption of average combination of vertical and horizontal motions available for a power installation must be regarded as purely conjectural.

Computations based on data recorded by the promoters, and in which the motor is given the benefit of every doubt, result in convincing one that the power which the motor is capable of developing is decidedly less than 100 horsepower.

Each of the six floats, 4 feet in diameter and 4 feet high, has a displacement of about 50 cubic feet, and as a cubic foot of water weighs approximately 62.5 pounds, each float, therefore, weighs

$$50 \times 62.5 = 3125 \textit{ pounds}$$

less when in the water than when out. No matter what may be the form or material of a body, when it is submerged it is at all times buoyed up by a force equal to the weight of the water which it displaces. Assuming that a float of the wave motor is at the lowest point of its vertical travel, that it displaces 50 cubic feet of water and that the float itself has a total weight, out of water, of 3125 pounds, then the rise of a wave would lift the float, but the buoyancy of the water would lift nothing additional to the weight of the float. Under that condition, no work could be gotten out of the upward motion of the float. On the downward motion, work could be obtained to the full effect of the weight of the water which had been displaced during the upward motion, and through the distance raised, provided the mechanism for absorbing the work of the downward motion is of such a character that the wave in dropping falls so much more rapidly than the float as to exert no buoyancy to retard the gravity of the float. If the float is lightened or counterpoised in any manner exerting a lifting action during its upward travel, tending to decrease the weight of the float in the water, then an effect equal to such a lifting effect will act against the downward motion of the float. It is immaterial what proportion of ballast is carried or how the parts are counterpoised, the total effect for a rise and fall of a wave can be only the displacement (3125 pounds) raised the hight of the wave, minus the half hight of the float. Assuming the effective rise to be 2 feet and the frequency of the waves once in 5½ seconds, the total power exerted by the waves in raising six floats would be,

$$3125 \times 2 \times \frac{60}{5\frac{1}{2}} \times 6 = 409{,}090 \textit{ foot pounds per minute} = 12.4 \textit{ horsepower.}$$

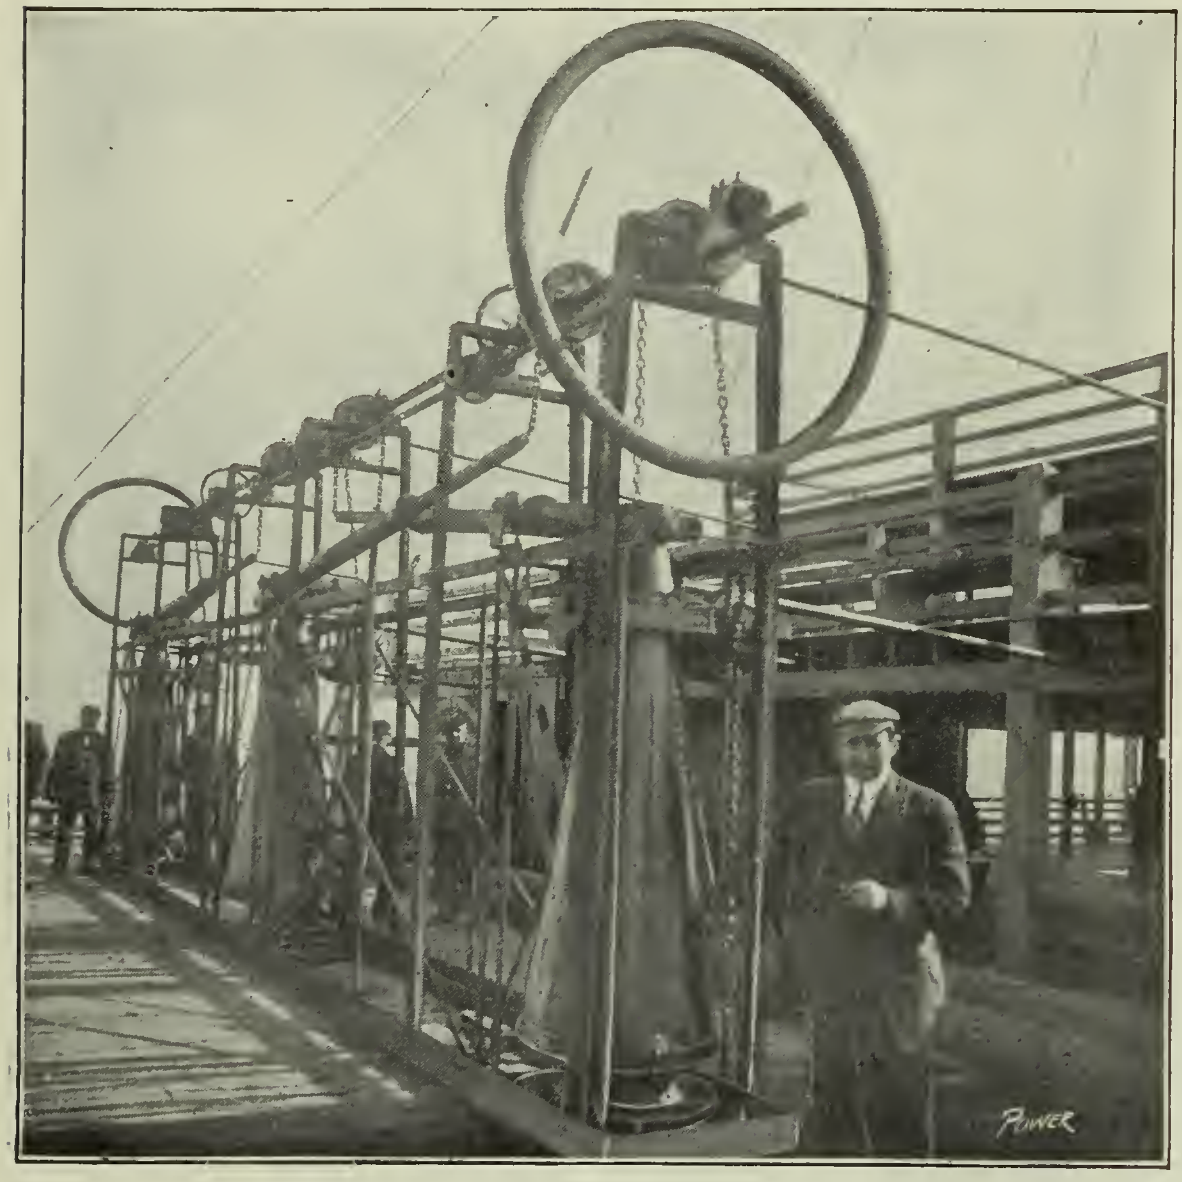

Fig. 4. View of One Section of the Superstructure

Conceding that the average lineal sweep of each float is six feet forward and six feet backward, occurring once every wave interval of 5½ seconds, then the total lateral motion per minute made by each float may be assumed to be

$$6 \times \frac{60}{5\frac{1}{2}} \times 2 = 130.9 \textit{ feet per minute}$$

According to the experiments of Poncelet, the highest efficiency in the conversion of the energy of the water is attained by a float in an unconfined channel, when the velocity of the float is one-half the velocity of the current. Therefore, to estimate on a basis of current velocity which would yield the highest efficiency for a float velocity of 130.9 feet per minute, calculation would have to be made on assumption of a current velocity of

$$130.9 \times 2 = 261.8 \textit{ feet per minute,}$$

assumed as an average velocity of water creating lateral pressure on the float. Each float being 4 feet in diameter and 4 feet high, a projected area of 16 square feet would be the greatest cross-sectional area of current acting on a float.

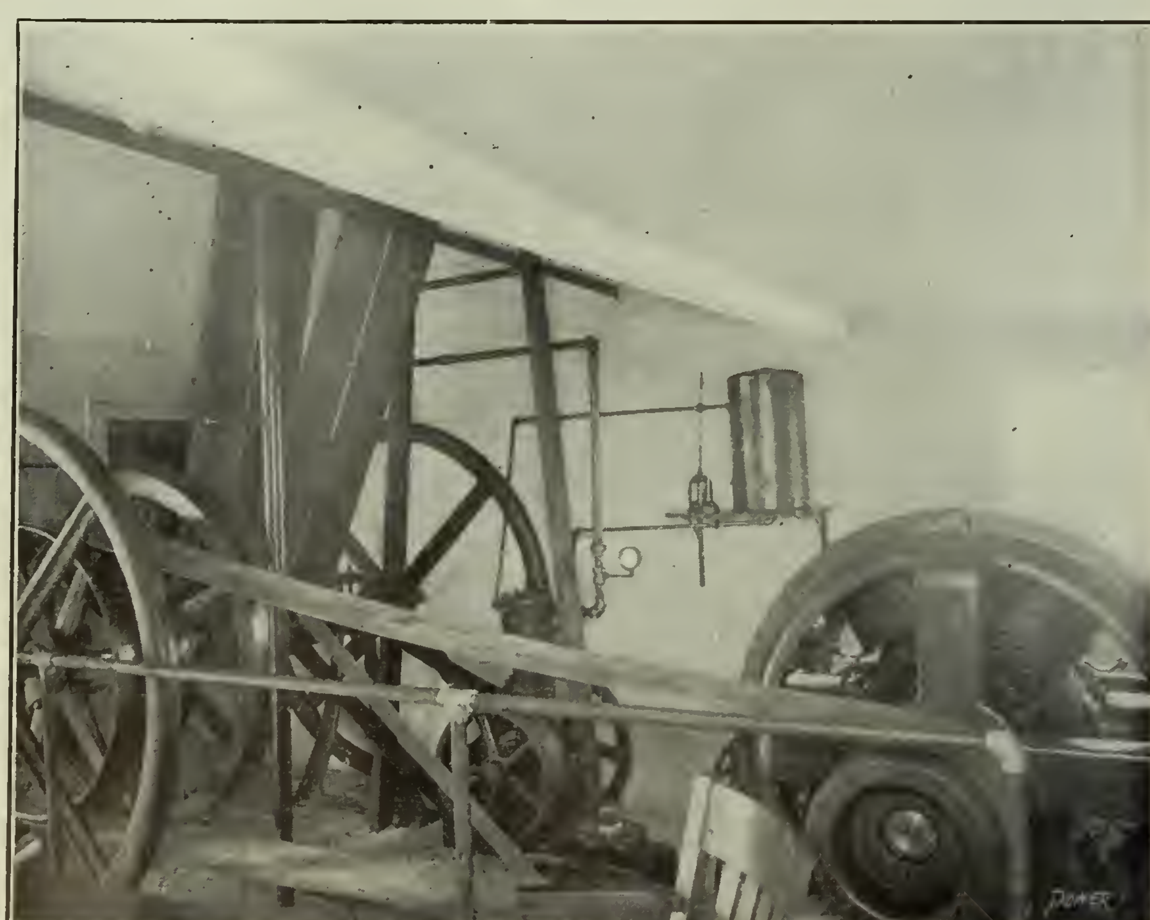

Fig. 5. The Countershaft, Generator and Air Compressor Driven by the Wave Motor

The assumed current velocity of 261.8 feet per minute is equivalent to a velocity of 4.36 feet per second. Each float would, consequently, have presented to it during a second of time

$16 \times 4.36 = 69.76$ *cubic feet of water,*

equal to

$$69.76 \times 62\tfrac{1}{2} = 4360 \textit{ pounds}$$

of water per second, at a velocity of 4.36 feet per second. Finding the kinetic energy of the water, in foot-pounds per second, by the usual formula,

$$K = \tfrac{1}{2} M v^2,$$

by substituting

$$M = \frac{4360}{g}$$

$v = 4.36$ feet per second and $g = 32.2$, we find:

$$K = \tfrac{1}{2} \times \frac{4360}{32.2} \times (4.36 \times 4.36) = 1287 \textit{ foot-pounds per second}$$

and presented to six floats would make,

$$1287 \times 6 = 7722 \textit{ foot-pounds per second.}$$

Poncelet determined that the highest percentage of energy obtainable from an unconfined current acting on flat float boards normal to the direction of the current was 40 per cent. of the kinetic energy of the obstructed current. In the case before us the surfaces acted upon by the current are convex-circular cylinders, a form well established as offering only one-half as much resistance to the motion of an unconfined fluid current as flat surfaces normal to the direction of the flow. Absorption of current energy by the cylindrical form of float could therefore not be in excess of 20 per cent. of the kinetic energy of the current. The maximum lateral or current energy absorbed by the six floats would therefore be but 20 per cent. of 7722 foot-pounds per second, or only 1544.4 foot-pounds per second, equal to 92,664 foot-pounds per minute, from which it becomes evident that the total power which the waves can impart to the six floats in lateral motion is

$$\frac{92{,}664}{33{,}000} = 2.8 \textit{ horsepower}$$

This, added to 12.4 horsepower, receivable from the up and down motions, gives 15.2 horsepower as the maximum power which the waves could impart by all motions to the six floats of the motor during continuance of the conditions which are conceded.

But, beyond this, the efficiency of the mechanism for the conversion of the energy applied to the floats into energy developed in the form of the rotation of the shaft and the losses of power consumed by the speed-governing mechanism have to be taken into account. From the character of the mechanism employed for these purposes it would appear that not more than 75 per cent. of the initial energy applied in the creation of the motions of the floats would be recoverable in useful work in the form of rotary power deliverable from the shaft of the motor. Thus, allowing 75 per cent. efficiency of the mechanism, the estimated actual or brake horsepower of the motor, operating under the conditions which are conceded, appears to net but 11.4 horsepower.

Commercial Value

The cost of operating a power plant is not made up of fuel and labor alone. The standing charges, made up of interest and depreciation, insurance, taxes, etc., form a considerable proportion. It is quite possible to put so much money into the development of a water power that the standing charges would pay those of a steam plant and the fuel and operating costs as well. This is the crux of the wave-motor situation. Can such a device be built for a cost that will permit its use in competition with established sources of power?

There is no authenticated test of the power which the motor under review will produce. On the day that the writer saw it, it was operating a small air compressor and furnishing air enough to blow a whistle occasionally. The generator could not be run because the belt was broken and something was the matter with the pump.

As has previously been mentioned, the promoters claim that they have gotten 100 to 125 horsepower out of the motor, and that its cost, including changes, revisions, substitutions of parts, etc., is in the neighborhood of $50 per horsepower. They also claim that they have estimates that show that a commercial plant can be built for $17.50 per horsepower, allowing $3 per horsepower for pier or crib work. The crib would be built of concrete and steel and the power transmitted to land by cable.

The plans of the company are to build a commercial plant at Boston or New York as soon as enough stock is sold to render this possible.

Intending purchasers of stock should satisfy themselves as to the correctness of the estimates of capacity and cost.

Flue Welding in Repairing Boilers

By H. S. Jeffery

If the condition of a boiler is such as to necessitate the removal of tubes in order to get at the inside of the shell, and the tubes are not pitted or otherwise rendered unfit for service, they may be used again by welding a small section on to the end which was cut during the process of removal.

It seems to be one of the first principles with many owners of boilers that the tubes shall not be removed until all efforts to keep them from leaking have been exhausted. However, when the efficiency of the boiler has been decreased to a marked extent due to the deposit of foreign matter, then it is often necessary to remove the tubes, whether they leak or not, and clean the boiler shell. The money expended for removing and replacing the tubes will be well spent, there being no necessity for throwing away the tubes which are removed from the boiler and replacing with new ones, unless they are badly pitted.

It is now the practice to again use the tubes which have been removed from a boiler. This is accomplished by welding on the end of the tube a section about six inches long, called a "safe-end." Frequently the safe-end is somewhat heavier than the tube, and the general rule is to install it so that this end of the tube is expanded to the flue sheet of the firebox or furnace. This is because the new end of the tube is firmer and stronger than the old tube, and consequently can be expanded into the fire-box tube sheet better than the old tube. Also, as a rule, the new section when expanded into the hole, produces a tighter joint than the older and thinner tube.

The chief difficulty with flue welding is the desire to weld a great many flues in a given time, and too often the quality of the work is sacrificed for quantity, the whole saving, however, is lost on account of the expense and time required to remove, reweld and replace those which get loosened or have defective welds when the boiler is tested. Although the flues may be sound when tested and after being installed in the boiler, a defective weld may not show until the boiler has been in service a short time.

The manner of scarfing the safe-end to the tube is very important, the attention to detail always being to scarf both the tube and the safe-end about ½ inch as shown in Fig. 1. This scarfing is open to the objections that the outer edge of the tube is liable to burn off, and unless the operator is experienced some parts of the flue when welded are liable to be welded thinner than the balance of the flue. Another method is to scarf the safe-end, opening up the flue to overlap the safe-end as shown in Fig. 2; while others reverse this process, scarfing and opening up the tube to overlap the safe-end. Many, however, have abandoned the practice of scarfing either the flue or the safe-end, depending upon the disk or cutter, used for cutting the flue and safe-end, to bevel the edges for the purpose of welding. Flues welded in this way are called "short lap-welded," the short bevel or scarf making a solid weld as it affords sufficient metal through the weld to be worked down to size. When welding the safe-end to the tube, the latter should be upset against a cross-bar at the back end of the welding furnace. It is also important to see that the welded portion is not oversize or undersize; a flue which is oversize at the weld will be hard to insert into the boiler, and if undersize the chances are that the walls at the weld are thinner than the balance of the flue. It is the practice in many shops to weld and swedge the flue in the same heat, but this requires that the whole safe-end be heated unless it is exceptionally long. This practice has in many instances injured the weld, the swedging operation being attempted when the safe-end was too cold. In other shops

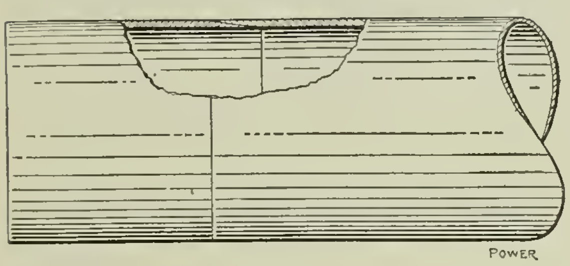

FIG. 1. BOTH TUBE AND SAFE-END SCARFED

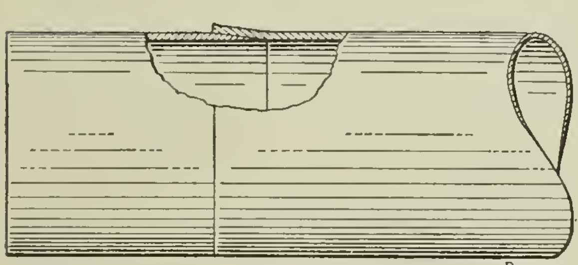

FIG. 2. ONLY SAFE-END SCARFED

the flues are welded, allowed to become cold and the weld tested, after which the ends of the flues are heated, swedged and annealed.

In some shops the welds of the flues are tested under pressure in a machine made especially for that purpose, although in the majority of cases a wooden plug is driven into one end of the tube; the tube is then filled with water under pressure, and the weld is hammered lightly with the peen of a chipping hammer. Still others test the welds after the flues have been installed in the boiler but this is poor practice. The flues when swedged should be turned several times, making the ends round and the swedged portion central with the balance of the flue. After the foregoing operations the flue ends while heated to a cherry red should be placed in a bath of lime, thus annealing the flue so that it can be expanded to the flue holes and beaded to the sheet without danger of splitting the flue.

Although a boiler may be opened and washed out periodically all the scale and mud will not be removed, and though the flues may not leak, it may be necessary to remove them so as to thoroughly clean the boiler. In such cases it is not usual to remove all the tubes, the practice with many being to remove the lower tubes as indicated in Fig. 3, which is called a V. This practice is more general with the locomotive type of boilers than with tubular boilers. The majority of the latter type of boilers are now being constructed with a manhole under the flues, which permits the scale and mud to be

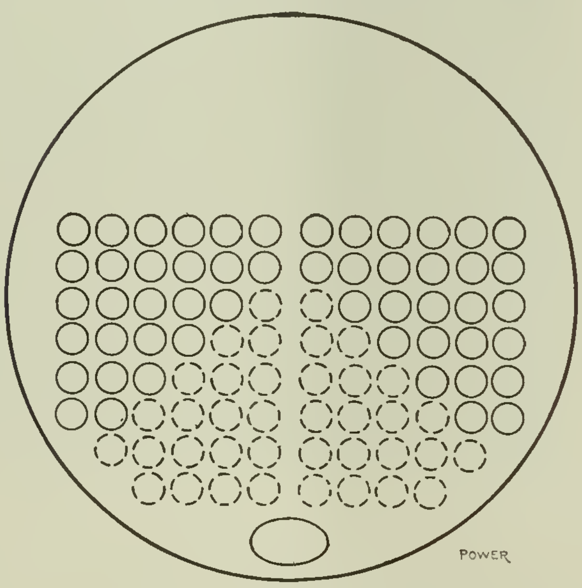

FIG. 3. DOTTED LINES REPRESENT TUBES REMOVED

removed from both the boiler shell and the flues without removing the flues.

It is important that the tubes be as straight as practicable. Those removed from the lower rows are liable to be bow-bent, especially if they are long and considerable scale has adhered to them. If installed in the boiler when bow-bent, some of the tubes may touch, or nearly touch, one another, creating unequal water spaces between the tubes and preventing proper circulation, also affording spots where sediment will lodge. The tubes which are cleaned in a revolving machine, called a "rattler," should be cleaned by rubbing against one another, the rattler revolving at a very slow rate of speed. Small pieces of iron and steel may be used in the rattler to aid in cleaning the tubes, but large pieces should not be used as they will cause dents in the tubes.

Frequently one or more flues will leak to the extent of practically putting out the fires. The leak may be the result of the joint between the flue and the hole becoming broken, or a hole being eaten in the flue or the weld in the tube parting. It is not always possible to cut the boiler out of service, in which case the flue is plugged by driving a cast-iron tapering plug into the flue.

Sometimes the joint between the flue and the hole will become broken and the bead of the tube partly broken off; in such cases, but only in an emergency, the flue may be repaired by cutting the bead off flush with the flue sheet and placing a section of tube inside of the tube as shown in Fig. 4. The old flue is first

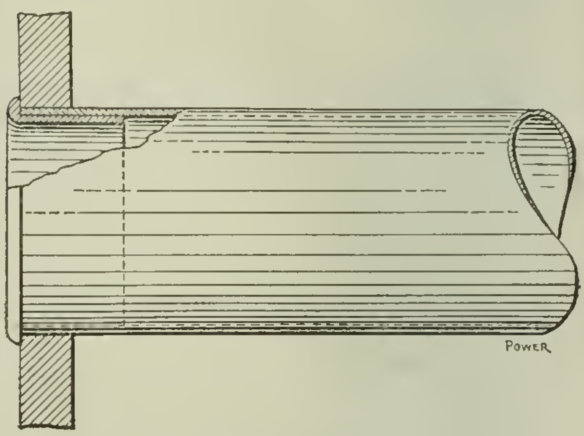

FIG. 4. TUBE HELD IN PLACE BY SMALL SECTION AT END

expanded hard against the sheet, after which the section is inserted within the old tube, expanded hard against it and beaded to the tube sheet in the same manner as the original tube. The section being only indirectly cooled by the water within the boiler is liable to become overheated, and especially if fine particles of coal, etc., are allowed to lodge around and within it. The only object in using the section in preference to plugging the flue is that the latter practically cuts out the flue and reduces the heating surface, while the former permits the flames and hot gases to pass through the tube as before, thus maintaining the heating surface.

The International Electrical Company, Limited, with offices in Nelson, B. C., and Portland, Ore., has filed plans for the development of a large electric power plant from the falls on the Pend d'Oreille river. The river runs from Canada to the United States, some 50 miles southwest of Creston, B. C., and for nine miles before reaching the boundary it is a series of rapids. At a point some six miles above, on the Canadian side, a site admirably adapted for the necessary development works has been staked, and it is expected that a city will be located in the vicinity, to be known as Falls City. W. E. Moore, hydraulic engineer, of Spokane, has made an investigation and report on the power sites of the river, in which it is stated that the upper site is capable of a total development of 65,000 horsepower and that the cost will be about $60 per horsepower. The Sheep creek and Ymir mining districts are only fifteen miles away, and the power sites are within 100 miles of Spokane.—*Electrical World.*

Gas Power Department

Everything worth while in the gas engine and producer industry will be treated here in a way that can be of use to practical men

Some Notes on the Operation of the Lackawanna Steel Works Engines*

By E. P. Coleman

The Körting engines used at the Lackawanna Steel Company's plant at Buffalo did not show satisfactory operation during the first three years of their existence, but the author believes that essentially all of the trouble can be traced to several major causes tending to produce premature combustion, and a number of minor details not well appreciated at that time.

The conditions tending to produce premature combustion and attendant failure of parts subject to the resulting high pressures and temperatures were imperfect piston rings, neither properly doweled nor provided with keepers; unsuitable oil used in the motor cylinders; and high hydrogen content in the gas. Minor causes of premature combustion were projecting portions of parts exposed to the fire, and accumulations of flue dirt which, in combination with the oil, baked on the surfaces of the parts; the projecting portions remaining incandescent and initiating premature combustion. Minor troubles were also due to various causes, such as wet gas which fouled the igniter points with its accompanying flue dirt; dirty gas which clogged the valves of the controlling devices, making the speed control more difficult; imperfect rod packing, which produced bad atmospheric conditions in the building; inadequacy of certain parts of the 1000-horsepower engines subject to high inertia stresses at 100 revolutions per minute.

Rectangular dowels are now applied to the piston grooves in such secure manner that the openings through the snap rings are confined to a location near the bottom of the cylinder, thus preventing leakage through the openings. The cylinder oil now used does not leave a carbonaceous residue of any considerable magnitude. The pressure of water supply to tuyeres, coolers and bosh plates is maintained slightly lower than the internal pressure of the furnace, hence cool water cannot enter the furnace to produce excessive hydrogen, following puncture of those parts.

As originally installed, the cylinders, pistons and muffling sprays were all supplied with water through individual connections, each wasting to a sewer. The system has since been modified so that the water passes through piston, cylinder heads, cylinder jackets and muffling sprays in the order named. A small portion of the water only is used by the muffling sprays.

Thermometers are set to indicate the temperatures of the water leaving the piston and cylinder jackets. The jacket water leaving each cylinder head discharges upward through a vertical pipe provided with a return-bend discharge nozzle. The water leaving the nozzle discharges downward into a funnel leading to the cylinder jacket, the stream thus being in full view of the operator.

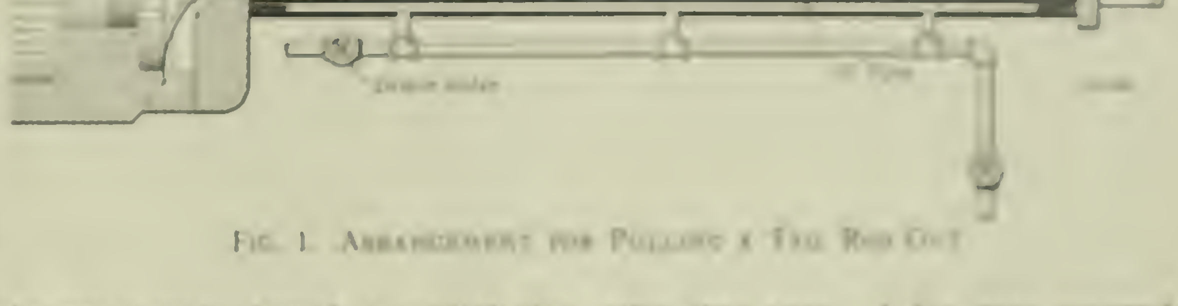

FIG. 1. ARRANGEMENT FOR PULLING A TAIL ROD OUT

Cylinders, Pistons, Rods, Etc.

The average life of a motor cylinder is about four or five years, during which time the wear as measured on a diameter is about 1/4 of an inch. The cylinder is then bored out and bushed. There are practically no cylinder failures from any cause other than wear.

Exhaust ports at power house No. 1* become clogged with flue dirt and require cleaning after about three months of operation. Exhaust ports at the blowing-engine houses do not foul at all. The difference is probably due to the cleaner gas at the blowing-engine houses, and possibly in some degree to the precipitation of moisture and dirt in the [illegible]-inch headers.

Cylinder relief valves require cleaning about once a month. Jackets of cylinders and heads are cleaned about once a year.

Cylinders and pistons are inspected only when conditions indicate. Their wear is measured and recorded at the same time. A test for tightness consists in placing the crank on the dead point and subjecting one end of the cylinder to air or exhaust pressure, the plugs being removed from the opposite head to indicate leakage, if any, through the piston.

The blowing-engine pistons have a life of from three to five years. There are but few piston failures due to any cause other than wear. A few have occurred which have been due to the water connections falling down inside the piston and wearing a hole through the bottom. When a piston has worn, say 1/16 inch at the bottom, it is turned over and used in a standard cylinder. There are at present two standard diameters, [illegible] inches for new cylinders and [illegible] inches for bushed cylinders.

In dismantling a piston the large piston nuts are heated, removed, cleaned up in the lathe and used again. About half of the small piston nuts have to be split off, the rest being utilized again. There is considerable corrosion around the studs and inner edge of the joint between rod and piston, forming what may be called a rust joint. The tail rods are removed from the piston either by means

*From a paper presented at the annual meeting of the American Society of Mechanical Engineers, December, 1910.

*[illegible]

of the special device shown in Fig. 1 or by means of screw jacks and rams. When using the former, the concentric pipes are first cooled with water and the nut at the end of the tail rod is set up; steam is then admitted between the pipes at atmospheric pressure to lengthen the pipes by heating them. This cycle is repeated until the rod is free from the piston. When it becomes necessary to remove the piston rod, the piston is broken away either with dynamite or under the drop hammer. The wear of piston rods occurs principally at the end of the stroke and amounts to about a quarter of an inch on the diameter in three years. It is then turned and will suffice for two or three years more.

The average life of the motor cylinder heads is not well established, but it may be set at three years or more. A few of the original heads at the blowing engines are still in service. Failures of these occur principally at the junction of the jacket wall and the main flange on each side of the inlet valve chamber, but this trouble has been substantially eliminated by employing proper fillets. Some heads have developed cracks through the inner wall; two or three have had the inner walls blown entirely away, but this was found due to faulty castings.

Gas-pump cylinders and heads require cleaning every six to eight months on account of dirt getting into the clearance near the bottom. By feeding a little kerosene through the pump valves cleaning is avoided.

Cylinder heads are packed principally with $\frac{1}{16}$-inch woven-wire insertion asbestos sheet. Piston joints are made up either with $\frac{1}{32}$-inch wetted asbestos paper, or with a paste of litharge and glycerin, or with another form of packing known under the trade name of "900." All give satisfactory results. The life of the $1\frac{7}{16}$-inch snap piston rings is about two years.

The piston rods are packed with four cast-iron rings of the Walker type in a casing exterior to the head. Packings are overhauled about every six months to renew broken springs and rings. Casings are trued up at the time of overhauling the piston once in two or three years.

The swinging connections for the piston water supply require to be packed about twice a year.

Valves, Cams, Shafts, Etc.

The inlet valves last about three years before turning and about the same time after they are turned down. They do not require grinding-in except when new. Stems are broken occasionally near the top yoke. Little cleaning of the inlet valve or the ports is necessary.

The inlet valves are operated through heavy push rods driven by cams and rollers. High inertia stresses are thus developed at the higher engine speeds. With present inlet-valve springs, which operate under a compression of 2500 to 3500 pounds at the blowing engines, the roller leaves contact with the cam at about 65 to 70 revolutions per minute. Many of the original push rods have been broken by the resulting inertia stresses and new and stronger rods have been made.

The life of the inlet cams is about six years. Wear of the steel gears of the layshaft occurs on four teeth at the end of four or five years; the gears are then shifted on the shaft so that unworn teeth are in action during the inlet-valve opening.

The shaft of the 2000-horsepower engine, which is of the built-up type, has caused no trouble whatever. There have been, however, several shaft breakages at the 1000-horsepower engines, which have shafts forged in one piece and operate at 100 revolutions per minute. The author has made no investigation relative to the stresses in these shafts, but believes that their life would have been longer had they been of the built-up type and of present diameters.

At the 1000-horsepower engines there has also been trouble with certain brackets and fastenings due to inertia stresses set up by the inlet gear. The governor being driven from the layshaft, considerable wear is imposed on the mechanism due to reversal of the torque at the layshaft as the point of each cam passes under the roller. Some trouble from premature ignitions by the 1000-horsepower engines was experienced, due to the indicator holes through the flanges of the cylinder heads, and water-cooled indicator connections were substituted.

Ignition

Ignition is effected by means of make-and-break igniters, of which there are two in each cylinder head. Until recently the ignition current was furnished by magnetos, one for each plug. The current is generated by this form of magneto in the following manner: The armature is first slowly rotated in opposition to the force of a spring through an angle of about 30 degrees from its initial position; it is then released and under the action of the spring executes a rapid return motion or oscillation. During this return motion the igniter terminals are mechanically separated and an arc formed, the motion of the armature being transmitted to the plugs through cranks and reach rods for this purpose. The magnetos are now being discarded in favor of a direct-current system of ignition of simple form.

The detailed construction of the igniter plugs is indicated in Fig. 2. The bronze bushing forming the spherical seat for the movable steel electrode is a driving fit in the cast-iron body of the plug. The cylindrical head of the stationary electrode seats on an asbestos gasket or washer carried by the porcelain insulating plug, which is formed as a conical frustum seated in a cavity in the cast-iron plug on a bedding of litharge and glycerin. Litharge also assists in maintaining tightness between the cast-iron plug and the bronze bushing. This construction is very satisfactory in every way.

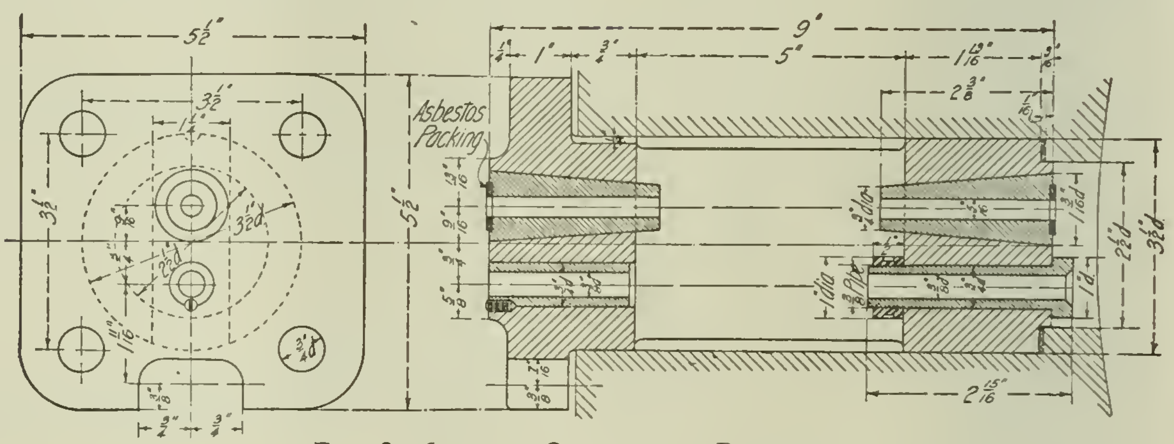

Fig. 2. Igniter Shell and Bushings

Using magneto or similar low-voltage current, there is little burning of the points, and the life of both electrodes is about one year. The bronze bushing lasts about six months, this material being the most satisfactory thus far used. The upkeep of the magnetos is relatively expensive, and a ten-volt direct-current system is being substituted.

Dirty plugs are caused by slipping furnaces and wet gas containing dirt which fouls and bakes at the terminals. The plugs require cleaning on an average of once or twice per month. The spherical seat requires regrinding once in two months, and the plug must be retubed once in six months.

With the type of ignition gear described there is an interval between the release of the magneto lever and the opening of the igniter terminals. There is also an appreciable time required to complete combustion. This time element being approximately constant, correct ignition requires that the timing of the release shall vary to some extent with the speed of rotation. The ignition gear may then be linked to the speed-adjusting device in such manner as automatically to maintain proper timing of the ignition at all speeds.

An Operator's View of the Diesel Engine

By G. H. Kimball

In an article in the May 31 issue, some very favorable statements were made in regard to the Diesel engine; these and others made in the catalogs convey the impression that the engine has no disadvantages whatever. If this were true, there is no reason why everybody should not install them.

It may be of interest to engineers and possibly to some owners of plants, to hear of some experiences in plants where these engines are in operation. As with all internal-combustion engines, there are many drawbacks which do not appear in a good steam plant, and where a steam engine will run under adverse conditions a Diesel will not operate at all.

Those of the three-cylinder and six-cylinder type, with 16x24-inch cylinders, seem to be the most successful. In one plant a six-cylinder unit was installed which gave excellent service for the first year, with no repairs other than a new governor gear. It was necessary, however, to spend about ten hours every week in inspecting and taking up connections and various other parts. One thing that made this type of engine successful in that plant was that there were both steam and water power besides, so that it was not necessary to hire any more help, as the firemen could be used when the steam was not required, and when there was plenty of water power available ample opportunity was given to thoroughly overhaul the oil engine and get it ready to give good service when needed. Moreover, when steam was depended on alone for auxiliary power it was necessary to keep a boiler in service for two or three months, in case of emergency, and this standby loss was saved by the Diesel engine. In this class of plant the Diesel engine can be used to marked advantage and with great economy.

In a plant where the whole load must be carried by the Diesel engine, however, we have a far different proposition. In one such plant where there were two units, one new and the other about three years old, it was necessary to spend all of Saturday afternoon, when part of the factory was shut down, and nearly all of Sunday in adjusting wristpin and crankpin boxes, inspecting parts and the condition of the crank-case oil. This was regular routine work, and in case of regrinding valves, renewing the oil or anything extra, just so much more time was required. The fuel valves gave trouble by breaking at the points and there was a great deal of wear due to the jar and shock of the six reciprocating systems working at such high pressures.

The governors gave a great deal of trouble in the way of unsteady running, so that it was necessary to replace them on both the old and the new units.

The first cylinder on the older engine after being overhauled gave great trouble by pounding at every second stroke, even when the clearance, as measured by compressing a lead wire, showed one-eighth of an inch, as required. Finally it was found that the piston head bulged upward by the heat to such an extent that when all the parts were hot it touched the cylinder head.

The cam-shaft gears of this unit were also badly worn, making new gears necessary. One cylinder of this and one of the newer engine were found to be worn from 0.015 to 0.005 of an inch large in places. The rings after a year's run became so badly carbonized as to require new ones to be substituted, and the wear of the wristpin boxes made either new boxes or shims on the wedges necessary in a short time.

Many of the published performances of Diesel engines have been those where the load factor is 25 to 35 per cent. The engines will run very steadily with such a load, because the heating and wear of the parts are not comparable to the heating and wear that occur with a load factor of 75 to 90 per cent. The load factor was the difficulty in the last mentioned plant; the management wished to carry full load all the time, and sometimes an overload, and it was disappointing to find that the cylinders must be made tight before such a heavy load could be carried. To this end the pistons were fitted with two more rings, which made a great improvement, but in a short time it will be necessary to rebore the cylinders.

In the article to which I have referred it was stated that after a four years' run the tool marks were not worn out of the cylinders. To anyone who has seen hard service by these engines this statement will seem rather far-fetched; in the plant which I mentioned last not only were there no traces of tool marks but there were deep grooves worn lengthwise of the cylinders, although there was plenty of cylinder oil in evidence.

When it is necessary to remove a cylinder head, about all the valve-gear and other parts related to the cylinder must come with it, which will consume no small amount of time, and everything must be replaced with the greatest care or the results will be very unsatisfactory.

The clearance must be maintained just right or the proper compression temperature to ignite the oil will not be attained.

Although the regulation is said to be equal to that of steam engines, it cannot equal that of a modern automatic cutoff or Corliss engine; regulation within 2 per cent. has not been shown in actual practice, 4 per cent. being considered good.

The crank-case oil is also a source of trouble and it is not surprising to find that the oil has disappeared after a hard week's run. Sometimes it is so thick that the bearings must be very warm before it will flow at all.

The air compressor is a very important part of the plant, and it must be capable of hard, continuous service, for any drop in pressure during a heavy load means a shutdown. Careless selection of a compressor will entail a great deal of trouble, for there are some designs that are very unreliable.

The fuel economy is very high and in plants where steam is not needed for other purposes than power there is a great saving in fuel. In the matter of labor, there is very little difference from a steam plant; it is customary to pay higher wages to Diesel engineers than to engineers in steam plants of like power, and while it is a simple matter to operate the engine, repairing requires plenty of help.

The first cost is excessive and unless a plant has a spare unit it cannot give the service that a steam plant would; and it is a question whether the engine would not have to be replaced after ten years of service.

In writing the foregoing it is not my intention to make any unfair statement; my experiences with the Diesel engine have been exactly as described in this article, and I have said nothing based on rumor or hearsay. Furthermore, I am convinced that this type of engine should, after some further experience and improvement, prove very successful and capable of continuous service at full loads.

[We do not question Mr. Kimball's sincerity, veracity or operating skill in the slightest degree, but we confess inability to understand why the cylinders of a Diesel or any other engine should be scored longitudinally when cylinder oil is plentifully applied, if the oil is of the proper kind and the air intake is carefully protected from dust and grit. We have known cases of extremely bad cylinder scoring caused by both unsuitable oil and unprotected air intakes.—Editor.]

The Navy Department is planning to experiment with electric lifting magnets for recovering torpedoes which are fired in practice and, through some fault of the controlling mechanism, go to the bottom after their energy is expended. These torpedoes are virtually small submarine vessels with self-contained power plant, steering mechanism, etc., and each one is worth a small private fortune. The points where they are lost will be marked by buoys and magnets then dropped down to grapple them and bring them to the surface. Owing to the lightness of the torpedoes magnets of relatively small lifting power may be used, but the magnets must be constructed to withstand the submersion and the temperature changes.

Catechism of Electricity

Single-phase Commutator Motors

1124. *Are commutators ever used on alternating-current motors?*

Yes; commutators are used on some single-phase motors. Fig. 363 illustrates one kind of commutator motor.

1125. *For what kind of work is this motor particularly intended?*

For driving machines which must run at variable speeds and those requiring considerable starting torque.

1126. *Explain the construction of the motor referred to.*

Fig. 364 shows the principal parts of the motor, and Fig. 365 is a diagram of its connections and windings. The field-magnet core *A* is fitted with a single-phase winding *N* of concentric coils, each coil being separately taped and insulated. For operation on 220-volt circuits these four nests of field coils are connected in series; for 110-volt circuits they are connected in parallel.

The armature is provided with a winding of the "twô-circuit" drum type, connected to an ordinary commutator upon which press two sets of brushes *E* and *C*, Fig. 365. The pair *E*, called the "energy" brushes, is permanently short-circuited and displaced at an angle to the lines of field or primary magnetization. The second set *C*, called the "compensating" brushes, is connected to a relatively small field winding which serves to induce in the armature an electromotive force which tends both to raise the power factor and to maintain approximately constant speed at all loads. By the use of a controller arranged to insert resistance or reactance in series with the energy and compensating circuits of the rotor, the speed can be reduced to any desired rate between full normal speed and half that speed. For example, if the normal speed is 600 revolutions per minute, any speed between that and 300 revolutions per minute can be obtained with the controller.

Fig. 364. Disassembled View of the Motor Shown in Fig. 363.

1127. *Will the speed be constant when reduced by the insertion of resistance?*

No. The motor behaves like a shunt-wound direct-current motor with resistance inserted in the armature circuit; when the load increases the speed decreases considerably, and *vice versa*.

Fig. 363. General Electric Single-phase Compensated Repulsion Motor

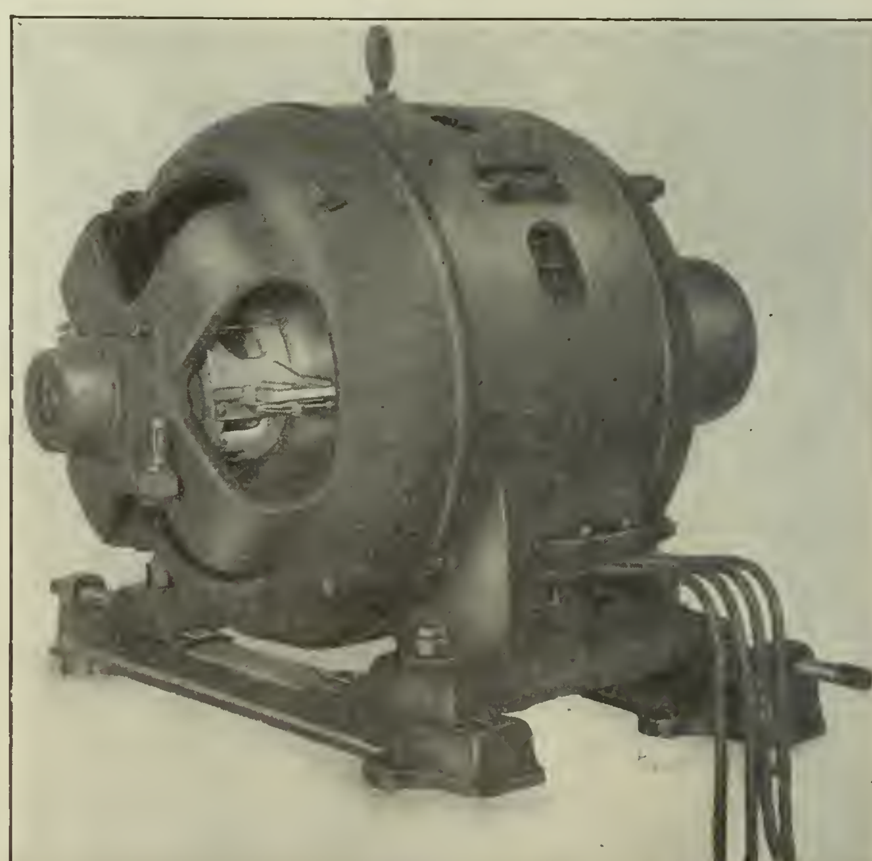

Fig. 366. Wagner Constant-speed Single-phase Motor

1128. *What kind of motor is the one just described?*

It is a compensated repulsion motor; this name is given to it because the motion of the rotor is due to magnetic repulsion between the current in the short-circuited part of the winding and the stator field, and the undesirable reactions

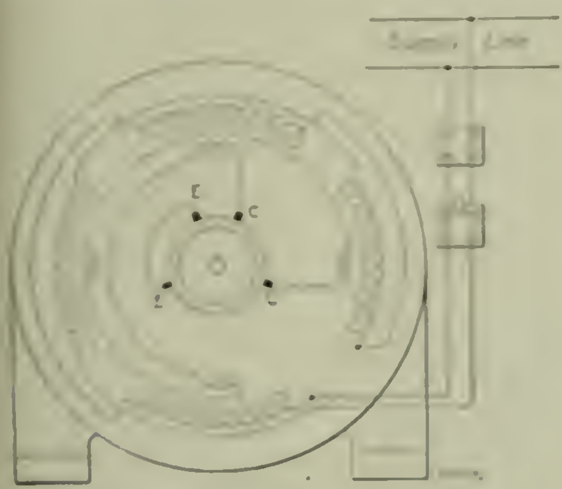

Fig. 365. Circuits of a Compensated Repulsion Motor

in the rotor winding are neutralized or compensated by the auxiliary field set up by the small stator winding connected to the compensating brushes.

1129. *Are there any other forms of single-phase commutator motor?*

Yes. There is a type of machine which acts as a repulsion motor while starting and is automatically changed to a simple induction motor when it reaches normal speed.

1130. *Illustrate and describe a motor of this type.*

Fig. 366 is a view of a 20-horsepower Wagner motor of this type, and Fig. 367 shows the commutator end of the Wagner armature. A disk-shaped commutator is used and the brushes press horizontally against it, as may be seen from close in-

Fig. 367. Rotor of Constant-speed Single-phase Motor Shown in Fig. 366. Commutator End

spection of Fig. 366, and these brushes are connected together electrically by the metal collar to which the brush holders are bolted. The brushes are therefore practically short-circuited, and they are so spaced with regard to the stator field poles as to produce a strong repulsion effect in the armature or rotor. This causes the motor to start and when it has nearly reached the regular speed, the brushes are lifted from the commutator and the commutator bars are all short-circuited; this changes the armature winding to what is practically the same (electrically) as a squirrel-cage rotor. Then the machine runs as an ordinary motor.

1131. *How are the brushes lifted and the commutator short-circuited?*

By a centrifugal governor which works against a spring. The governor weights are located within the rear end of the rotor spider, as shown in Fig. 368. By means of levers and links the governor weights slide the brushes away from the commutator and at the same time press a short-circuiting ring against the back face of the commutator, connecting all the bars together.

1132. *How does the governor mechanism move the brushes away from the commutator?*

A barrel slides along the shaft under the influence of the governor weights and the opposing spring; the governor weights move this barrel toward the commutator end of the shaft and the spring moves it in the opposite direction. The collar to which the brush holders are bolted is

Fig. 368. Pulley End of the Rotor Shown in Fig. 367.

cup-shaped, as shown in Fig. 369, and inside this collar a brass ring "floats" between the ends of the brush-holder fingers (which project into the cup through slots) and the end of the sliding barrel on the shaft. When the speed is high enough for the centrifugal force of the governor weights to overcome the opposing spring, the barrel is pushed against the ring in the brush-holder collar and the ring, pressing on the ends of the brush-holder fingers, pushes the brushes away from the commutator. The

Fig. 369. Brush Rigging of Century Motor

brush mechanism here shown is the one used on the Century motor, illustrated in Fig. 370.

1133. *How is the stator winding of this type of motor arranged?*

Exactly like that of an ordinary single-phase induction motor. Fig. 370 is a picture of the stator and rotor of the Century motor, from which it is evident that the stator core consists of slotted rings mounted in a circular frame or housing, and the winding is of the distributed type used in all induction motors of appreciable size. The machine here illustrated has four groups of coils which produce *four* magnetic poles on the inner face of the core.

Combination Piston Rod Packing

The following tells of a trouble I had with a badly scored piston rod on a locomotive.

Being a long way from the shop on a logging road, I had to pack the piston every night and then could not see for the steam that leaked out of the stuffing box. I had some graphite which I mixed into a stiff paste and then put in a round of ring packing in the stuffing box and filled the stuffing box full of graphite, put in another round of ring packing and screwed the gland up tight. The gland was then removed and more graphite put in, followed by another ring of packing. I had no more trouble for thirteen months and the packing was still in the box when I left the job.

Economic Boiler Feeding

An open heater is at its best when so designed and operated that all of the condensate from the heating system is returned to the boilers, and the amount of make-up water is reduced to the minimum. These conditions give the water the highest temperature possible with an open heater, unless live steam is used. And these conditions can best be obtained when a variable-speed pump is used with a variable delivery to feed the boilers, the speed or delivery of the pump to be controlled by a float in the heater connected to the pump governor or delivery-control valve, and not by connecting a float in the heater to the inlet or make-up water valve and regulating the speed of the pump by hand.

While the amount of condensate returned to the heater in an hour cannot equal the amount of water evaporated in the boilers in an hour, the maximum flow will raise the water level in the heater until it runs over the overflow and is lost if the speed of the pump is controlled by hand or by a feed-water regulator connected to a float in the boiler. While the periods of maximum flow are not long enough to raise the water level in the boilers perceptibly, owing to the larger area affected when the pump is controlled by a float in the heater, they are long enough to run a large quantity of water to waste via the overflow when the pump or water taken from the heater is not controlled by a float in the heater, owing to the comparatively small storage capacity of the ordinary open heater. Where the float in the heater is connected to the inlet valve, the make-up water is shut off altogether during maximum flow, and is admitted in so large a quantity during minimum flow that it has no time to be heated in the steam or trap space above the hot water but falls to the bottom, cooling the hot condensate in the heater. When the float valve in the heater is connected to the pump governor, the make-up water may be admitted continuously or nearly so. The fireman, having a mark on the inlet-valve wheel and only changing the amount, admitted slightly to keep the water level nearly constant in the boilers. In this way the make-up water has the longest possible time to remain in the trays and mingle with the steam in the upper part of the heater. The spasmodic flow of condensate from the heating system to the open heater is accounted for by the fact that nearly all heating systems contain pockets and water seals and in hotels, guests are opening and closing radiator valves at all times, traps are dumping and any slight change in pressure will change the flow from minimum to maximum. If the valve in the engine-exhaust pipe to the heater is nearly closed, as it often should remain, the condensation in the heater caused by admitting cold make-up water irregularly will cause a variation of pressure in the heater and at times quite a vacuum is formed, thus inducing an increased flow of condensate.

From the above it will be seen that a belt-driven plunger pump should never be used with an open heater, and if any constant-speed pump is used, we have a very undesirable and wasteful combination, unless the amount of water taken from the heater can be regulated by a float in the heater. There may be such an accessory on the market but I have not as yet seen one or an advertisement of one in any mechanical paper. A boiler-feed regulator might be attached directly to the heater and its motion reversed, so that as the water level in the heater rises, the main discharge from a centrifugal pump would open, and as the water level in the heater fell, the discharge from the pump would be throttled down. This would be a departure from any equipment I ever observed and, I think, from general practice.

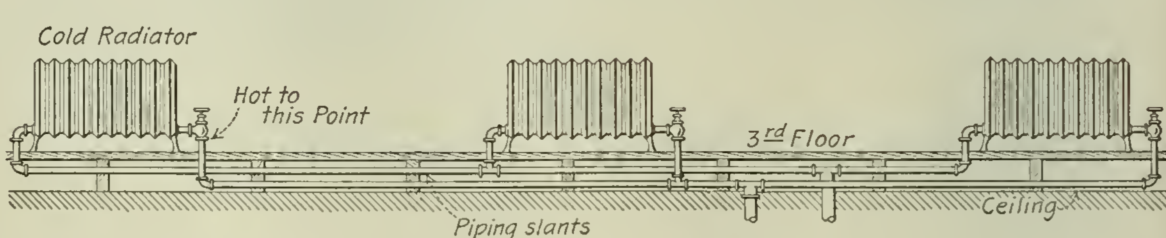
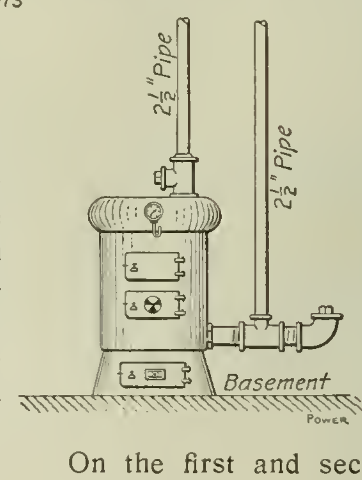
Worcester, Mass.

Radiator Failed to Heat

I would like to know what other engineers think of a radiator trouble in a heating system I recently installed.





Piping of Radiators

On the first and second floors, all of the radiators heat up nicely, but the three radiators on the third floor, which were put in later, did not heat satisfactorily.

When putting in the pipe to these radiators I tapped the feed pipe for a 2½-inch riser and also a 2½-inch pipe to the return pipe and carried them through to the third floor, and then branched off to each radiator with a 1¼-inch pipe, as a feeder, and a 1¼-inch pipe to each radiator for the return piping. On getting up steam two of the radiators heated up nicely but one failed to heat at all. The feed pipe to the radiator that did not heat was hot up to the valve, but the radiator remained cold.

I would appreciate the advice of engineers who have had experience along similar lines.

Willits, Cal.

Moisture Caused Trouble

A few years ago I took charge of a plant located at a coal mine. The boilers were each fitted with a dome and a 8-inch steam connection from the top of the dome to a 10-inch header, which extended across the engine room.

Steam was taken from this header through 6-inch outlets to each engine and a third outlet had been provided for a future installation in the engine room.

I was informed that the generators had been giving a great deal of trouble from sparking at the commutators, which proved to be correct, for I never saw such a display of fireworks as those machines were capable of exhibiting when carrying a load.

It was necessary to sandpaper the commutators two and three times a day and turn them down about every ten days.

I was also informed that there had been trouble with water in the engine cylinders and to overcome this they had connected a 6-inch pipe to the extra outlet in the header, and after turning downward this pipe extended below the floor level and ran out near the door, where it was reduced to 1 inch and fitted with a valve which was left slightly open to keep the pipe cleared of water.

This drip was located between the boilers and the first engine. Where it made connection to the header a very bad steam leak existed. As the weather was cold, and the engine room likewise, there was a great deal of moisture precipitated in the engine room from this leak. I wanted to take this pipe down at once, but the superintendent said No! very decidedly. Finally, one cold morning when the moisture was more in evidence than usual, I remarked to the fireman that the pipe was coming down that evening even though it cost me my job; and down it came. The outlet was blanked, thus stopping the steam leak.

In a short time I noticed that my generators were giving less trouble than formerly and they continued to improve until they finally got back to normal operating condition.

Then I took a tumble—the machines had been saturated with moisture and as they gradually dried out the trouble disappeared until finally all was once more in good shape, but the repairs to one armature which were necessitated by the work of that steam leak cost $600. Further, I never had any more trouble with water in the cylinders.

In this same plant they were using about twelve barrels of engine oil per year when I took charge of the job. After some persuasion I induced the superintendent to invest in an oil filter, and we used less than three barrels of oil that year.

A. Ramage.

Wheeling, W. Va.

Air Pump Cleaned the Boiler

There are four boilers in the plant where I am employed and it was desirable to inspect three of them one Sunday. Accordingly they were cut out of service Saturday night and cooled ready for the inspector. When he came he could not go into the boilers, they were so filled with hot vapor.

I cut out the boiler that was under steam from the others and opened the throttle valve to the engine room and freed the main of steam. Then I opened the steam valve on the head end of the cylinder and disconnected the exhaust valve on that end and did the same on the low-pressure cylinder. The independent air pump was started and the stop valve on the first boiler to be inspected was opened, and inside of five minutes the inspector was inside of it. When he got through with that boiler I opened the valve on the next two, as required. Naturally the stop valves were made tight before the next inspection.

Louis Kurtzmann.

Fall River, Mass.

Water Wrecked the Cylinder

One night the low-pressure cylinder of an 18- and 36- by 36-inch vertical cross-compound Corliss engine, running at a speed of 125 revolutions per minute, was wrecked. The engineer on watch at the time said that there was a very light load on the engine prior to the crash, and that the receiver pressure kept going up until it reached 30 pounds. He found upon investigating that the crank-end valve on the low-pressure cylinder had not been picking up, owing to worn catch blocks. When he made the blocks engage, the cylinder head was knocked off with the flange. The cylinder was also cracked in several places.

At first it was thought that water accumulated in the receiver, and was taken over to the low-pressure cylinder, but the receiver trap was found to be in good working order and there was no chance for an accumulation of water there. It was reasoned that, owing to the high receiver pressure on one side, and a 26-inch vacuum on the other, and the valve not hooking up, considerable condensation had accumulated at A in the sketch.

When the valve was made to hook up,

Where Water Accumulated

the high receiver pressure forced the pocket of water through the lower valve, under the piston which knocked it off the rod, and the next stroke brought the piston up against the head, which knocked it off.

Thomas [illegible].

[illegible]

Emergency Pump Packing

A short time ago the packing in the water end of our boiler-feed pump became so badly worn that it would no longer supply the boilers. As I had no packing of the proper size on hand, and the pump was the only means of supplying the boilers with feed water, I decided upon the following plan:

After carefully removing the old packing, I took some new tin and made a sleeve to fit nicely around the water piston.

After slightly softening the old packing, by putting it in hot water, I replaced it and found that the tin sleeve made it fit nicely. The pump was put into service and it ran two weeks until new packing arrived.

Cherokee, Okla.

He Got an Increase in Pay

Several years ago I went to work for a wood-working company in northern Michigan. Before I took charge of the steam plant, which consisted of one 54-inch by 14-foot shell boiler and a 10x16-inch slide-valve engine, they had one man firing and another cleaning the shop, bring refuse into the fire room and acting as a helper. These two men were paid $1.25 per day, and another man was paid $2 a day to look after the engine, which was located about 50 feet from the boiler. This made $4.50 for wages and they were burning eight cords of 4-foot wood costing $1.50 per cord, or $12, a total daily expense of $16.50.

I did the work of three men, except cleaning the shop. I started in for $1.50 a day and a promise of a raise, and I never got such a roasting in my life as I got the first day, firing with 4-foot wood. I knew something was wrong with the engine, but I did not want to stop to investigate until night; but at 4 o'clock I was all in and stopped the engine, took off the steam-chest cover and found the lock nuts on the valve stem loose and the valve sliding ¾ of an inch on the stem.

I got the valve centered, but on turning the crank to the center, I found the valve had no lead until about one-third stroke. I got busy with the eccentric, and moved it around until I had 1/32-inch lead with the crank on the center. When the engine was started the men all ran out of the shop for, instead of 165 it was making 247 revolutions per minute. I soon got the governors set for 220, the speed wanted. I next began burning coal that the former engineer said could not be burned without shaking grates, and it required 2700 pounds for 10 hours. Coal cost $3 per ton, or $4.05 for the day, and my $1.50 made $5.55 against $16.50 they were paying before I came. Furthermore, I was giving all the power wanted for 10 hours a day, while before there was not enough power any of the time, and the engine had to be shut down several times a day to get up steam, which made a difference of at least $100 per day in the output of the factory.

After my ten days' trial, I got my increase in pay and my experience since has proved it to be a typical engineers' raise. I saved the company $10.95, increased the output $100 a day and I got a raise of 25 cents a day.

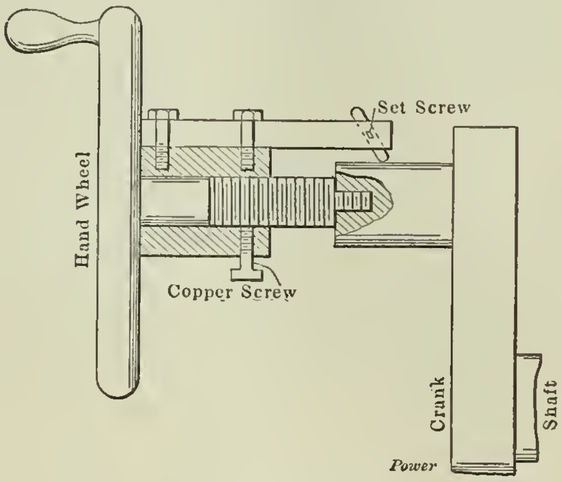
Detroit, Mich.

Device for Turning a Crank Pin

The accompanying sketch illustrates a device that I made to true a crank pin. On taking charge of my present plant, I found the crank pin on the ammonia compressor in very bad shape. It had been allowed to get hot and was badly cut and scored, and it was almost impossible to keep the bearing cool.

On calipering the pin I found that it was not only badly cut, but that it was out of round 3/32 of an inch. The diameter of the pin was 4⅞ inches, with a bearing 5 inches long. I took a piece of $1\frac{15}{16}$-inch shaft, 9 inches long, and got



Turning Device

one end turned down and threaded to screw into the end of the crank pin, 1 inch, as shown in the accompanying sketch. A fine thread (24 to the inch) was cut on the remaining part of the 9-inch pin. A sleeve was made to fit over the shaft, and a copper set screw passed through the sleeve to tighten on the thread.

A piece of ¾-inch square steel was attached to the sleeve with two set screws, and a slot was provided near the end to hold the cutting tool that was secured by a small set screw. A small solid balance wheel fitted with a handle was bored out to fit on the sleeve, which completed my apparatus.

Having all my toggles together, all was ready to go to work on Sunday morning, and with one assistant I turned up the pin and made a splendid job of it in about three hours.

The only mistake that I made in constructing my machine was that the feeding thread was a little too coarse.

After removing the machine from the pin I took two pieces of hard wood of the proper width and about 18 inches long, bolted them together and then bored a hole through them. Then emery cloth was tacked in the bore, the device was put in place and the pin smoothed up.

The boxes were rebabbitted and scraped, which completed the job.

William G. Walters.

Stratford, Can.

Making Engineers

In almost every issue of Power one reads about engineers' hours, engineers' wages and engineers' associations, but I cannot recall seeing any article on making engineers.

When I took charge of my present plant, I had fourteen men under me and not one of them subscribed for an engineering magazine or devoted any time to studying engineering subjects. It took me but a short time to find out that they were ignorant of the most elementary parts of steam engineering.

I suggested to my assistant engineers and firemen that they subscribe for Power and other magazines, which they cheerfully did. I also suggested that they procure "Power Catechism," and showed them my own well worn copy and allowed each man to take it home for one evening's perusal, with the result that I placed five orders for the book. When any of my men asked me about any new appliance he saw advertised, I gave him stationery and the use of my desk at noon to write for a catalog and particulars.

At the end of one year eight men have procured engineer's licenses of various grades, two have left my employ and are running a plant of their own, three are studying hard for fireman's license and three are still in the same old rut, only wishing for 6 o'clock and the largest schooner of beer in the nearest saloon.

Where do I benefit and what recompense do I get for spending my evenings with my men? First, I have a thoroughly reliable crew of eleven men, and, with everyone trying his best to improve conditions in the plant it is kept up in better shape for less money, although the men have been given an increase of 25 cents per day. Second, I am a more uptodate engineer, as I continually have my memory refreshed, for when my men ask me a question I cannot answer I reply, I do not know but I will find out.

Now, some of you chief engineers get down off your "high horse," go down to the fire room and explain to your firemen that brains in the boiler room, as elsewhere, are worth more than muscles, and I will venture to predict that you can operate your plant for less money and with more satisfaction.

William T. A. Faulkner.

Seattle, Wash.

Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

Pumping Problem

In the November 15 issue of POWER, Mr. Ellethorn contributes a pumping problem for which I offer the following solution:

Briefly, his problem is as follows: A 6x12-inch duplex pump, driven by a 12-horsepower engine, pumps 235 gallons of water per minute, through a 4-inch discharge line, which runs horizontally 200 feet from the pump, then vertically 200 feet and discharges into a tank. The water is drawn from four open wells, located 100, 110, 120 and 150 feet from the pump. The water level in these wells is 10, 12, 18 and 22 feet respectively below the ground. The main suction pipe is 5 inches in diameter, and the risers from the wells, all of which terminate in the main suction line, are of 2½-inch pipe. In the absence of any data to the contrary, I assume that the pump and suction line are at ground level.

The discharge, which is given as 235 gallons per minute, is equal to

$$\frac{235}{60 \times 7.48} = 0.523 \textit{ cubic feet per second}$$

The problem is to find how much of this comes from each well.

Numbering the wells 1, 2, 3 and 4, in the order in which they are mentioned above, it is first assumed that all of the water comes from well No. 1, in which the water level is 10 feet below the ground or datum. This water is lifted against, not only a static head of 10 feet, but a friction head, which is given by the following equation:

$$\textit{Friction head} = \frac{4fl}{d}\,\frac{v^2}{2g}$$

wherein

v = Velocity of water in pipe in feet per second;
g = Acceleration due to gravity = 32.2 feet per second;
d = Diameter of pipe in feet;
l = Length of pipe in feet;
f = An experimentally determined coefficient, depending not only upon the velocity of the water and diameter of the pipe, but also upon the condition of the pipe as regards corrosion, etc. A clean iron pipe is assumed in this case.

The area of the 2½-inch pipe equals

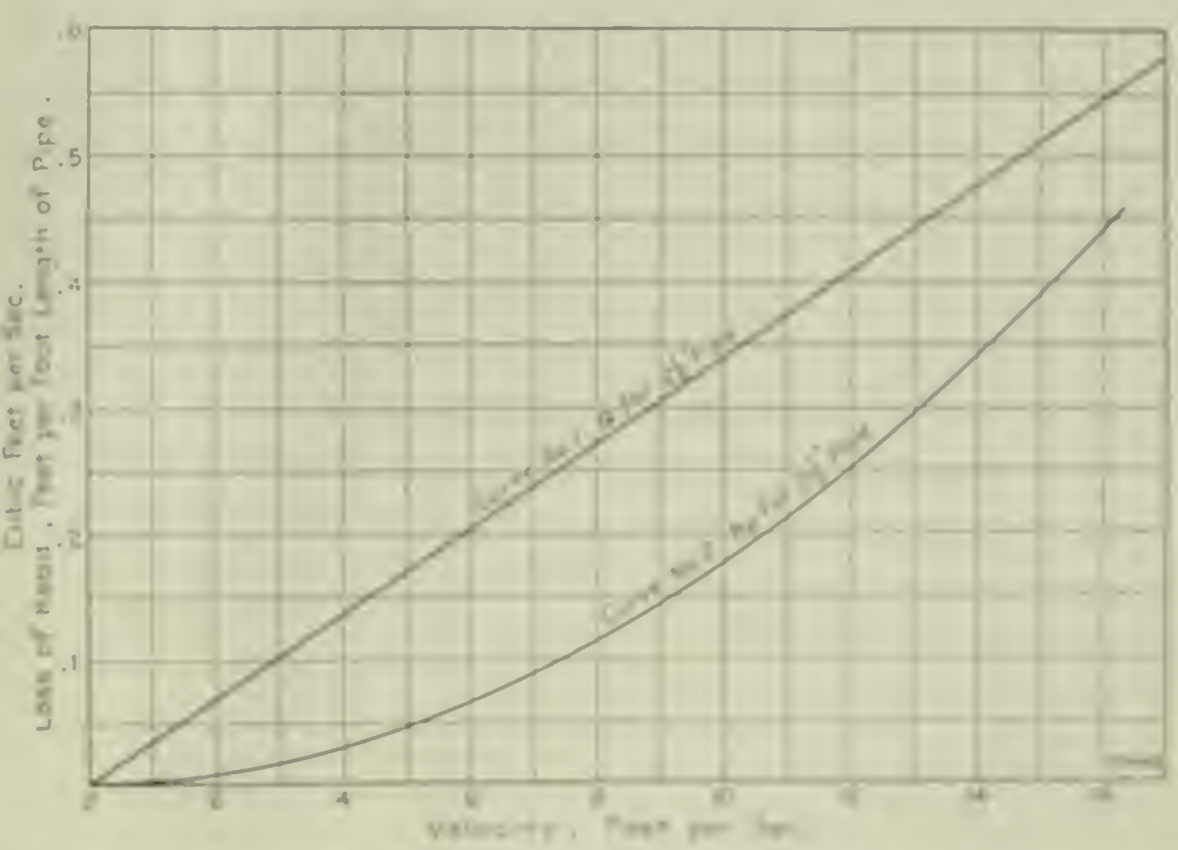
$$\frac{\pi}{4}(2\tfrac{1}{2})^2 = 4.91 \textit{ square inches} = 0.034 \textit{ square feet}$$

The velocity in the pipe equals

$$\frac{0.523}{0.034} = 15.38 \textit{ feet per second}$$

For a clean iron pipe, 2½ inches in diameter and a velocity of 15.38 feet per second, Fanning gives a value for f of 0.00580.

Substituting these values, the friction head is,



CURVES SHOWING VOLUME OF WATER DELIVERED AND LOSS OF HEAD

$$\frac{4 \times 0.00580 \times 10 \times (15.38)^2}{\frac{2.5}{12} \times 2 \times 32.2} = 4.12 \textit{ feet}$$

The total head (up to the 5-inch main suction pipe) is

$$10 + 4.12 = 14.12 \textit{ feet}$$

This being greater than the 12-foot static head of well No. 2, indicates that some water is drawn from that well; but no water will be taken from wells Nos. 3 and 4, because their static heads (18 and 22 feet respectively) are greater than this.

Let

Q = Total flow (0.523 cubic foot per second);
Q_1 = Flow in riser No. 1;
Q_2 = Flow in riser No. 2;
h_{f_1} = Loss of head due friction in riser No. 1, expressed as feet per foot of length;
h_{f_2} = Same for riser No. 2.

The problem now is to divide Q or 0.523 cubic foot per second between wells Nos. 1 and 2, so as to balance the following equation, which expresses the condition of equilibrium:

$10 + 10\,h_{f_1} = 12 + 12\,h_{f_2}$ = *friction head in 10 feet of 5-inch main suction pipe due to the flow of Q cubic feet per second.*

This problem necessitates using the "cut and try" method, that is, assuming a certain division of the 0.523 cubic foot per second and finding the resultant friction heads, until such values are found as will balance the above equation.

To save the work of solving the long formula for friction head for each assumption, curve No. 2 is plotted, with head lost in friction per foot of length of pipe as ordinates and with the velocities as abscissas. The variation of the coefficient f with velocity is taken into account in plotting this curve. Curve

No. 1 is that of cubic feet per second platted to velocity. All values are for 2½-inch pipe.

Assuming for the present that the friction loss in the 10 feet of 5-inch main suction pipe between wells Nos. 1 and 2 is negligible, the equation of equilibrium becomes,

$$10 + 10\, h_{F_1} = 12 + 12\, h_{F_2}$$

Assume that $Q_1 = 0.400$ and $Q_2 = 0.123$.

Referring to the diagram, pass horizontally across the line $Q = 0.400$ until it intersects the straight line, thus obtaining the velocity. Dropping vertically down this velocity line until it intersects curve 2, then horizontally to the scale at the left, we find,

$$h_{F_1} = 0.245 \text{ and } h_{F_2} = 0.025$$

Substituting in the equation of equilibrium,

$$10 + 10 \times 0.245 = 12 + 12 \times 0.025$$
$$12.45 = 12.30,$$

which indicates that the assumed value of Q_1 is too large.

Trying again with $Q_1 = 0.390$ and $Q_2 = 0.133$, from the diagram we find,

$$h_{F_1} = 0.233 \text{ and } h_{F_2} = 0.029$$

and our equation of equilibrium becomes,

$$10 + 10 \times 0.233 = 12 + 12 \times 0.029$$
$$12.33 = 12.35.$$

This being sufficiently close for our work, we will say that 0.390 cubic foot per second comes from well No. 1 and 0.133 cubic foot per second from well No. 2.

Now, knowing the value of Q_2, we must figure the friction loss in the 10 feet of 5-inch main suction pipe between wells Nos. 2 and 1 and see if our assumption that it is negligible, is sustained.

The area of the 5-inch pipe equals 0.136 square foot and the velocity in the 5-inch pipe is

$$\frac{0.133}{0.136} = 0.974 \textit{ foot per second}$$

For this velocity and a 5-inch pipe, Fanning gives $f = 0.007$. Substituting in the formula,

$$\textit{Friction head} = \frac{4 \times 0.007 \times 10 \times (0.974)^2}{\frac{5}{12} \times 2 \times 32.2}$$
$$= 0.00949 \textit{ foot}$$

which is negligible.

The pump or delivered horsepower is equal to the weight of water pumped per minute multiplied by the total head pumped against and divided by 33,000.

The total head is made up of four items, as follows:

(1) Discharge head = 200 feet.

(2) Friction head in 400 feet of 4-inch discharge pipe.

(3) Friction head in 100 feet of 5-inch main suction pipe.

(4) Static and friction heads (up to the main suction pipe) = 12.35 feet.

The manner of finding items (2) and (3) is exactly the same as that previously used, employing the formula,

$$\textit{Friction head} = \frac{4\, f\, l}{d}\,\frac{v^2}{2\, g}$$

using the proper values of f, as determined by the velocities and sizes of pipes. Item (2) comes out equal to 16.23 feet while item (3) proves to be equal to 1.41 feet.

Hence, the total head is,

$$200 + 16.23 + 1.41 + 12.35 = 230 \textit{ feet.}$$

The weight of the water pumped per minute is,

$$235 \times 8.34 = 1960 \textit{ pounds,}$$

8.34 pounds being the weight of one gallon.

The pump horsepower is,

$$\frac{1960 \times 230}{33{,}000} = 13.66 \textit{ horsepower}$$

Economic Engineering

With so many past records to uphold Power in its editorial in the September 27 issue, it seems superfluous to make additional comment on this subject. The argument offered by R. L. Rayburn in criticism, in the November 22 issue, however, makes further annotation necessary. Organization heads with manifold duties of office cannot take the part of the economic engineer; past performances have indicated this, and the particular type of the former which he depicts is considerably in the minority. The efficiency engineer called in on certain work possesses knowledge of many plants; the local superintendent has definite data on one—his own; the information that Mr. Rayburn mentions as being in the power of the superintendent becomes the property of the efficiency engineer; this is what he is placed in his position for—to investigate and learn actual existing conditions; he does not go blindfolded to his work. To afford efficient production his initial expenditures for new equipment may be large; he may change the system of the entire plant for future betterment—the results are manifested over a period of time, inclusive of interest on investment and depreciation; his arguments are based over a wide territory and, as Power states, he is not prejudiced. Is it not reasonable then to suppose that the economic engineer is in a far better position to offer suggestions for efficiency than the "man on the job"? The present Santa Fé Railroad system stands as a notable example of what an efficiency engineer can accomplish. The average superintendent, as found, is greatly in accord with keeping all expenses down—this is his province; in many instances (taken from actual experience) a superintendent has refused an installation which later the efficiency engineer has recommended.

I am under the impression that the superintendent is usually considered as an employer, and Mr. Rayburn contradicts his statements in noting, "I have found a great deal more unwillingness on the part of employers to furnish new equipment with which to improve the methods of operation, than unwillingness on the part of operators to break away from old established customs."

Efficiency work in its various branches is and has been for some time past a paramount issue with leading technical publications; the great results achieved, made known through this channel, leave no doubt in the mind that "the economic engineer is in a much better position to produce an effective solution of the problem" than any member of an organization, and that he is here to stay.

Knocking Slide Valves

In the November 1 issue of Power W. H. Keller gives an account of trouble with a valve rattling or knocking.

I have had the same trouble with several engines. In one of these engines the pressure plate was held in place with two coil springs which rested over pins, and there appeared to be no cause for the trouble other than that the spring had become slightly weakened by the heat of the steam. Washers were put on and the rattle stopped.

In another case the trouble was with an engine which always ran well in warm weather, but when it was cold the valve rattled very badly. Owing to a very large heating system it was necessary to carry about 8 or 10 pounds back pressure on the heating system in order to heat the buildings. This high back pressure made the compression run up to about 10 or 15 pounds above boiler pressure. This trouble was also stopped by putting washers behind the spring.

Many automatic shaft-governed engines give trouble when running with a light load on account of the high compression, which occurs with a very early cutoff. This high compression not only makes the valve and pressure plate rattle, but often causes the engine to knock in the bearings. If the exhaust lap be trimmed off to remedy this, the compression will not be high enough when the engine is running under a heavy load. This difficulty may be overcome by running a pipe containing a check valve from the cylinder drain across to the steam-chest drain, or to any opening in the steam chest. The compression then cannot run above boiler pressure because the check valve will relieve it and let any excess steam return to the steam chest, but will prevent any steam being admitted except through the valve.

Leakage Past a Piston Valve

It is true that the leakage past a solid plug or piston valve is a hard matter to determine, but that there is leakage is well known. The amount depends on many things; probably the first is the quality of the material of which the engine was built, the second, possibly, the accuracy with which the engine was built and third, the care with which the engine is handled.

Many builders claim tight piston valves, yet they design these on the expansion principal, so that a valve can be expanded or adjusted to compensate for wear. With some rectangular plug-valve engines, such as use a much modified Sweet valve, an adjustable pressure plate is used; this must be for the purpose of taking up wear or preventing leakage past the valve. From operating experience as well as building, I know that when there is motion there will be wear, and unless we provide amply for such wear we are sure to find leakage. Many of the makers of engines having the Sweet valve could better their machines by carrying out the inventor's ideas—plenty of travel and plenty of surface means more life and a tighter valve.

Experience teaches that few engineers will take pains and care to keep rebuilding an engine so as to maintain a steam-tight valve, but instead, most of them allow the coal bill to run away with itself. The thing to do is to care for the machine properly, testing it at intervals for leaks and setting up the pressure plates so that leakage is reduced to the minimum; much coal can be saved in the engine room in this way. The steam-tight engine is a more difficult thing to find than many engineers think. Engineers should make more frequent tests so as to see that their engines are not leaking. This is just as important as locking the "cash drawer" and it is not for the want of knowledge upon the part of the operating engineer that tests are not made more often. Many engineers are past master machinists, know how to use the hand scraper and let down a pressure plate with as much skill as the engine-shop man. Thousands of dollars can be saved by following this suggestion.

While many piston-valve engine men say that these engines do not leak, they would be very shy of putting up their own money on a bet. If it is not a case of leaking or not leaking, examine your engine and see that the valves are tight; do this on behalf of the company you are working for.

In taking up the expansion-ring valve it is necessary to take it up slightly and allow it to run a while and then take it up again as in expanding the ring it changes the circle and has to find a new seat or bearing so as to become tight in the port. In testing these engines I have found many to leak, not only those of the horizontal type but also those of the vertical type in which the wear was less than in engines of the several marine types.

I have never been able to see but one advantage that the piston valve possesses, that is, the round piston valve. This advantage is that it runs light and is light on the governor.

To test an engine for leakage, place it on midcenter, disconnect the exhaust, if possible, remove both indicator plugs and turn on full steam pressure just as you would when starting. The fact that an engine runs well is no indication that the engine is not leaking. In some cases the engine that is leaking the most will be running the smoothest.

Only a few days since I had the opportunity of examining and measuring with standard gages a piston valve of the plug type and found that there was more than 0.033 of an inch play between the valve and the seat. The engine was of about 100 horsepower capacity, so one can imagine what the loss amounted to.

Frequent tests should be made. Engineers do not test and inspect enough; as a rule these matters are sadly neglected.

Underground Steam Piping

I note the answer given to a correspondent recently relative to underground steam piping. I have had a fair amount of experience along that line and rather doubt if the advice would apply to all conditions. With a gravelly ground which takes the water away the problem is fairly easy if your expectations are not too high. We have put the pipe in all the ways we could think of that promised success. Our ground is a water-tight clay which makes it a hard proposition. And, not only that, but in certain sections it is saturated with salt. The first pipe we put down was laid in a box and packed with cinders. As might be expected, this lasted only about six months; the sulphur in the cinders destroyed the pipe quickly.

Our next job was to put several hundred feet of return pipe from a steam-heating system in the ground. This was placed in a box of 2-inch plank and packed with mineral wool; the job was a rank failure. The ground held the water and the wool kept the moisture up to the pipe, causing a rapid corrosion. This job lasted one winter and was in bad condition when the steam was turned on the following fall. Mineral wool is not the best material for this line of work; it has a way of settling down in the box and leaving the top of the pipe exposed. We would not have had such poor results if the ground had been of a nature to let the water drain away. We realized that we had to get a better method and we tried two ways of protecting the pipe, both of which have been fairly successful.

A part of the pipe was placed in a box of 2-inch plank, as in the first case, except that it was not packed with anything and the pipe was supported in the center of the box by a cradle of iron rods that left it quite free to move lengthwise. This installation has been in nearly six years and has given no trouble at all. Of course, there is some loss by radiation but probably less than if any packing was in contact with the pipe. Several hundred feet of this same pipe was laid in a different way but with equally good results. In this case we wrapped the pipe quite loosely in two or three turns of tar roofing paper, wiring the ends. Around this we placed about 3 inches of mortar composed of cement and sand in the proportion of 1 to 3. This keeps the pipe in good shape and the roofing paper forms a core in the cement large enough to allow the pipe a free movement. I like this plan very well.

About three years ago we laid a 2½-inch pipe from the shop across the commons, 300 feet to the house. In this case we pitched the 2½-inch pipe down for a distance of 150 feet, then put in an expansion joint and a trap, raised the pipe size from 2½ to 3 inches and pitched it up to the cellar of the house. The extreme low point was over a sewer into which the trap discharged, all condensation from the radiators returning in the 3-inch to the trap. The system works well. The pipe is placed in a box of three thicknesses of [illegible]-inch plank with two [illegible]-inch air spaces and packed with pine shavings. Underneath the box is a 6-inch drain tile covered with gravel and over the whole is one thickness of tarred paper. This pipe has given no trouble whatever and we feel that it is fairly well insulated. The job was too small to pay for returning the condensation, especially as we had plenty of hot water for the boilers and a purifying system to remove the impurities.

Our last work was that of taking care of the returns from the heating system in a building 150x150 feet square and two stories high. Next to the side walls we made trenches 2½ feet wide and 3 feet deep to carry the main returns. The laterals are in cement ducts with boxes in the cement so that the pipe can be got at with the least damage to the floor. We use a plain gravity system with return pipes of a size that allows them being only partly filled with water, thereby balancing the pressure on the system and allowing the air in the wall coils and radiators to gravitate to the receiver, where it is expelled through simple means.

To my mind, there is no really successful way of burying a steam pipe in the ground so as to have it last well. The only way is to place it in a tunnel where it can be kept in repair and properly insulated.

I have seen 10-inch mains taken up in a district heating system that were practically destroyed after three or four years' use. If pipe has to be placed in the ground, make the covering as near moisture proof as possible. Even then there will probably come leaks in the joints that will keep the insulation wet and cause its destruction if the pressure is high.

Handling Men

Much has been said in the columns of Power in regard to the treatment of men employed in the power house.

To know just how to treat each and every man in a power plant is no easy task, for if you try to act fair with all, there is bound to be some who will not appreciate kind treatment.

The men of a certain class do not seem to know when they are well off; they kick and complain about their surroundings, their hours of labor, etc., and they are always complaining about not getting a chance. Yet, when their conditions are bettered they abuse them, and whenever a chance for a better job turns up they are not prepared to accept it. The question is, what is the best thing to do with these men.

Men who are ambitious and ever ready to acquire a better working knowledge of their business as engineers, firemen or oilers, do not as a rule find much difficulty in commanding respect from the superintendent or chief engineer, especially if they can show that they are awake on their job. It is only the men who have to be told to do every little thing around the plant, or the men who try to see how much time they can kill without being discovered who find it hard to get along with the operating engineer. A majority of subordinates do not fully understand the position that the engineer in charge is placed in; they do not or will not reason the matter out to see that the owner or manager holds the engineer responsible for everything pertaining to the engine room, and yet when the engineer thinks up ways and means for saving fuel, oil or supplies and divulges his little schemes to his helpers, nine out of every ten of these men criticize him as soon as his back is turned, for catering too much to the boss.

To my mind the positon of engineer in charge of any plant is no sinecure, and I can positively state that you must treat the men that you are responsible for in a manner best suited to them, based on personal observation of them.

If, as Mr. Levy says in Power for December 20, a man finds fault simply because he wants it understood that he is it, he certainly shows his lack of sense and cannot expect the men who work for him to have any confidence in his judgment.

Referring to the article submitted by Mr. Carr in the same issue, in which he says that he treats his men as he would like to be treated himself, I must say that I agree with him in this respect, providing he is dealing with the class of men who have brains enough to know that they are being treated right. Mr. Carr further states that we all make mistakes, which is all too true, but here, as in all other things, a lot of judgment is needed to decide whether or not the mistake is pardonable.

Certain men when given an inch will take a foot; that, to my mind, is a very true saying and if this class of man is not kept in his place there is no telling what else he may take.

Regarding his statement as to a man who is frank enough to say he is not familiar with this, that or the other thing, I would like to say that as a rule this kind of a man usually makes the one on whom you can rely most, owing to the fact that what he has learned has to a large extent been gained from the knowledge which has been imparted by you; the right kind of man will show his appreciation of this fact by faithful service as long as he is in your employ.

H. H. Burley.

Introducing Solvents into Boilers

Under the above heading, Charles H. Taylor had an article in the December 6 issue of Power in which he described his method of introducing solvents. I believe that it is better to feed the solvents in with the feed water, so that all the feed water will carry along with it into the boiler the required amount of compound necessary to precipitate the scale-forming matter contained in it.

One method of accomplishing the desired result is to have a small pipe connected into the suction pipe of the pump and extending up a little higher than the level of the water in the heater. The pipe should end in a funnel. Above should be mounted a tank large enough to hold at least a day's supply of the solvent used, dissolved in water. The outlet pipe from this tank should end in a petcock just above the funnel, so that the attendant can see and regulate the amount of the solution he is feeding. Of course, the above method will not apply where the feed water is supplied to the pump under city pressure, but as I never had that problem to solve I will leave suggestions along that line to those who have.

Where compounds are used that will act on the feed water below the boiling temperature and where an open heater is used, I introduce the compound into the inlet pipe to the heater, so that the compound can act on the water as it passes through the heater. The heater thus becomes a sort of a feed-water purifier. Under some conditions large quantities of scale-forming matter can be removed by the heater and if a heater is used that is easily cleaned there is a decided gain over the method of treating water after it leaves the heater.

On waters that soda ash has produced little or no effect outside of the boiler, trisodium phosphate has been found to act efficaciously even while the water is quite cold, so that by introducing this latter compound into the feed water before it enters the heater a large part of the scale-forming matter is precipitated and removed from the water before it enters the boilers.

Liquid Discharging Device

An article by Earl Pagett, on page 2196 of the December 13 issue of Power, interested me a good deal, as I have had some experience with a somewhat similar device for emptying barrels.

Several years ago I conceived the idea of making a similar arrangement, but to start with I applied the air at a separate opening. My arrangement worked beautifully on several barrels. One day I got hold of a barrel with a very short chime and when the air pressure came on, the head came out of the barrel. Forthwith I lost all interest in that means of emptying barrels.

A. G. Knight.

Omaha, Neb.

Lubricating Piston Packing

An article in the November 22 edition relating to a ring or sleeve between sundry rings of fibrous packing, with a hole in the said ring or sleeve through which oil is run by gravity onto the piston rod while it is in reciprocating motion, reminds the younger generation of engineers of their daddy's lectures that, say, a 40-horsepower stationary engine must have a cylinder diameter of, say, 14 inches and a stroke, say, 36 inches long—the longer the better and more effective—no cutoff and a speed of 50 revolutions per minute.

We wish to learn, and concede that we know very little, why it would not be well to utilize graphite instead, fed through a modern lubricator. Perhaps one reason has been the likelihood that graphite, mixed in oil for the purpose, would stop up or clog up the openings, which experience has proved to be so. Our idea is, however, to use graphite in connection with the lubricator in which the drops of oil pass over a bed of fine graphite, to the cylinder, lubricating the inside of the cylinder, the valves and, particularly, the *piston rod,* dispensing with the ring or sleeve for lubricating the rod and the packing.

POWER

The Consumer Pays the Bill

Not many years ago the anthracite coal companies of Pennsylvania could market only their larger sizes of coal which was used largely for domestic purposes.

The smaller sizes now known as pea, buckwheat, rice and barley coal were dumped in great piles together with bone, slate and other refuse from the mines. These immense culm piles grew in number, and in some instances to almost mountainous proportions, but no attempt was made at that time to reclaim the fuel mixed with the noncombustible matter.

Just when the burning of the smaller sizes of anthracite coal was begun is not definitely known, but many large power plants are now using buckwheat coal extensively as a fuel.

Naturally, the growing demand for the smaller sizes of anthracite coal has not been from a desire on the part of the power-plant manager to reduce the culm pile or to add profit to the coal producer, but that the cost of operating the steam plant might be reduced by using a cheaper fuel. Accordingly he has devoted much attention to experimenting and the training of his fire-room force in handling the cheaper grades of coal.

It did not require much urging on the part of the consumer to awaken the coal producer to the fact that there were thousands of dollars to be had almost for the picking up, and as a result washeries were built, old breakers remodeled and the reclaiming of coal from the culm piles became a most prosperous enterprise.

The demand at first was for the larger size of the buckwheat coal, which was cheaper than the pea and chestnut sizes, but the price was put up as the producer saw the demand had become permanent. This forced the consumer to either purchase a cheaper grade of coal or increase the cost of the manufactured product, and the cheaper grade was bought.

As the purchase price increased on a certain grade of coal, still cheaper and finer sizes were tried until barley, the smallest of all except "[illegible]," became the cheapest grade of anthracite coal that could be used.

Barley coal, until recently, has been selling for $1.50 per gross ton of 2240 pounds, f.o.b. vessels at Hoboken, N. J.; rice, $2; buckwheat, $2.50; and chestnut, $[illegible]. Each of these coals has been advanced in price during the past month at the rate of 25 cents a ton.

To one known company using rice and barley coal this increase will make a difference of about $40,000 yearly in the cost of fuel. There is no cheaper grade of coal to fall back on and the additional cost must be met.

It is not at all probable that the manufacturer will stand the increases in the coal bill, and as there is not much chance of decreasing the amount of coal consumed per year, the logical conclusion is that the consumer will in the end pay for it.

It is not the cost of reclaiming this coal from the culm pile that warrants a selling price of $1.75 per ton, as a ton of buckwheat coal can be washed and loaded in a car for something like 10 cents per ton. The balance of the coal price is divided between profits and transportation rates.

And the consumer, who has created a demand for a byproduct of a mine at one time thrown away, must now pay an increase per ton just because the coal producer determines to make a greater profit on coal that costs practically nothing to market, and because there is no substitute in sufficient quantity to supply a B.t.u. at an equal cost.

Impossible Boiler Performances

There are being circulated printed records of tests conducted by John R. [illegible] at the plant of the American Printing Company, Fall River, Mass., upon horizontal return-tubular boilers, in which evaporations of over sixteen pounds of water from and at 212 degrees are claimed. Mr. [illegible] is the master mechanic of the above named corporation and evidently believes that he obtained those results.

To evaporate a pound of water from and at 212 degrees requires 970.4 units of heat. To evaporate [illegible] pounds, as Mr. [illegible] claims was done in one of his tests, would require [illegible] heat units.

Assuming that each pound of combustible makes twenty pounds of gas and that the gas leaves the boiler four hundred degrees above the room temperature, it would take some two thousand heat units to the chimney with it. Adding this to the heat put into the steam it is seen that such a performance would call for a coal of over eighteen thousand British thermal units per pound of combustible, even allowing nothing for radiation; and no such coal has ever been mined.

At the time that this impossible performance is claimed to have been effected the boilers were fitted with a device known as the Cornell fuel economizer. This consists of a number of metallic retorts behind the bridgewall, into which steam is admitted, and it is claimed that the steam in passing through them is decomposed into its constituent gases, oxygen and hydrogen, and that it is the combustion of the hydrogen which supplies the extra heat necessary to obtain the high evaporation reported.

This claim has been exploded over and over again in POWER. Even if the steam is so decomposed it takes as much heat to decompose it as the gases produced will generate in combustion. When hydrogen is burned, two atoms of hydrogen unite with one of oxygen to form H_2O or water vapor—steam. The decomposition of steam into hydrogen and oxygen is a reversal of the process, and takes just as much energy in the form of heat as was produced, or will be produced again, by the reunion of the gases in combustion.

If those in authoritative control of the Cornell Economizer Company do not know this, they had better inform themselves as to the elementary principles of combustion before entering the market as practitioners in this line.

Natural Sources of Power

Man has often been called a tool-using animal, this seeming to be the only characteristic difference between him and other animals. But more than a tool user he is a power user and as civilization advances the per capita demand for power increases in geometrical ratio.

Scarcely a century ago the modest demands of each community were met by the utilization of the energy of small, rapid streams by the means of crude waterwheels built in place by the local millwright. In some instances the ebb and flow of the tide furnished the power needed by small industries and, where both waterfall and ocean tide were lacking, great canvas-covered wind wheels turned the stones that ground the grain for man and beast.

With the parallel development of the steam engine, electric transmission and the factory methods of production came increased demands for power for manufacture and transportation.

Steam has been almost universally used as the medium of transmission. But the steady increase in the price of coal has turned the attention of men toward the natural forces of wind and wave and their utilization in power production. "The wind that bloweth where it listeth" and the sea which is never still could if intelligently harnessed be made to furnish power at a rate far beyond the dreams of the wildest enthusiast.

But at what price per unit?

Some of the oldest mills in the country were and perhaps are today driven by wave power. Built before the steam engine became the common prime mover and costing little for upkeep they have, where equal to the demand, been continued in operation. An investment once made, the interest cost of the capital goes on forever, and it will doubtless be found on investigation that the interest on the investment in any of the old-time water or wind powers at prevailing rates would operate a steam plant of equal capacity and leave a margin of profit.

With the ever-increasing demand for power for every conceivable purpose it is not to be wondered at that every move tending toward the development of unused forces of nature should attract attention, but it "passeth understanding" that palpably inefficient and expensive methods of utilizing the rise and fall of the tides, the heat of the sun and the current of rivers beyond the reach of a possible market should find such ready support from even a guillible public.

No investor would buy land without having the title examined by competent authority on such matters. But the first successes of a Keely or a Carroll show that the professional promoter of any kind of a scheme to beat the law which affirms that action and reaction are equal and opposite, finds ready buyers for his wares.

No one should consider the investment of money in any enterprise to control and direct natural forces until he has paid a competent engineer to make an exhaustive examination of the proposed program.

A Pioneer

For his work in advancing condensing and compound-engine practice in this country, William Coutie, who died recently at Troy, N. Y., deserves attention from the engineering fraternity. Mr. Coutie was in his ninety-second year. He came to the United States from Scotland before he was thirty, and in 1849 he was working as a machinist at the Starbuck shops in Troy, then located close by the river. Near the shop was a coffee and spice mill doing a large business for those days and driven by an ordinary high-pressure noncondensing engine. He arranged to take the exhaust from this engine, placing a valve in the pipe which guaranteed that there should be no back pressure, and with this steam he drove a condensing engine which supplied him with power for a machine shop which he started in 1850. This was his sole source of power for ten years or more and it was an incontrovertible example of the economy of condensing.

He made a specialty of simple and compound steam engines, always condensing, and built quite a number for Troy and the immediate vicinity. The engines never proved to be what would be considered high-class machines, but they saved fuel and cost little for repairs. He was one of the first builders of "Troy laundry machinery" and did a general and repair trade, but never anything big, and discontinued business in 1899.

Mr. Coutie was spoken of as a scientist and had affiliations with some of the societies. He wrote a number of papers of a pseudo-scientific character which could scarcely be considered seriously. They all had the somewhat unusual merit of being short. His hobby for fifty years was the commutation of metals, and he is said to have died in the belief that this he had actually accomplished.

In utilizing exhaust steam that had previously been wasted, Mr. Coutie allowed his Scotch thrift to come to the front. In effect his engine was merely a low-pressure cylinder added to the engine in the spice mill, but for so early a period in steam-engine history, his work was ingenious to say the least, and he should be given due credit.

The following is a squib which appeared in one of the Pittsfield, Mass., papers on the day following the disastrous boiler explosion, described in the January 10 issue of POWER:

"When asked by the reporters for a statement concerning the exact cause of the explosion, Inspector McNeil spoke in full as follows:

"...............................
....
....
..............................."

If an engineer takes a lively interest in all matters pertaining to his vocation he will be a successful engineer.

Some idea of the importance of apparently small things may be had when it is realized that in a 30,000-kilowatt plant one inch in vacuum represents a total of $14,000 in the operating expenses for one year.

With the water-power developments and the adaptation of the internal-combustion motor to all classes of power service, how long will it be before steam engines will be unfashionable?

San Francisco started the new year with an earthquake. That's nothing. Pennsylvania and Massachusetts had three boiler explosions just before New Years, and killed twenty men.

Low Pressure Steam Turbine

Osborn Monnett

At the works of a rubber-manufacturing company live steam at 40 pounds pressure, after being used in the vulcanizers, is utilized in a low pressure turbine.

No installation better demonstrates the possibilities of the low-pressure steam turbine than does that of the Diamond Rubber Company at Akron, O. The power plant originally contained a 1500-horsepower, cross-compound, Corliss engine, direct connected to a 1000-kilowatt generator, the set running condensing. In addition there was a 250-kilowatt, tandem-compound noncondensing engine and numerous auxiliaries exhausting into the low-pressure system, which supplied the heating coils of the indirect heating system.

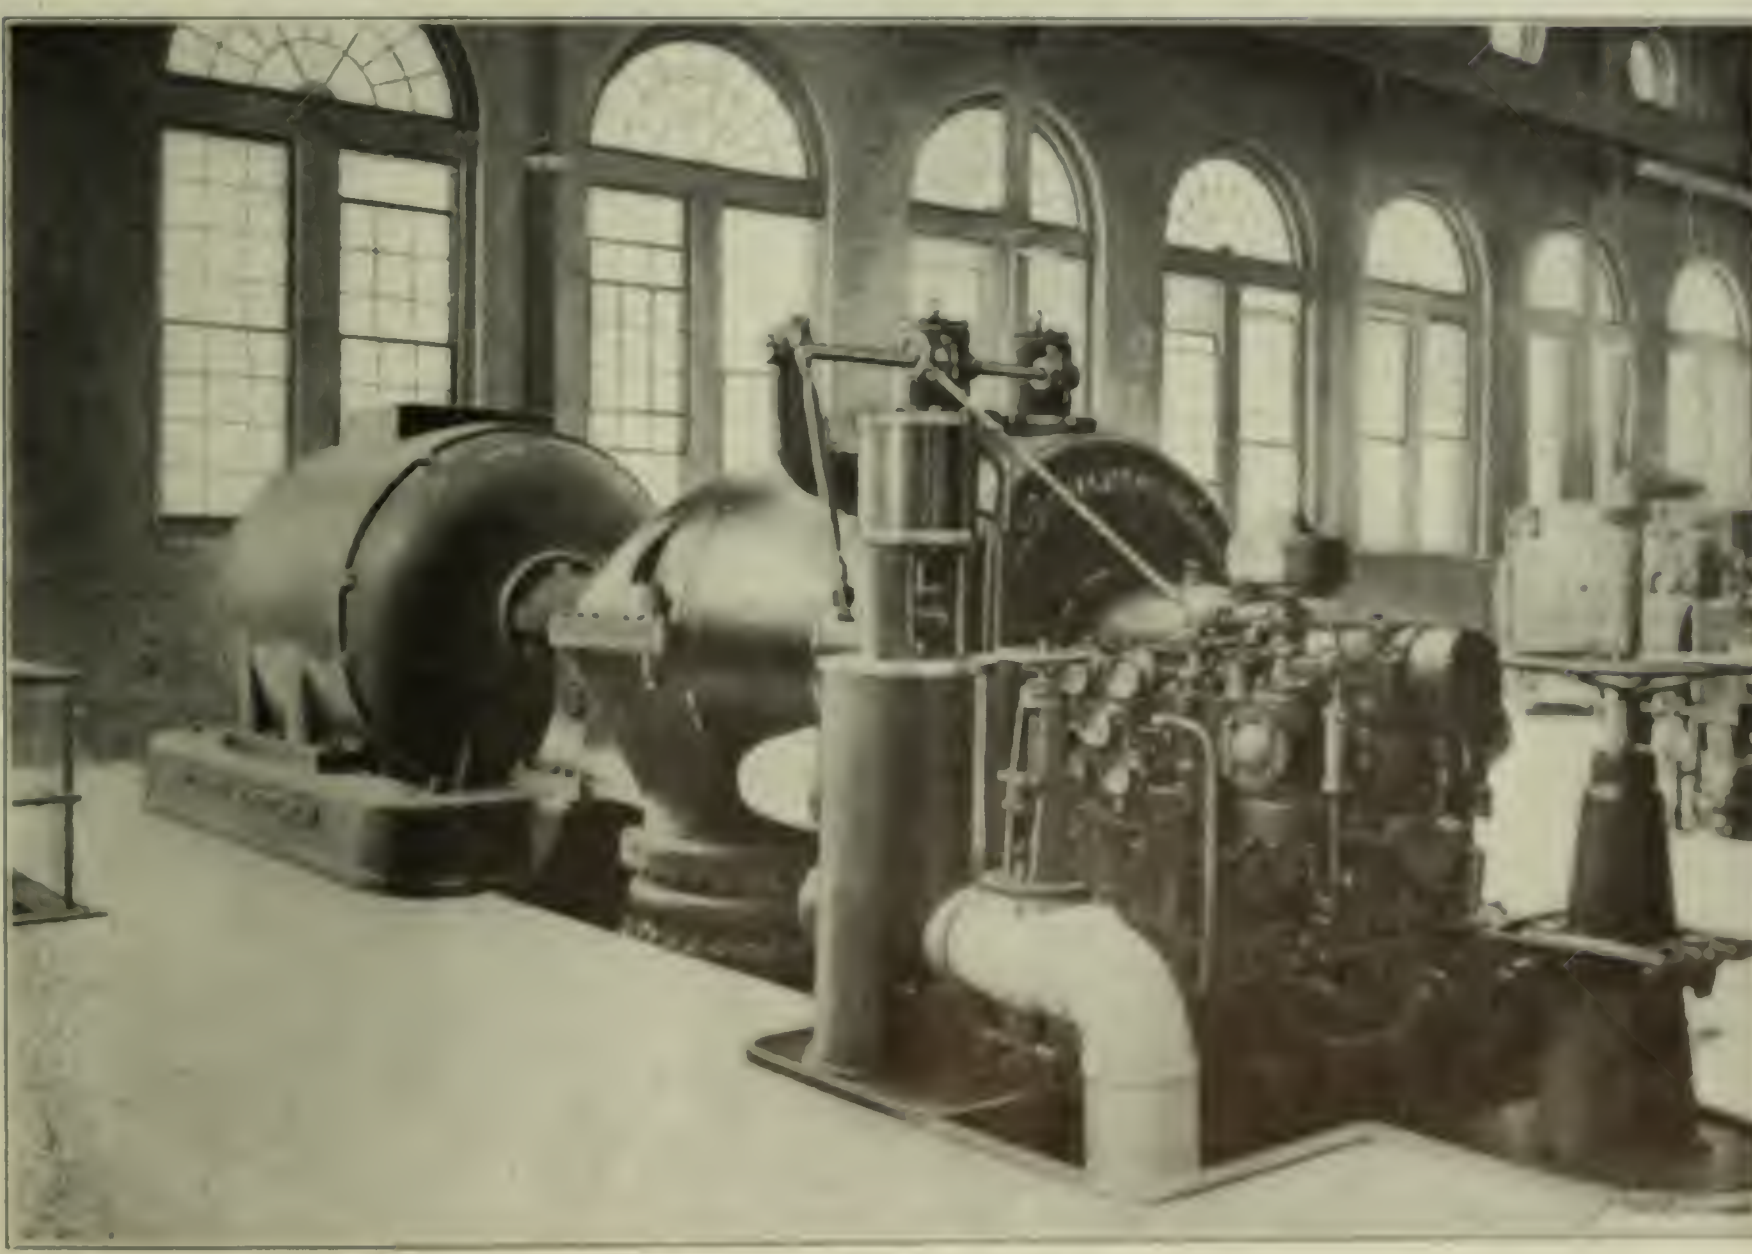
In the process of manufacturing rubber goods a large amount of heat is necessary, and at these works this is furnished by live steam at about 40 pounds pressure. Formerly this steam was considerably in excess of that used in the power plant itself; only a comparatively small amount of the exhaust steam available from the engines and the vulcanizers was utilized, while the rest was exhausted into the atmosphere. Realizing this loss and looking for a means to stop it, the idea was conceived of collecting all the exhaust steam in a large receiver which would serve as a source of supply to a low-pressure turbo-generator. Accordingly, this plan was finally worked out and a 1000-kilowatt, 25-cycle, two-phase, 240-volt Allis-Chalmers turbo-generator was installed to operate in parallel with the main generator.

The success that has attended this arrangement is apparent from the fact that even under extremely adverse conditions the turbine has been able to carry the entire electrical load, thus allowing the Corliss engine unit to be shut down.

One difficult feature of the installation was the selection of the proper condensing apparatus to meet the conditions existing. Due to the use made of the steam before it enters the receiver it carries a large amount of air. Also, owing to the source from which the condensing water is secured, it is impossible to obtain this at as low a temperature as would be desired. An Allis-Chalmers jet condenser with a special dry-air pump was finally installed. The circulating water and condensed steam are removed from the condenser by a centrifugal pump driven by a small impulse turbine, the exhaust steam from this small turbine discharges into the main receiver on the inlet side of the low-pressure turbine and consequently does work through the complete range of pressure.

To handle the large amount of air that passes to the condenser, a 12 and 30 by 24-inch dry-air pump was installed; this is of the rotative crank and flywheel type, and has about twice the capacity that would normally be required for a turbine of this size.

Condensing water is obtained from the lock of an old canal just behind the power house, which also serves as a supply for other manufacturing plants. This lock also receives the discharge from all the condensers and, as it is comparatively small, the water soon becomes warm. During the summer months the temperature of the water frequently rises above 100 degrees Fahrenheit, yet the turbine carries its load successfully.



1000-Kilowatt Low-pressure Turbine

Inquiries of General Interest

Questions are not answered unless accompanied by the name and address of the inquirer. This page is for you when stuck—use it

Compound Engine Balance

When a compound engine is said to be balanced, does it mean that the load is balanced between the cylinders or that the cranks are balanced so that the engine will run quietly?

C. E. B.

In a compound engine the load is balanced when it is equally divided between the cylinders. The engine itself is balanced when the inertia effect of the reciprocating parts is neutralized by weights on the cranks.

Number of Expansions

What is the rule for finding the number of expansions in any size of cylinder?

N. O. E.

The diameter of the cylinder has nothing whatever to do with the number of expansions. This is determined by the point of cutoff. The number of expansions is the reciprocal of the cutoff; that is, 1 divided by the fraction of the stroke completed at cutoff. If the cutoff is at 1/4 stroke, the number of expansions will be 4, because 1 divided by 1/4 equals 4. If the cutoff is at 1/3 of the stroke, there will be 3 expansions, and so on.

Size of Steam Chest

What is a simple rule for proportioning the size of the steam chest of a slide-valve engine?

S. S. C.

Make it no larger than is necessary to accommodate the valve and give room for the passage of what steam will be used.

Double Acting Pump

What is a double-acting reciprocating pump?

H. A. T.

One in which the piston acts in both directions, alternately for suction and discharge, drawing in the water at one end of the cylinder while discharging at the other.

Direct Acting Pump

What is a direct-acting pump?

P. D. A.

One in which there is no rotary or walking-beam motion. The piston movement is reversed by an impulse controlled by itself. The steam and water cylinders are in a direct line and the movement of the water piston is identical with that of the steam piston.

Steam Furnished by Compression

If an indicator diagram shows 85 pounds initial pressure and the compression runs up to 42 pounds, what proportion of the steam which fills the clearance space to initial pressure is furnished by compression?

S. F. C.

One cubic foot of steam at 85 pounds gage pressure weighs 0.2296 pound. The same volume at 42 pounds pressure weighs 0.1355 pound. Then

$$\frac{0.1355}{0.2296} = 59 \textit{ per cent.}$$

of the steam in the clearance space furnished by compression.

Compound-Engine Valve Setting

How should the valves of a compound-condensing engine be set?

C. E. S.

The valves of condensing engines having the same duties to perform as those of noncondensing engines should be set the same. A slight improvement may be made in some cases by giving the low-pressure exhaust valves more lead than is common for a noncondensing engine.

Pressure in Condensing Engine

If the steam pressure in the boiler is 75 pounds and a condenser is attached to the engine, how much will it increase the pressure in the engine cylinder?

P. C. E.

The pressure in the cylinder will be the same as before the condenser was attached, but the difference of pressure on the opposite sides of the piston will be increased, because the condenser removes a part of the atmospheric pressure from the advancing side of the piston. This is equivalent to increasing the pressure on the other side and amounts in average practice to 10 or 12 pounds per square inch of piston area.

Racing in Compound Engine

When the load is thrown off of my compound-condensing engine it races. What is the cause?

R. C. E.

Incorrect valve setting or maladjustment of the governor. The connections between the governor and the valves should be so adjusted that when the governor is in its highest position the admission valves on neither cylinder will be opened.

Change of Cutoff

How can I change the point of cutoff on a Brown engine?

C. O. C.

By changing the load or the steam pressure. The point of cutoff is controlled by the governor and takes place at that point which will keep the engine at the right speed.

Condensing above Sea Level

At a hight of a mile, is the vacuum in an engine cylinder as effective as at the sea level?

C. S. L.

It is.

Legal Ownership of Patent

If, while working for another, I invent, make and patent a machine or tool, using his time, tools and materials, does the patent belong to him or to me?

L. O. P.

If a man working at a machine conceived a better way of producing the piece that he was making and got up an attachment to the machine for doing so on his own initiative it would be unreasonable for his employer to claim the rights to the patent because it was developed while the man was in his pay and perhaps used a pound or two of brass and steel.

If, on the other hand, an employer wanting a machine or process worked out, hires a man to develop it, he pays for brains and ingenuity and is entitled to whatever is evolved in that connection. Between the two cases there are many gradations, the equities of which are often difficult to settle.

The legal ownership of a patent is vested in the one to whom it is issued.

New Power House Equipment

What the inventor and the manufacturer are doing to save time and money in the engine room and power house. Engine room news

New Method of Flanging Pipe

This method of flanging pipe by the cold hydraulic process was devised for the purpose of cutting down expense and eliminating the necessity for skilled labor, the latter being so essential to many of the methods now in use. A rectangular groove is first cut around the inside of the flange, which is then placed in position

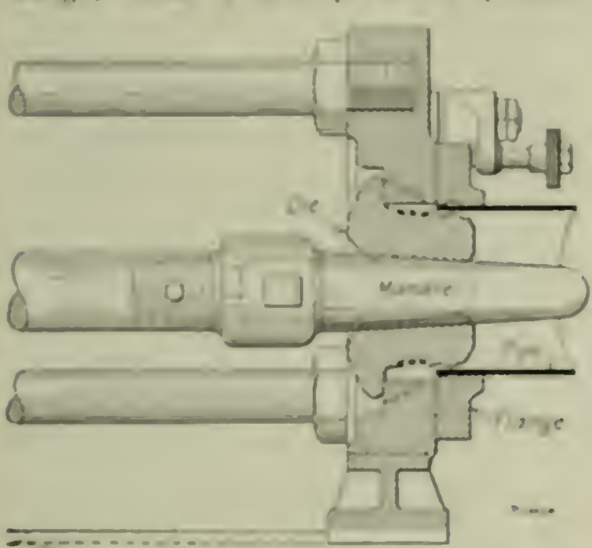


Fig. 1. Portion of Flanging Machine, Showing Flange and Pipe in Place

over the pipe as shown in Fig. 1. The die, consisting of a number of segments having projections corresponding to the groove in the flange, is then expanded by the hydraulically-driven tapered mandrel. Thus the flanging is accomplished, practically, in a single operation. A hydraulic chuck, which is shown in Fig. 2, and consists of six radial hydraulic pistons, is placed over the flange and takes up any radial strains produced by the mandrel. Each machine is fitted with an adjustable pipe rack and an attachment for bringing the flange face exactly parallel, thus doing away with the necessity of refacing and at the same time permitting extreme precision in measurements. Another significant fact is that it is not essential for the pipe to fit closely the bore of the flange; and, when so desired, the flange may be put on at an angle with the axis of the pipe. By fitting a collar over the flange a flexible joint may be had the same as with a welded or rolled flange.

Recently one of these joints was subjected to a severe test by being placed in service under superheat at a tempera-

Fig. 3. Flange Showing Finished Joint

ture of 750 degrees for six consecutive days, and twice each day a stream of cold water was directed against it. An examination of the joint at the end of the test revealed no signs of weakness.

At present machines are built to handle pipes from 2 to 20 inches in diameter and it is claimed that one man and a helper can flange forty 4-inch or twenty-five 8-inch ends in an hour. The process is applicable to either cast-iron, wrought-iron or steel flanges and is allowed in the marine service by authority of the United States Steamboat Inspection Bureau.

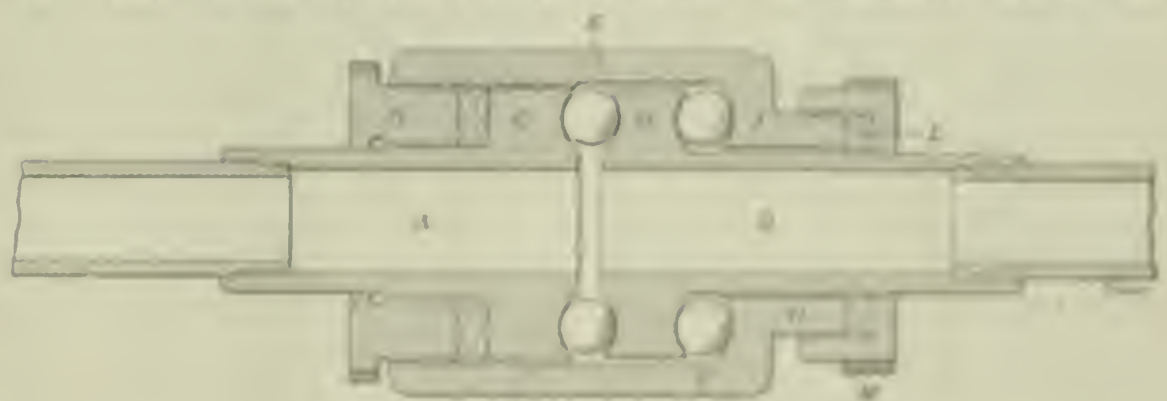
The machines are built by the Patterson-Allen Engineering Company, of Jersey City and 2 Rector street, New York City.

Walder Rotary Joint

This joint is a connection for steam or other pipes containing fluid under pressure and is designed to form a liquid-tight connection between ends of two pipes and at the same time to permit such pipes to have free turning movements.

In the accompanying illustration is shown a longitudinal section of two pipes connected by this type of joint. The spaced ends of the pipes are threaded to the outer ends of the tubular members A and B, respectively. These members each have at their inner end annular shoulders or enlargements, as shown at C and D, the end faces of which are divided with annular concave seats or runways E for the interposed balls. A sleeve F is threaded to the enlargement C, as shown at G, and its opposite end is reduced as shown at H.

Between the shoulder I, which is formed by reducing the end of the sleeve F, and the shoulder D, are placed a set of balls, the shoulders having their



Walder Rotary Joint

faces concaved to provide suitable runways for the balls. Leakage is prevented between the members B and the reduced end H by a suitable packing ring L, which is pressed closely to the member B and to the reduced end of the sleeve by a gland M.

N designates a nut which is screwed into the large end of the sleeve and onto the member A and serves to lock the sleeve F in an adjusted position relative to the member A. To overcome any leak-

Fig. 2. Pipe Supported by Rack and Hydraulic Flange Chuck in Place

age, which might otherwise occur between the sleeves and the shoulder on *A*, a suitable packing is used.

It is evident that with this construction the member *B* and its attached pipe are permitted to have free turning movement relative to the member *A*, as shown, the sleeve *F* and the packing parts, and that the opposite thrusts of the shoulders against the sets of balls may be adjusted to a nicety to prevent longitudinal play between such parts.

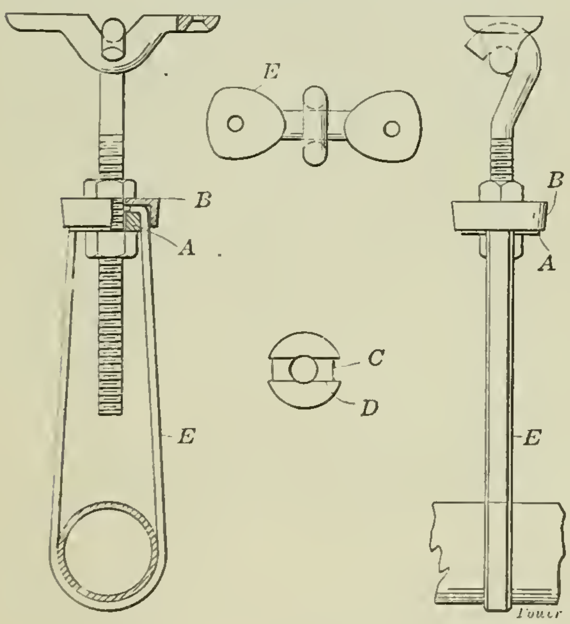
This joint is the invention of August Walder, Archibald, O.

Improved Pipe Hanger

This hanger, illustrated herewith, is constructed so as to be put up either before or after the piping is hung. It is adjustable, so as to maintain the alinement of the pipe and also to allow for expansion and contraction.

The drawings show an elevation of the hanger, partly broken away to illustrate the construction, and also a side view. The hanger consists of a threaded shank that passes through a sliding block *A* and sliding cap *B*, both of which are provided with a central opening for the shank piece to pass through. The block is provided with side recesses, as shown in *C*, being opposite to each other, and a top recess *D* is also provided.

The pipe is supported by a spring loop, the upper turned-in ends of which lie in the side recesses in the block *A*.



Two Views of Pipe Hanger

When the two nuts are screwed down tight, the ends of the spring loop is held in place between the block and cap. The whole swings on the. head of a shank piece, which is suspended by the holder shown at *E*. This allows for expansion; the adjustible nuts permit of raising or lowering the pipe. The device is the invention of Elmer A. Roberts, Norwalk, Conn.

If the wood handle has been broken from a monkey wrench, a serviceable substitute can be made by slipping a piece of hose over the wrench, then filling the hose with babbitt.

Minneapolis in Darkness

On January 6, the power plant of the General Electric Company, furnishing current to the city, was visited by fire. Crossed wires in the engine room started the trouble. Electrical machinery of 6000 kilowatts capacity was reported to be totally destroyed. The city was dark on Friday night, but on Saturday normal conditions were restored with the load on the St. Croix station. Full particulars will be given in an early issue.

OBITUARY

At the age of 54, Patrick Mullen died on Tuesday, January 3, at the New York home for the aged, where he had held the position of chief engineer for the past twenty-eight years. Mr. Mullen was an earnest and active member of the Eccentric Association of Engineers No. 1, of New York City, and was always an energetic worker for the betterment of the condition of the engineer. His ambition was to see the engineers of Greater New York united in one body. Mr. Mullen had a host of friends and his loss will be keenly felt.

The Germantown council, American Order of Steam Engineers, announce the demise of Past Chief William M. Leitch. Mr. Leitch took an active interest in the affairs of the American Order, both subordinate and supreme. The American Order of Steam Engineers Exchange, of which he was chairman, was a direct result of his activities in securing employment for engineers. Practically, during the time he was a member of Germantown council, he took special interest in this important work, and during the time prior to organization of the exchange, he had through his own efforts secured more than 150 positions. His reputation in this respect became circulated throughout the engineering fraternity of Philadelphia.

At the Baltimore convention, 1908, Mr. Leitch was nominated for supreme chief engineer, and, although unsuccessful at that time, he did not allow this defeat to affect his attitude or efforts toward the welfare of the members of the American Order. He was conscientious in everything that he did, and was considered one of the most capable engineers in Philadelphia. For a number of years he had been employed by the William H. Hoskins Company, Philadelphia, as chief engineer, and was still connected with that company at the time of his death.

PERSONAL

C. O. E. Sanders has associated himself with the Thermoid Rubber Company, of Trenton, N. J., which will put upon the market a line of mechanical rubber goods, including packings, in which field Mr. Sanders has already made a reputation.

On January 4, W. H. Whiteside resigned the presidency of the Allis-Chalmers Company, which position he has held for about six years. Mr. Whiteside's first industrial connection was with the Hercules Powder Company in 1881. Four years later he went over to the Cleveland Electric Manufacturing Company, where he remained 12 years. He then became manager of engine sales for the Gates Iron Works, of Chicago. Two years later he was placed in charge of the Wilmington office of the Westinghouse Electric and Manufacturing Company. D. W. Call, formerly assistant to the president of the American Steel Foundry Company, has been chosen as successor to Mr. Whiteside.

International Municipal Congress

Hon. John MacVicar has been selected for the position of commissioner-general of the International Municipal Congress and Exposition, to be held in Chicago, September 18 to 30, 1911. John MacVicar is a well known authority in this country on all that pertains to municipal government and the administrative affairs of cities. He has been in active service in municipal work for more than twenty years. He was named to the office of president of the League of American Municipalities upon its organization, fifteen years ago, and has ever since been actively connected with that organization, for the past ten years as secretary. Mr. MacVicar is at present a member of the commission, and superintendent of streets and public improvements, at Des Moines, Ia., which city has recently attracted some attention because of its advanced form of government.

This congress and exposition will cover in a practical as well as theoretical manner matters of interest to all branches of municipal service. Upon each day of the congress, papers will be read and discussed by prominent municipal officials, and prominent municipalities of this country and foreign countries will have attractive exhibits of municipal undertakings in which they excel.

NEW INVENTIONS

Printed copies of patents are furnished by the Patent Office at 5c. each. Address the Commissioner of Patents, Washington, D. C.

PRIME MOVERS

HYDRAULIC MOTOR. William C. Kelly, [illegible], Mich. 979,511.

INTERNAL COMBUSTION POWER GENERATOR. Alfred [illegible], Chicago, Ill. 979,554.

TURBINE. Thomas James [illegible], [illegible], Wash. 979,619.

BUSINESS ITEMS

The Robb Engineering Company, Ltd., has purchased the Robb-Mumford Boiler Works, at South Framingham, Mass. The management and manufacturing organization will be continued as at present.

Franklin Williams, manufacturer of engineering specialties, 39 Cortlandt street, New York, is issuing a rather unusual calendar, which is so compact as to include the whole year within very small compass. It might be called a thumb-nail calendar, and should prove useful to busy people.

The Nelson Valve Company, Philadelphia, Penn., is sending to engineers on application a set of danger signs to hang on valve wheels, etc., to show that the wheel is to be left alone until the sign has been removed by the proper authority. Send and get a set, they are handy and useful.

The Murphy Iron Works, manufacturer of the Murphy automatic furnace, has arranged for an office in Atlanta, the same to be in charge of Roland B. Hall, Jr., who will handle its business in connection with that of the Harrisburg Foundry and Machine Works, whom he has represented in the southern territory for some time. Mr. Hall's offices are located in the Empire building, and he will be very glad to furnish any information regarding the Murphy automatic smokeless furnace that may be desired.

Bulletin No. 130 has been issued by the Bristol Company, Waterbury, Conn. It is a 56-page illustrated catalog of the Wm. H. Bristol electric pyrometers and includes description and lists of both indicating and recording forms of these pyrometers with explanation of the special patented features, as for instance basic patents on means of compensating readings of thermo-electric pyrometers for changes in cold-end temperature. On pages 48 to 55 of this catalog partial list of more than 700 users of the Bristol pyrometers is given.

The Royersford Foundry and Machine Company, of Royersford, Penn., manufacturer of the Sells roller bearings, found, it so difficult to obtain a satisfactory lubricant for its roller bearings that it has brought out a lubricant of its own, which is especially adapted to meet the requirement of bearing lubrication. "Rollerine" is the name it has adopted for this special bearing lubricant. Anyone writing to the Royersford Foundry and Machine Company, at its Philadelphia office, 52 North Fifth street, can obtain full information on both Rollerine and Sells roller bearings.

NEW EQUIPMENT

Gleichen, Alberta, will install a new waterworks system.

New Carlisle, Ohio, will construct waterworks system.

The citizens of Rush, Tex., voted to issue bonds for waterworks.

Chilliwack, B. C., will spend $40,000 extending waterworks system.

C. F. Melinde, Hudson, N. H., is building an addition to his engine room.

Whittemore, Iowa, has voted to issue $7000 bonds for municipal waterworks.

Swift & Co., of Chicago, will erect a cold-storage plant at Muskogee, Okla.

Falls City, Ore., will issue $30,000 bonds for the construction of waterworks.

Leavenworth, Wash., will construct a water-supply system to cost $40,000.

Hopkins, Mo., is considering the construction of a municipal waterworks system.

The Lynn (Mass.) Storage Company will erect a warehouse and cold-storage plant.

The city of Alturas, Cal., has voted $33,000 bonds for improvements to its waterworks.

The Farmers Union, Chico, Cal., will erect a warehouse and install refrigerating plant.

The Calexico (Cal.) Creamery Association will build a creamery and cold-storage plant.

The Canadian General Electric Company will erect a $100,000 power house at Auburn, Ont.

S. S. & T. B. Davis, Rock Island, Ill., will erect and equip a large power house on Rock river.

The town of Woodbury, N. Y., is considering the construction of a municipal water plant.

The city of Fairburn, Ga., will vote on issuance of $10,000 bonds for electric-light plant.

The citizens of Lyndhurst, N. J., voted to issue $25,000 bonds for extending its waterworks.

The Standard Furniture Company, Portland, Me., is in the market for an air compressor.

Smithfield, Va., will vote on issuance of $55,000 bonds for electric-light and sewerage systems.

Martinsville, Va., voted to issue $35,000 for improving its electric-light plant and waterworks.

The Libby (Mont.) Water Works, Electric Light and Power Company will install a lighting system.

Strathcona, Alberta, will considerably increase electrical equipment in the municipal power plant.

The Truckee River General Electric Company, Reno, Nev., will build a power plant on the Truckee river.

Improvements will be made to the power and light plant at the Boys Industrial School, Lancaster, Ohio.

It is reported the Jacksonville (Fla.) Electric Company will erect a power house on Riverside avenue.

The citizens of Sierre Madre, Cal., voted to issue $40,000 bonds for waterworks. P. C. Carter, city clerk.

The Duquesne Light Company, Pittsburg, Penn., will erect a new power house on Shakespeare street.

The citizens of Boone, Iowa, voted to issue $180,000 bonds for extending waterworks. Otto Hile, city clerk.

The Siloam Springs (Ark.) Ice and Cold Storage Company's plant was destroyed by fire. Loss, $150,000.

E. B. Hillman, of Peoria, Ill., has been granted franchise to erect an electric-light plant at Hamburg, Iowa.

The Olympia Railroad and Power Company, Elma, Wash., is planning for extensive power-plant enlargement.

The Pacific Mill, Lawrence, Mass., will install a steam turbine and electric generator of 3250 kilowatts capacity.

The Wilkes Barre (Penn.) Railway will erect a three-story addition to its power house on South Main street.

A five-story packing plant will be erected for the Hammond-Standish Company, 20 Cadillac square, Detroit, Mich.

The Morrison Electrical Company, Boston, Mass., is in the market for a 15-kilowatt direct-connected generating set.

The Eastern Oregon Light and Power Company, Canyon City, Ore., will build a hydro-electric plant at Lagoon lake.

The Steelton (Penn.) Light, Heat and Power Company is reported to be planning the erection of an electric plant.

The city of Polytechnic, Tex., is considering the construction of a municipal waterworks plant to cost about $32,000.

The Oklahoma City (Okla.) Railway Company will spend $125,000 in making additions to its power station at Belle Isle.

The People's Power Company, Rock Island, Ill., is planning extension and improvements at its gas and electric-light plant.

The Atlantic Ice and Coal Corporation, Albany, Ga., has awarded contract for the erection of a new engine and power house.

The Norfolk & Western Railway will enlarge its power house at Bluefield, W. Va. Two additional boilers will be installed.

The city of Georgetown, Tex., will spend about $30,000 improving its waterworks and electric-light plant. R. E. Ward, mayor.

Vancouver, B. C., will buy one 1500-kilowatt steam turbine generating unit and one 500-kilowatt, direct-current generating unit.

J. A. Haberer, town clerk, Rippey, Iowa, will receive bids until February 6, for furnishing material and constructing waterworks.

The Northwestern Development Company, Spokane, Wash., will build a 30,000-horsepower hydroelectric plant to cost about $1,800,000.

The town of Roberta, Ga., will receive bids through W. J. Marshall, Lizell, Ga., for the construction of an electric power and pumping plant.

The board of water and light commissions, of Bayfield, Wis., has completed plans for a new boiler house for the municipal water and light plant.

The Eastern Michigan Edison Company, of Pontiac, Mich., is said to be planning the erection of a 5000-horsepower steam-electric plant, near Amy.

The Woodlawn (Ala.) Ice Company has been incorporated with $40,000 capital to manufacture ice. W. J. Worthington, president and treasurer.

The Union Power Company, Hagerstown, Md., has had plans completed for a new power house. O. G. Keilholtz, Continental building, Baltimore, is engineer.

The Twin City Light and Traction Company will erect a new generating plant at Chehalis, Wash. Headquarters are in the Trenton building, Portland, Ore.

The Leader Publishing Company, owners of the *Cleveland Leader*, is planning to erect a 14-story building with an estimated cost of $1,000,000 to $1,500,000. An electric power plant for operating the presses will be installed.

Bids will be received until January 19 by R. G. Arthur, secretary, board of water commissioners, Douglas, Ariz., for furnishing material and making improvements to waterworks, including pumping plant, pump house, etc. About $85,000 will be expended.

E. M. Statler, of Buffalo, N. Y., will erect a hotel building in Cleveland, at the corner of Euclid avenue and East Twelfth street, and has commissioned George B. Post & Sons, architects, Cleveland, to prepare the plans for the structure. The estimated cost of this work is $2,500,000.

HELP WANTED

POWER

NEW YORK, JANUARY 24, 1911

WHY all this squealing, hissing, pounding, knocking and groaning? Why all these young clouds of steam, showers of oil and hot breezes bearing suggestions of scorched metal and burnt insulation? Why all the apparent confusion—is this a blast furnace?

No, this is not a blast furnace, this is an engine room.

You see, the engineer here is *getting results*. He has no time to put on "frills"—he is a *practical* man, he says, and glad of it. None of your nonsense about appearances for him.

He is too busy keeping the wheels turning to monkey with such details.

What if a joint or two is sprung or needs a new gasket! "Ain't" he delivering the goods?

What if the valves complain a bit and the engine booms every time it passes a center? "Ain't" he keeping the mill agoin'?

What if the stuffing boxes wheeze and squeak just a little? "Ain't" he furnishing all the power needed?

Two years ago he came here to get results—so he said. And, by the looks and sound of things, he *has* got them.

If a thing doesn't fit, he fits it—with a sledge. If a nut doesn't turn home as easily as it ought, he persuades it with a bigger wrench. He gets his results by the most direct methods.

This engineer is a "world beater"—you don't have to prove it, he admits it. He *knows* that he is always right. Was he not engaged to keep the machinery running? And has he not kept it running?

Economy? Nonsense!

A machine can do so much work. In order to do a certain amount of work the machine must have so much steam. It doesn't matter if a stuffing box leaks a bit or if a bearing or two is a little warm—set up on the box a little harder and run some water into the bearings. The amount of steam used is about the same in any case—he says so, and isn't he always right? Besides, the boilers are big enough anyhow. So, "let her rip."

He argues that to correct *little* defects such as those just mentioned would cost more than they are worth, not to mention the fact that it would cause him lots of bother and trouble, and take up too much of his time which is fully taken up as it is, getting results—and telling about it.

* * *

The foregoing concerns what may be termed a horrible example. Such an engineer does not realize that it is his duty not only to furnish power, but to furnish it as economically as he possibly can.

Genius has been described as the ability to take infinite pains, to be thorough, in other words.

In a given plant, that engineer is the best who can seek out and stop the greatest number of leaks and losses, no matter how small some of them may be. It is just as true in the power plant as it is anywhere else that if you take care of the cents the dollars will take care of themselves.

Wherever you are, whatever your duties, you are not making the best of your opportunities if you do not get results with the best economy that the equipment under your charge can be made to show.

Hydroelectric Power at Wausau, Wis.

By D. B. Hanson

A brief description of three small plants drawing their power from the waters of the Wisconsin river and the possibilities of further development.

Slightly north of the geographical center of the State of Wisconsin, is situated, on the banks of the Wisconsin river, the town of Wausau, the county seat of Marathon county. The town has been built up largely on the lumber industry, and is still noted for the sawmills, tanneries and paper mills in its vicinity, which depend upon the forest products for a large share of their raw materials.

A portion of the power developed for these various industries is obtained from hydraulic plants situated on the Wisconsin river which, here, is capable of producing a head of about 25 feet, and is absorbed within the city limits by three installations.

The first of these, as shown on the map in Fig. 1, is McEachron's flour mill, situated on the west or main chan-

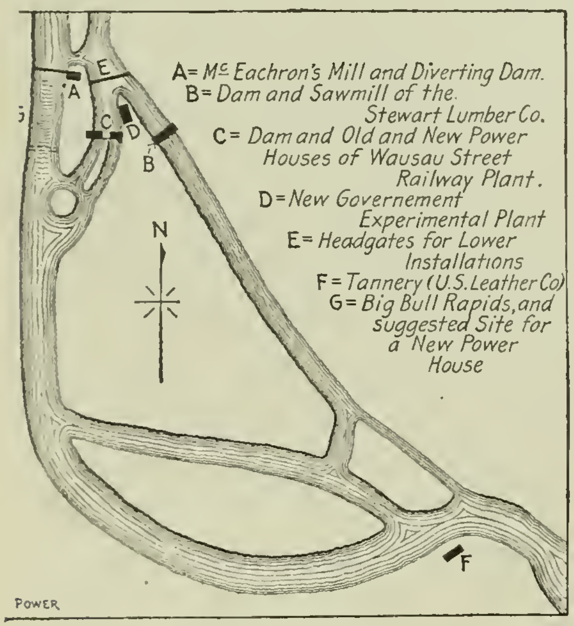

FIG. 1. WISCONSIN RIVER NEAR WAUSAU

nel of the river. The mill is driven by single vertical turbines aggregating some 250 horsepower when operating under a 7-foot head, which is the maximum obtainable under the conditions prevailing at that point. The dam here is of the rock-filled timber-crib type and, while serving to maintain the head for this installation, also serves as a diverting dam for the other two, which are situated on the east fork of the river. At this point the river flows through several channels among a number of islands. The dam also serves for a spillway for the entire river in times of flood, there being no space provided at the dams of either of the other two developments for this purpose; to control the head in the eastern channels, a second dam has been built across their upper ends, thus converting these portions of the river into mere head and tail races, whose supply is determined by the regulation of the head gates in the second dam shown at the reference *E* in Fig. 1; the western channel is thereby made the main course of the river, only enough water being admitted to the east branches to supply the demands of the lower power houses which are situated about 1000 feet below the two dams above mentioned.

Plant No. 2, that of the Stewart Lumber Company, is the smaller of the lower installations and is equipped with three horizontal shaft turbines of 275 to 300 horsepower aggregate capacity when operating on a 14-foot head. It drives a portion of the lumber mill of this company, its head race being used also to float down the logs to the conveyers of the main mill. It is decidedly a surprise to the ordinary man, who, though well informed, is not familiar with the large scale upon which the sawmills of this district were wont to operate in their earlier days, to see the immense storage yards and thousands of feet of elevated platforms carrying the extensive system of tramways used by this company in transporting its finished products from its sawmill and planing mill, which, for many years, averaged a cut of 30 million feet per season.

The third installation, that of the Wausau Street Railway Company, equipped with two independent turbine units and an auxiliary steam plant, is the largest of the three and operates under the highest head. It consists of two sections known as the old plant and the new. The old plant is a fair example of what one might expect to find in a plant which started in a very small way and was gradually enlarged to meet the increased demand for the electrical service which the plant supplies. This plant consists of a quadruplex horizontal tur-

FIG. 4. OLD AND NEW WAUSAU PLANTS

bine of Leffel make, which is direct connected to a line shaft driving two main generators, each of 350 kilowatts capacity, one generating current at 2200 volts, the other, being installed later, generating at 2300 volts. Both machines were originally two-phase, 60-cycle units operating at 150 revolutions per minute, but were later rewound to generate three-phase current. This new arrangement naturally resulted in a decreased output and a high overload upon the exciters, of which there are two 30-kilowatt machines, each belted to the main shaft of a generator.

The two generators are operated in parallel, and considerable trouble has been experienced. These units will shortly

FIG. 2. McEACHRON'S MILL DAM

FIG. 3. HEADRACE OF STEWART LUMBER COMPANY

Fig. 5. Old Wausau Plant

Fig. 6. Switchboard Corner of Old Plant

be changed back to generate two-phase current, and their output will be transformed to three-phase before being sent out on the transmission lines. The electrical load of this station consists of factory motors, incandescent and arc-lighting and street-railway load, the latter being very severe in its fluctuations.

Fig. 7. Main Generator in New Wausau Plant

Fig. 8. Oil-pressure Governor of Main Unit

On account of the small number of cars operating, it is comparatively easy to have nearly the whole system at rest or starting all at the same time, thus making the change from no load to the heaviest accelerating load occur in a very short space of time, often not more than ten seconds. This street-car load was originally handled by means of two 100-kilowatt direct-current Westinghouse generators, belt driven from a line shaft. Later, as these machines became inadequate, a 300-kilowatt motor-generator set was installed, the motor taking three-phase current at 2300 volts from the main generators. A number of 50-horsepower pump motors, installed in a paper mill some five miles away, still further complicate the fluctuations of load, as they have no starting boxes, and their starting current when they are cut in directly across the line, is naturally heavy.

The usual switchboard apparatus, which serves both plants, completes the hydroelectric installation in the old plant, and a twin simple noncondensing slide-valve 18x30-inch engine with its battery of boilers comprises a means of driving the main line shaft through a friction clutch, in cases of low water or other emergencies which would cripple the hydraulic plant. This old plant with its machinery poorly chosen for its ultimate use became overloaded by the constantly growing demand in the town for electrical energy, and a new plant to supersede it became necessary. The new power house contains up-to-date machinery of sufficient capacity to meet the

Fig. 9. Big Bull Rapids at Time of Average Flow

Fig. 10. Tail Race of Two Wausau Plants

present load, with a generous margin. It is built of cement block and is approximately 35x40 feet. The machinery installed consists of a quadruplex horizontal-shaft turbine, with 45-inch runners arranged in pairs and discharging into a common concrete draft tube. This unit is rated at 1700 horsepower at 150 revolutions per minute when operating under a 20-foot head. It is direct connected to a 900-kilowatt alternator, generating three-phase 60-cycle current at 2300 volts. A twin-turbine-driven exciter unit furnishes current for excitation. Both units are controlled by oil-pressure governors which are so connected to the wicket gates of the turbines as to eliminate the possibility of any lost motion occurring, the resultant regulation obtained being exceptionally good.

The present plan is to operate the new station at all times, holding the old plant in reserve for emergencies, and the steam plant for times of low water when the head races are fouled by large amounts of sawmill refuse and driftwood. Due to the close proximity of the several mills, this is very troublesome, as no means of ridding the forebays of this trash, except unwatering them and cleaning them by ordinary hand labor, are provided.

Taken collectively, the installations at Wausau show a chance for considerable improvement in the engineering details; the dam at McEachron's mill leaks badly, thus wasting power which in a dry season cannot be well spared. Further, its low head of 7 feet allows but a small amount of the natural power easily obtainable to be absorbed. At the sawmill of the Stewart Lumber Company, the head is still much too low, as a proper location of the installation could easily double the head used, while at the Wausau Street Railway Company's plant the normal head of 22 feet still falls at least 25 per cent. short of the possibilities of the situation.

Referring to the map, Big Bull Rapids, indicated at *G*, is an ideal location for a hydroelectric plant. The river here flows between banks at least 50 feet high and 600 feet apart over a solid rock bottom composed of a tough, brown granite, and at normal flow for nine months in the year at least 1000 kilowatts yet remains to be developed. This location would give ample room for proper forebays, and would also provide a chance for spillways that would readily take care of the large quantities of driftwood that now form such a disturbing and annoying factor in the operation of the present plants. It would provide the finest of foundations for a dam, and, last but not least, would increase the head from 30 to 400 per cent. of that used by the existing plants. It would also permit of the whole flow of the river being utilized, while now but a small part can be used in times of high water. In fact, the advantages are so many and so obvious that one can scarcely discern a reason for the neglect of the opportunity, and with the growth of the demand for power at this point it would seem that a plant must eventually be erected on this site.

In view of the agitation now prevailing over the question of conservation of our forest and other natural products, and the growing scarcity of pulp woods which are largely utilized by a large number of paper mills in this section of Wisconsin, it would seem but fitting to mention in this connection the experiment station now being erected by the United States Government at *D* in Fig. 1. This plant is being installed with the idea of conducting an exhaustive series of tests to discover methods which will permit of new varieties of timber being used in pulp making and will thereby, it is hoped, open up new fields of raw material to supplement those now being rapidly exhausted by present operations. This plant will absorb in its motors some 500 horsepower, which will be largely furnished by the street-railway company, and will load the plant to its fullest capacity.

Keeping Power Plant Records

By Warren O. Rogers

A most complete system of daily and monthly reports which show at a glance the cost of fuel, wages and any charge that should be credited to the cost of operation.

The one way of knowing what a power plant is doing is to keep a suitable set of records, so that it can be known at any time just what the cost of operation is or has been, not only as to the cost of fuel, upkeep and wages, but of other

charges that should be credited to the cost of plant operation. It is not a simple matter to get up a set of report sheets that will exactly fit individual conditions, the tendency being to border on the incomplete, rather than overdoing matters in recording power-plant data.

Keeping records does require considerable time on the part of the engineer and, for this reason, many fail to take a right view of the matter, contending that it is the business of the office to keep track of the power-plant costs.

There are engineers, however, who believe that it is their business to keep the records of the plant, not only so that a monthly report can be submitted to the manager, but for their own satisfaction and protection. Among the latter is Asa P. Hyde, chief engineer in the building of the Security Mutual Life Insurance Company, Binghamton, N. Y. A set of report sheets, gotten up and kept by Mr. Hyde, consist of daily, weekly and monthly reports.

The daily reports are used as a check on everything that occurs in the plant, and have much to do with the results obtained. A second factor is good help, all working together for the one purpose of seeing how much and how cheaply the work can be done.

The coal man takes quite an interest in the daily-record sheet shown in Fig. 1. This report and the chart from the re-

Ash Ticket. ______________ 190

CANS FILLED	FIREMAN.	CANS TAKEN.	CARTMAN.

FIG. 2.

cording steam gage are filed daily in a glass case in the boiler room for the inspection of the men. As the plant operates day and night, the report of both the day and night firemen are put on the same card. Each fireman, one for each watch, records the number of pounds of coal burned during the time he is on duty, also the weight of ashes made during his run. The percentage of ash obtained is what interests the coal dealer, and the knowledge that an ash record is kept, as well as a record of the amount of water evaporated per pound of coal, tends to keep the quality of coal up to the standard. No. 1 buckwheat coal is burned and must not contain more than 16 per cent. of ash. Other fuels and sizes have been carefully

FIG. 3.

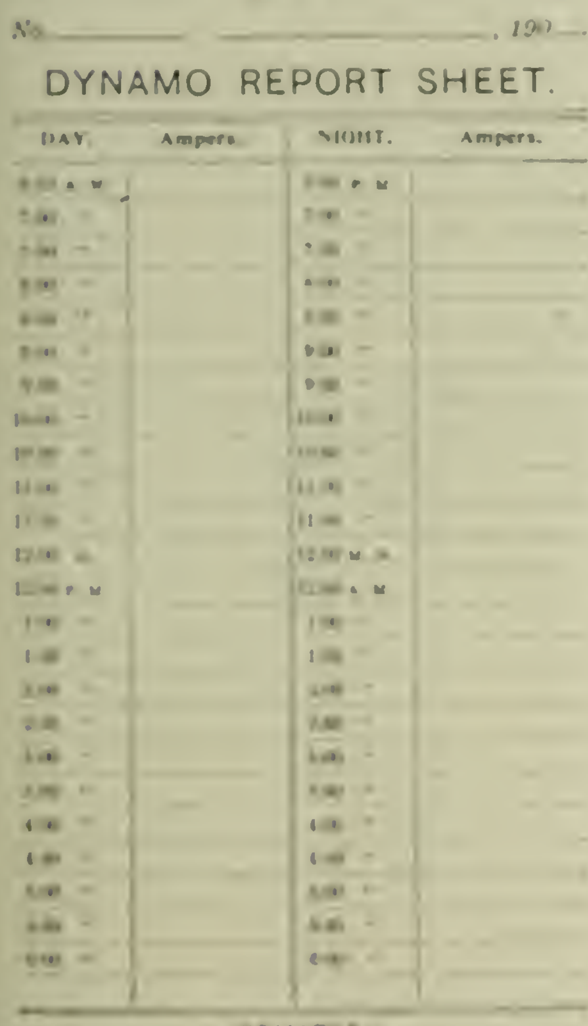

FIG. 7.

tested, but it has been found that more current can be produced at less expense with No. 1 buckwheat coal than

FIG. 4.

from any other, if it is carefully handled, as is done in this plant.

The ash ticket, Fig. 2, looks simple, hardly worth bothering about, but it prevents the cost of cartage of refuse from the building being charged up to the cost of power-plant operation. For instance, if the firemen get four cans of ashes per day and the cartmen remove six cans of ashes and refuse the cost of removing

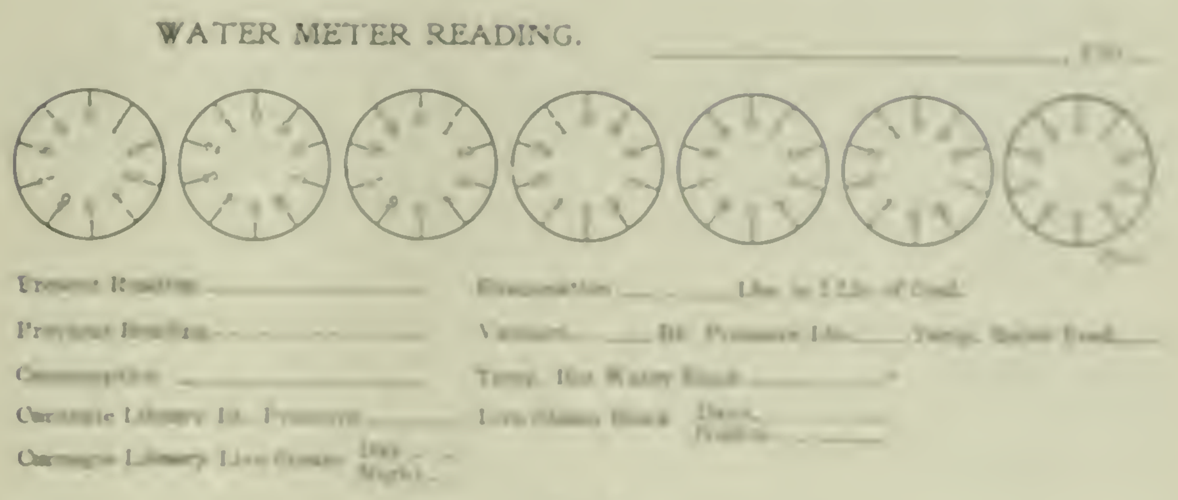

FIG. 5.

six cans would ordinarily be charged up against the plant, when the cost of removing two cans of refuse should have been charged against the building. The ash ticket prevents this and the charges for cartage are correctly made.

Figs. 3 and 4 show both sides of the daily coal ticket which is filed with the chief engineer. One side shows the kind and amount of coal burned and ashes obtained by each fireman from 6 a.m. to 6 p.m. and 6 p.m. to 6 a.m., also the amount of water used in gallons and pounds and the amount of water evaporated per pound of coal with boiler-water tests.

The reverse side of the ticket contains the fireman's reports of the quality of the coal used, how it burns, whether the fires have been worked during a shift and other items that might shed light on the performance of the plant.

Water-meter readings are recorded on a card similar to that shown in Fig. 5. Fig. 6 is used for recording the total output of electrical energy to the various tenants.

FIG. 6.

The daily dynamo-report sheet is shown in Fig. 7, the number of amperes carried being recorded each half hour, this being done to check the peaks and for charts if wanted later.

All renewals, repairs and new work about the building are performed by the engine-room force, but their time is credited to the plant. For instance, if a tenant of an office desires changes made in the arrangement of lights, or anything else, the man put to work making the alterations files the report shown in Fig. 8. It includes by whom the work was ordered, also the labor and material used, the cost of each being recorded. From this report sheet the work slip, Fig. 9, is filled out and the signature of the tenant is affixed thereto, as all material and supplies remain the property of the Security Mutual building. In case the tenant moves he must leave all fixtures, charged up to him over his signature.

Fig. 10 shows the engine and pump report which indicates when the various units were started, how long they were in operation and when shut down, also all work done on them and the materials used. This is all of the daily-report cards and from them the weekly report is compiled.

For instance, Fig. 11 shows the weekly report of the amount of coal burned, ashes made, water used, kilowatts generated and the total number of elevator trips made during the week.

Expenses for the month for the plant, block and elevators are tabulated on the sheet shown in Fig. 12. The data found on the expense sheet for the month of October were taken from the workman's daily-report sheet shown in Fig. 8. The monthly expense report shows at a glance when the work was done and what material was used and to what department of the building it has been charged.

A more complete power-plant expense sheet is shown in Fig. 13. It designates the expenses for the month and what they were for; it is made up of five departments, as shown in the margin. The items having a check mark are charged to the operating expenses of the plant, but they should not be as they are of foreign character and are carried by the plant as a matter of convenience.

Data relating to the machinery of the plant are kept on a report sheet ruled as shown in Fig. 14. Here the daily record is tabulated and the items not filled in with daily readings are entered monthly.

A fuel-evaporation report sheet for October, November and December, 1910, is shown in Fig. 15, the month of October only being tabulated. These reports also

contain the monthly switchboard reading. The readings of all items are the totals of the weekly reports.

A comparison of the corresponding three months for three years is recorded on the card shown in table form. The totals are given for each month for coal, loads in kilowatt-hours and elevator trips. In the margin is recorded the increase in coal used one year over another, and per cent. the increase in output.

At the bottom of this sheet remarks are entered which may have any bearing on any increase or decrease in coal consumption during the year.

Referring to the bottom of the record sheet, Fig. 13, it is shown that $640.53 has been charged up against the plant for operating expenses and an income of $1345.20 from the electrical output, making a profit of $704.67 per month, a large profit for a $15,000 investment, the cost of the plant. During the six years that this plant has been in operation it has never been run at a loss.

Details relating to the plant and the method of operating it will be published in another article. It is through the courtesy of the chief engineer, Asa P. Hyde, that the data and accompanying report blanks have been obtained.

Power from the Sun and Wind

Next to discovering perpetual motion, probably one of the most alluring fields for experiment on the part of scientists in search of great reward is that of utilizing the radiant-heat energy of the sun and the kinetic and potential energy of the wind and waves. The problem of converting the energy from these sources into a form which is suitable for commercial use is extremely complicated and, so far, has baffled complete solution. Of course, windmills have been successfully used for centuries in the performance of certain kinds of work, principally that of pumping water. However, the power derivable from a windmill, depending as it does on the variable weather conditions, would not be suitable for driving an electric generator connected directly to the mill because the apparatus would be dead still in a calm and working very much "overtime" whenever a gale happened to be blowing. Hence, no dependence could be placed on any forecast of the quantity of power to be obtained at a given time.

It has often been proposed to have the windmill work a pump to raise water from one reservoir to another, say, 100 feet above the first, at whatever rate the winds will drive the mill; then, to allow the water to flow back into the first reservoir at a given steady rate of flow, and, in so doing, operate a waterwheel-driven dynamo. For such a scheme to be suc-

around the reservoir must be large enough to hold the excess water while the windmill pumps during high winds so that this excess water will be available to keep the waterwheel running when there is a calm and the windmill is "dead." This arrangement would be commercially successful if the cost of the windmill, pumping apparatus, reservoirs, piping, waterwheel and dynamo were not so great that the interest on the money spent, together with the operating cost and the upkeep charge, would exceed the interest on the investment in another system, such as steam or gas power, plus the cost of operation, upkeep, fuel and water.

To build a tower 1000 feet high sufficiently large and strong to support the quantity of water needed by a system of commercial size would involve such an expenditure that a plant for commercial use could not be built.

Another popular proposed system of obtaining power without using fuel as a source, is that of converting the heat energy radiated by the sun into electrical energy. In one system for doing this a

Fig. 15.

multitude of thermoelectric couples is used. The hot junctions of the couples are exposed to the heat of the sun and an electric current is generated. The current so made is used to change a storage battery. The number of couples used must be large enough not only to furnish current for the day load, but also to change the battery so that current can be drawn from it at night and on cloudy days when the couples are not generating, due to the fact that there is no heat from the sun available. As in the previous case, the cost of constructing a system of this kind more than offsets the gain due to the fact that there is no fuel or water expense involved.

Another means devised to utilize the sun's radiant energy consists of an air-tight glass chamber or boiler, in which water is heated by the sun rays and steam at atmospheric pressure is generated, and a low-pressure turbine outfit to utilize the steam so generated. The turbine may operate either an electric generator or, preferably, a pump for raising water to an elevated reservoir from which the water flows as needed to run a water-wheel and generator.

Recently, Prof. R. A. Fessenden, of Washington, D. C., in a paper presented to the engineering section of the British Association for the Advancement of Science, outlined a plan whereby power on a commercial scale may be obtained from the sun and wind. He proposed to combine wind- and sun-power apparatus in order that a plant might be capable of furnishing a fairly constant output with only moderate storage capacity. His paper aroused considerable interest, especially as he intimated that he has a 3000-horsepower plant under construction at a worked-out copper mine. By locating the plant at the mine it will not be necessary to provide any tower for the upper water-storage reservoir, for it will be built at the mouth of the shaft while the lower reservoir will be placed in one of the bottom chambers of the mine, 1000 feet below.

The two features of novelty in Professor Fessenden's scheme seem to be the combination of windmills with sun-radiation power apparatus and the subterranean reservoir. In his "sun-heat boiler" the water is to be directly exposed to the sun's rays under the double glass roof of a building which forms really the shell of the boiler. The steam or vapor is to be generated at, or near, atmospheric pressure and led off to a low-pressure steam turbine discharging into a condenser. Details of the design have not been given out, but it is stated that the water to be used will contain a small amount of potassium bichromate and flow in thin streams over the floor of the absorption room, the thickness of the streams being regulated to the amount of sun radiation being absorbed at any moment. The glass of the roof will be tinged green by a slight amount of iron sulphate so as to reflect back into the interior any radiation from the water itself, while still being fairly transparent to the sun's rays.

It is assumed that the low-pressure turbine will either pump water when the wind and commercial load are slight, or will furnish power direct when the wind and load are heavy.

One large windmill, or series of smaller windmills mounted upon a turn table, is proposed for utilizing the energy of the wind, particularly when the sun is not shining. These windmills are to be connected in some way by rope drives to a common shaft drive which will pass down the shaft of the mine and operate the pumps located at the lower reservoir to elevate the water to the surface reservoir, thereby storing the energy secured from the wind.

Without going into the details of the estimates submitted as to the cost of constructing the proposed plant, suffice it to say that, based on reasonable impartial figures, the cost of the plant will so much outweigh the cost of a steam plant of equal capacity that the scheme is shown to be wholly impracticable. The results obtained, however, will be interesting.

Automatic Stokers Which Throw Coal

By F. R. Low

This type of stoker is used extensively in Europe upon internally fired boilers. It spreads the fuel evenly over the fuel bed and will handle a variety of coals.

In many European plants I found in use mechanical stokers which threw the coal more or less continuously over the surface of the fire. These were especially used upon furnace-tube and other internally fired boilers with constricted furnaces to which they are more adaptable than the traveling grate or the underfeed. They are used successfully with all kinds of hard and brown coals, and to some extent with small brown-coal briquets. Lignite is used by mixing with other combustibles of larger lump. They are exceptionally well adapted to the use of gassy coals on account of the thin fires which they carry and the rather free admission of air. In order to prevent too great an ingress of air through the hopper, it is recommended when stoking with briquets to mix them with a smaller coal to fill the interstices.

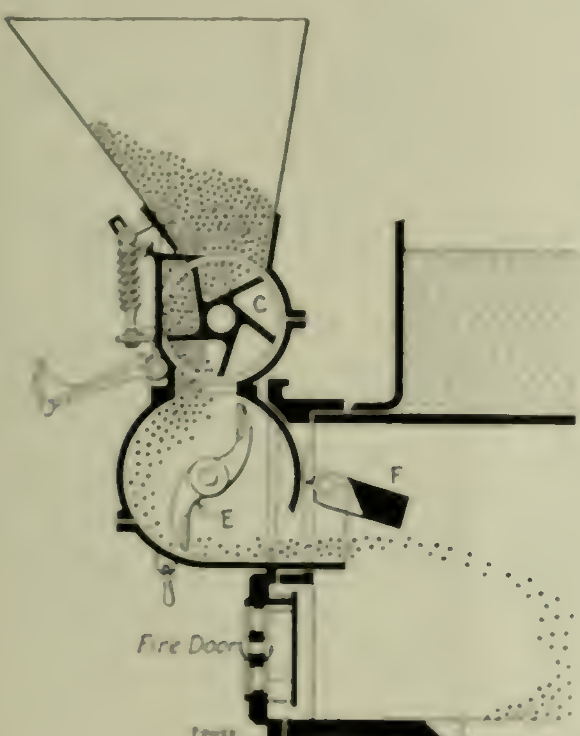

Fig. 1. Leach Stoker as Made by Saxon Machine Works

The wide range of variation in rate of feeding and the uniform distribution of the coal upon the grate, whatever the rate at which it is provided, adapt the stoker to varying demands, and several engineers whom I asked said that they had very little trouble with burning out the exposed parts. If the shovel and deflecting plates are eroded by impact with the coal they are easily and cheaply renewed. I did not meet with any case where what we would call large rates of combustion were being used with this type of stoker.

One important advantage of the type is that it may be used with any kind of a flat grate, and hence with a bar adapted to the fuel used, whatever that may be. The ordinary fire door is left intact and accessible so that the fire may be worked with the ordinary tools and in the ordinary way, or may be hand-stoked through the door in case of interruption to the operation of the stoker. For the long, narrow grates of internal-furnace boilers they are particularly adapted. They are used singly for such narrow furnaces or in batteries for the wider furnaces of externally fired boilers.

These stokers, although I found them largely in use on the Continent, are based upon English inventions, and naturally divide themselves into two types, one in which the fuel is brushed or projected into the furnace continuously, as in the type invented by Leach, and the other where the action is somewhat intermittent as in that of Proctor. From a paper presented at a meeting of the International Association of Steam Boiler Inspection Societies at Lille, by Herr Ober-Inspektor Pröbsel, of Chemnitz, I am able to present several sections of the principal examples.

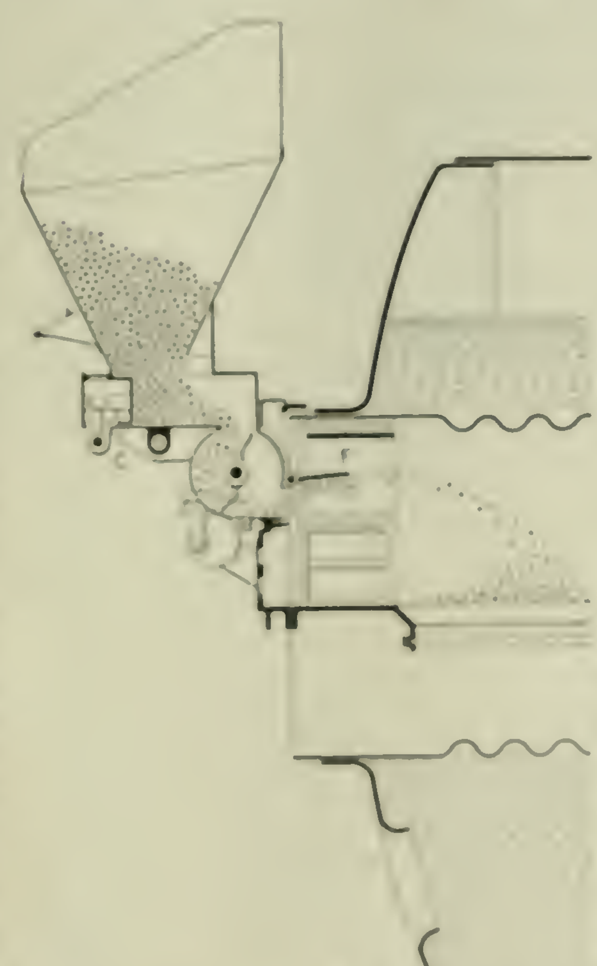

Fig. 2. Leach Stoker as Made at Meerane, Germany

Fig. 1 shows the Leach stoker as it has been made by the Saxon Machine Works at Chemnitz for twenty years. At the outlet of the hopper is a feed roll C operated by a ratchet movement which delivers the coal to a housing in which is a blade wheel E turning at a speed of 300 revolutions or higher, which throws the coal into the furnace. Between the wheel and the furnace is a hinged baffle plate F against which the coal strikes and which is automatically and continuously moved up and down, distributing the coal over the entire fire bed. The ratchet wheel which drives the feed roll has a sliding cover adjustable by hand over a greater or less number of its teeth so as to control the rate of feed with about ten gradations independent of those afforded by cone pulleys on the drive. This stoker is best adapted to sized coal, in particular, nut coals of from one-quarter to three-quarters of an inch in size. The use of briquets, except in the smallest sizes, is precluded, but the Leach apparatus, although thus restricted, and the more so because the price of so suitable fuel is relatively high, is much used, about 350 of them being under the care of the Saxon Steam Boiler Association.

Fig. 3. The Proctor Stoker

In the Whittaker design, also an English invention, the feed roll C of Fig. 1 is replaced by a pair of crushing rolls which, being driven at a greater or less speed, control the rate of delivery of the fuel as well as reduce it to the proper size. The baffle plate F is adjusted by hand. This furnace is quite popular in Austria.

Fig. 2 shows another modification of the Leach. It is made by F. L. Oschatz, of Merane, Germany, who replaces the rotary feed roll *C*, Fig. 1, with the re-

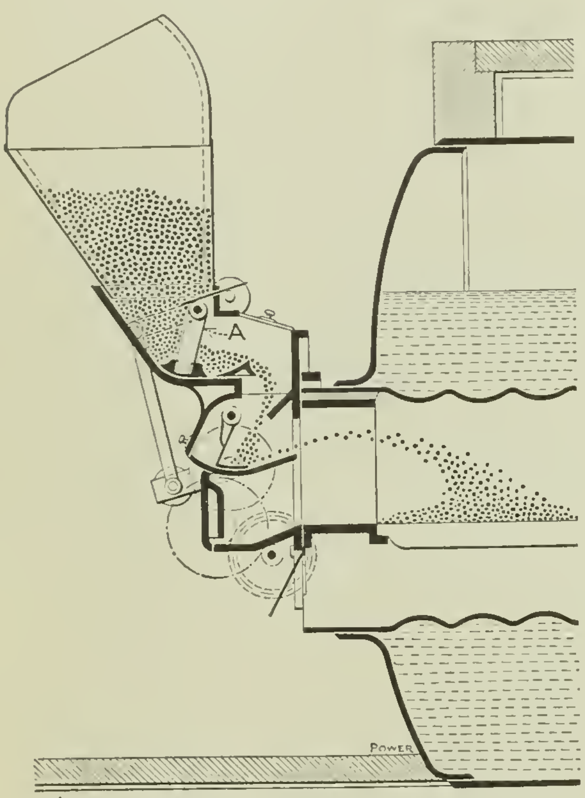

FIG. 4. STOKER MADE BY C. H. WECK

ciprocating-piston arrangement *C*, Fig. 2. This is said to permit a larger size of coal to be handled, run-of-mine, lump and brown-coal briquets up to 2¾ inches being available. The baffle moves continually and the feed is regulated by the simple turning of a screw controlling the movement of the piston *C* from nothing to the maximum.

In the Proctor type the coal is periodically flung upon the grate by a pivoted plate, usually spring actuated. This plate, because it performs at least the projecting part of the work of that tool, is called the shovel. On one end of the shovel shaft is a toe engaging a cam wheel which has a number of protuberances, usually three or more, and is turned from the driving shaft. A lever on the other end of the shovel shaft is connected with one or two strong helical springs. When one of the protuberances of the cam comes in contact with the toe the shovel is thrust back away from the fire and the spring stretched. When the cam lets go. the spring throws the shovel toward the grate, hurling the coal, which has fallen before it, onto the fire. In consequence of the different hights of the protuberances upon the cam the shovel is drawn backward and the spring stretched to different degrees, throwing the coal successively onto different parts of the furnace and preserving a uniform fire bed. The rises upon the cams may be adjustable so that the stoker can be adapted to different grades of fuel, greater spring tension being needed for the larger sizes. They can throw sorted coal and run-of-mine up to 3¼ inches, in which they have an advantage over the type already described.

Illustrative of the Proctor type is the stoker built by Munckner & Co., of Bantzen, Germany, and shown in Fig. 3. The coal falls into the funnel in which there is a ring pusher, driven by the vertical shaft, which gives it a turning movement back and forth, pushing the coal forward in the direction of the boiler.

At each stroke of the pusher a determinate quantity of coal falls over the overflow nose *N* on the throw plate *P* in front of the shovel *S*, the guide *L* assisting in landing it within range of the stroke. The overflow nose *N* keeps the coal from dropping on the wrong side of the shovel.

In the stoker of C. H. Week, Dolau near Greiz, shown in Fig. 4, the coal is sent down to the shovel by a hinged pusher *A*. Passage is afforded for lumps of four or five and a half inches in size; the quantity fed may be adjusted by means of a handwheel during operation.

In the "Katapult" stoker, made by J. A. Topf & Sons, of Erfurt, and shown in

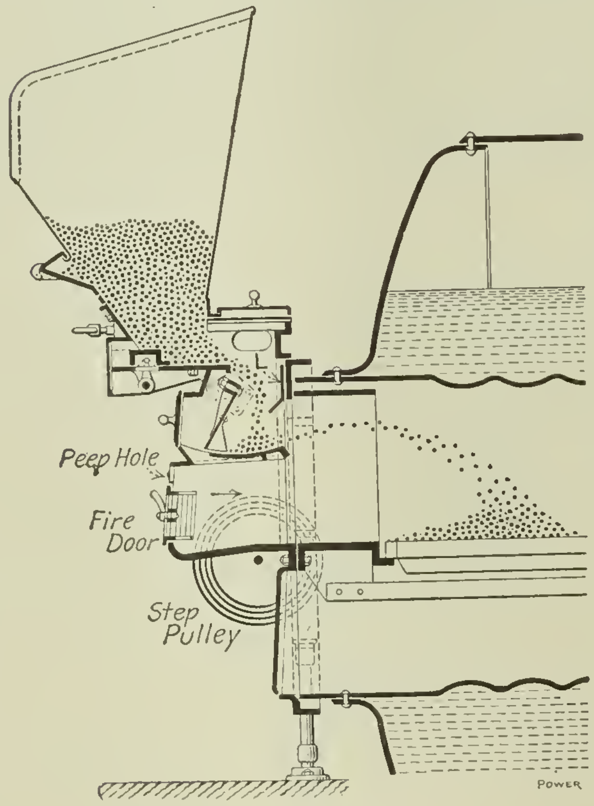

FIG. 5. "KALAPULT" STOKER

Fig. 5, a relation is established between the movement of the feeding pusher and the shovel-operating cam whereby the amount of coal fed varies with the throw, being greatest for the longest throw and least for the shortest. This takes account of the fact that the combustion is most intense at the back part of the grate and also of the obvious certainty that some of the coal always falls short of its destination. The fuel is dropped in front of the shovel for its entire width instead of being allowed to fall in a heap.

The deflecting plate *L* is made adjustable. Coal up to fist size, as well as briquets, can be used.

The trouble seems to be not so much with handling large sizes within reason as from the tendency of the finer stuff to pack, especially if it is wet. In the "M. A. N." stoker, Fig. 6, made by the Augsburg-Nürnberg Machine Company, an agitator *A* is provided just above the

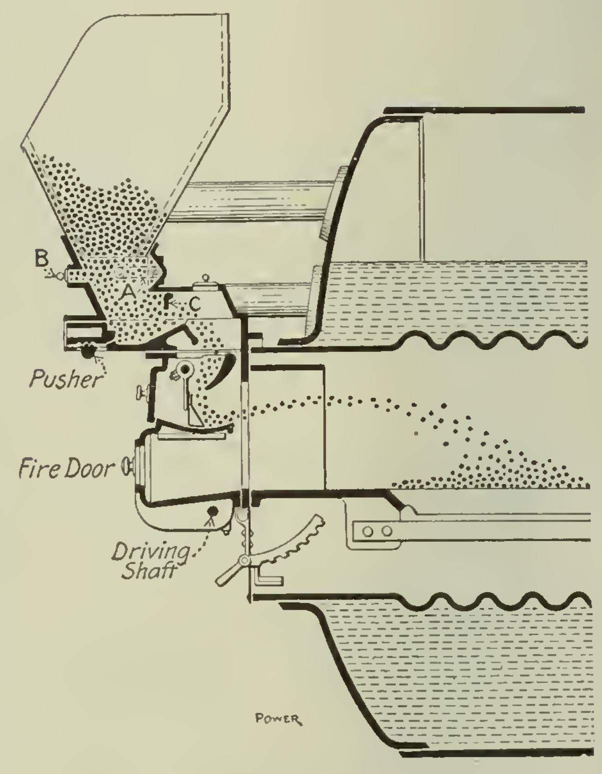

FIG. 6. "M. A. N." STOKER

throat of the hopper and a poke hole *B* in the front of the funnel. A gate *C*, adjustable for fuel of different sizes, is placed where it will restrain the falling coal and place it more directly under the control of the pusher.

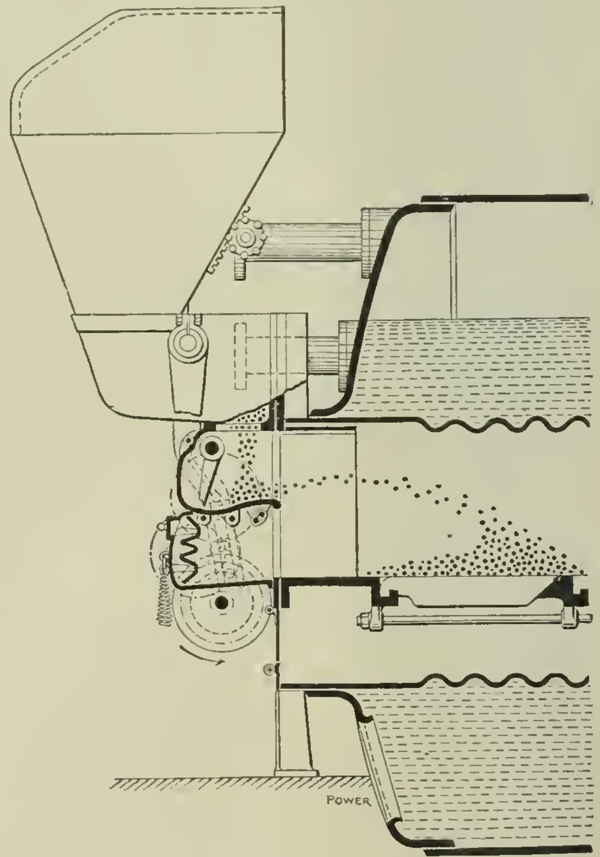

FIG. 7. STOKER MADE BY RUF & CO.

The Seyboth stoker, made at the Zwickauer foundry of Emil Selbmann, Zwickau, embodies a feed roll with many cavities whose dividing walls have edges which break up the large lumps. By this means irregular mixtures of coal or briquets can be used. It is pointed out that one advantage of equalizing the size arises from the fact that large lumps are thrown farther than smaller ones and require a more forcible impetus. The mode of varying the throw of the shovel is somewhat different from that employed in the machines already described. Instead of having a series of projections or rises, the cam is an eccentric disk, each revolution of which corresponds to one throw of the shovel. By a gradually changing lever movement the same is brought into contact with the tension toe on the shovel shaft earlier or later, thus putting the springs through a long cycle of variations in tension and apportioning the distance to which the coal is thrown upon the grate by a series of small gradations. A stoker of this type is also built by the Esslingen Machine Works in Esslingen; and the "Cyclop," made by Mehlis & Behrens at the Cyclop Machine Works at Berlin, contains also the rotary-crusher feature. The separated throw plate is also used in the stoker made by the Dingler Machine Company, of Zweibrücken.

The stoker of Ruf & Co., Bautzen, Saxony, Fig. 7, differs from the others in having the throw plate beneath the shovel made in two parts, the front one of which is hinged and by its inclination determines, in connection with the varying force of the shovel push, the distribution of the coal. It may be easily adjusted while the furnace is in operation. The varying impetus is obtained with the usual cam and toe arrangement. The pusher is of a form designed to prevent clogging and is almost entirely relieved of the pressure of the coal in the hopper; lumps four inches and more can be handled.

There may be mentioned another type of throw stoker which has lately appeared in which the shovel is not pivoted above but beneath the stoking plate, of which the shovel forms to a certain extent a part. This system is used in the Seemer stoker, made by the Kaiserslautern Iron Works in Kaiserslautern, Pfalz.

Less than one-half a horsepower is required to operate any of these stokers when crushing rolls are not included.

In our own country this type of furnace is of comparatively recent introduction. A description of that made by the Erie Foundry Company appeared on page 700 in our issue of April 13, 1909, and of the Vulcan, made by the Vulcan Furnace Company, in our issue of January 11, 1910. A still later type, made by the Parsons Manufacturing Company, of New York, in which the fuel is injected intermittently by air blast, is described on page 2046, November 15, 1910.

Control of Indirect Heating System

By H. R. Rogers

Leakage through the walls and doors of the plenum chamber produced too high a temperature in the mixing chamber and made it almost impossible to maintain the desired temperature.

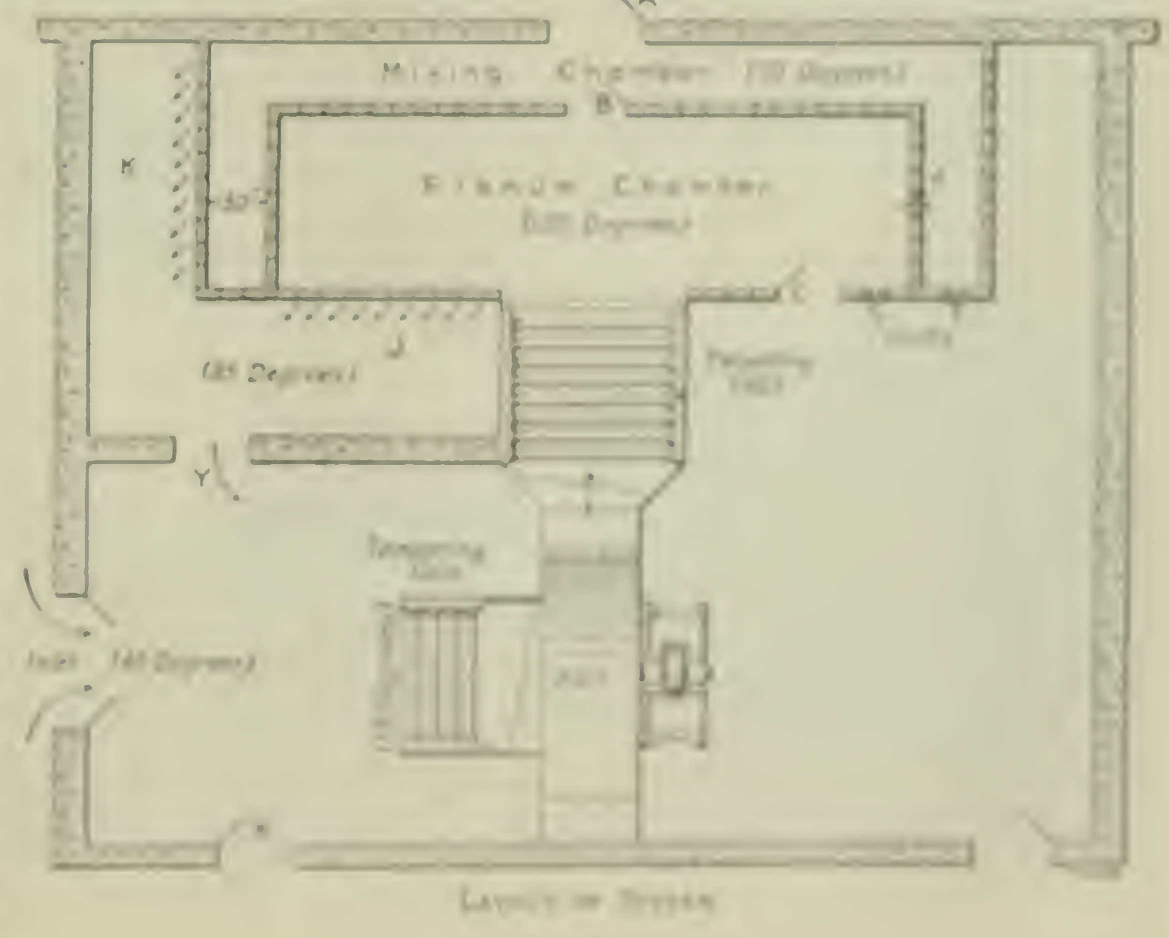
The cubical content of a certain building was about 800,000 cubic feet, and the capacity of the fan was about 40,000 cubic feet per minute; this gave a change of air every twenty minutes. The average outside temperature was 40 degrees and the temperature maintained inside was 68 to 70 degrees. The accompanying sketch shows the plan of the plenum chamber, the mixing chamber and the fan inlet; also the temperatures are indicated as observed after it was discovered that the system was not fulfilling the requirements.

The plenum chamber was about 14x32x12 feet, with four brick walls and a concrete floor. The mixing chamber was 30 inches wide, surrounding three sides of the plenum chamber and having an outer door at *A* through which to enter the mixing chamber, and an inner door at *B* to enter the plenum chamber. As the latter door was found to leak badly, it was taken out and the aperture was bricked up and the same door installed at *C*, where the leak could not affect the tempered air.

The tempered air passed under the plenum chamber (directly under *H*) to reach the mixing chamber. But it was found that the floor of the plenum chamber at *H* had not been completed up to the edge of the reheating coils, and there existed a crack about three inches wide and nine feet long. This proved to be one cause for the temperature being too high in the mixing chamber. At the place indicated by the small arrows *J*, it was found that the 4-inch brick wall leaked at almost every joint, the current of air coming from any of these leaks being strong enough to extinguish a lighted match, and the pressure in the plenum chamber was barely ½ inch.

The temperature carried in the plenum chamber was at times as high as 120 degrees Fahrenheit, and the outside temperature was usually 40 degrees. It was impossible to keep the proper temperature in some of the rooms, especially those that had 12-foot ceilings. The temperature in those rooms would reach as high as 90 degrees, as they were situated only about 50 feet distant and were receiving the air direct from the plenum and mixing chambers, and the velocity of the air into them was approximately 325 feet per minute. The dampers in the plenum and mixing chambers were controlled by an apparatus for regulating the temperatures, but as this was found to be in perfect working order, the lack of control could not be laid to it.

It may be noted from the sketch that air would be drawn through the door *Y*, which was proved by hanging a thermometer directly in front of the temper-



Layout of System

ing coils, when it was found that the temperatures ran as high as 58 degrees, with an outside temperature of 40 degrees. The air would go through the fan and either under or through the reheating coils, and the reheated air that did not go through the hole in the floor at this point went into the plenum chamber. Enough air, however, passed through the hole to raise the temperature in the mixing chamber to 70 degrees, even after the steam was shut off from the tempering coils.

With the air coming in at 70 degrees, the heat from the occupants and from the lamps raised the temperature to 80 degrees at times, about 12 degrees too high to be comfortable.

To remedy the matter a door was placed at *Y* and kept closed, after which there was no perceptible leak through *J* and *K*. Before this door was hung and kept closed, the pressure in the plenum chamber and the suction of the fan would cause all the air that came through the leaks to be reheated and recirculated.

The hole in the floor was stopped up in a permanent manner and ports were made into the plenum and mixing chambers, as shown at *S* and *T*, and thermometers were placed there. It was then found that 120 degrees could be maintained in the plenum chamber and 55 degrees in the mixing chamber when the outside temperature was 45 degrees, and there was no trouble in controlling the temperatures in the rooms where there had previously been difficulty.

If those who are experiencing trouble in maintaining temperatures would hang thermometers in various places, they might learn a great deal. I consider it just as essential to have a thermometer in the plenum and the mixing chambers as it is to have a pressure gage on a boiler, for without these it is impossible to be sure of just what is going on, especially when some ventilation is required and very little heat is needed.

It is bad practice to build plenum chambers with 4-inch walls unless they are plastered on both sides with a coat of cement, as the difficulties mentioned are apt to occur, and without the thermometers no one would be the wiser.

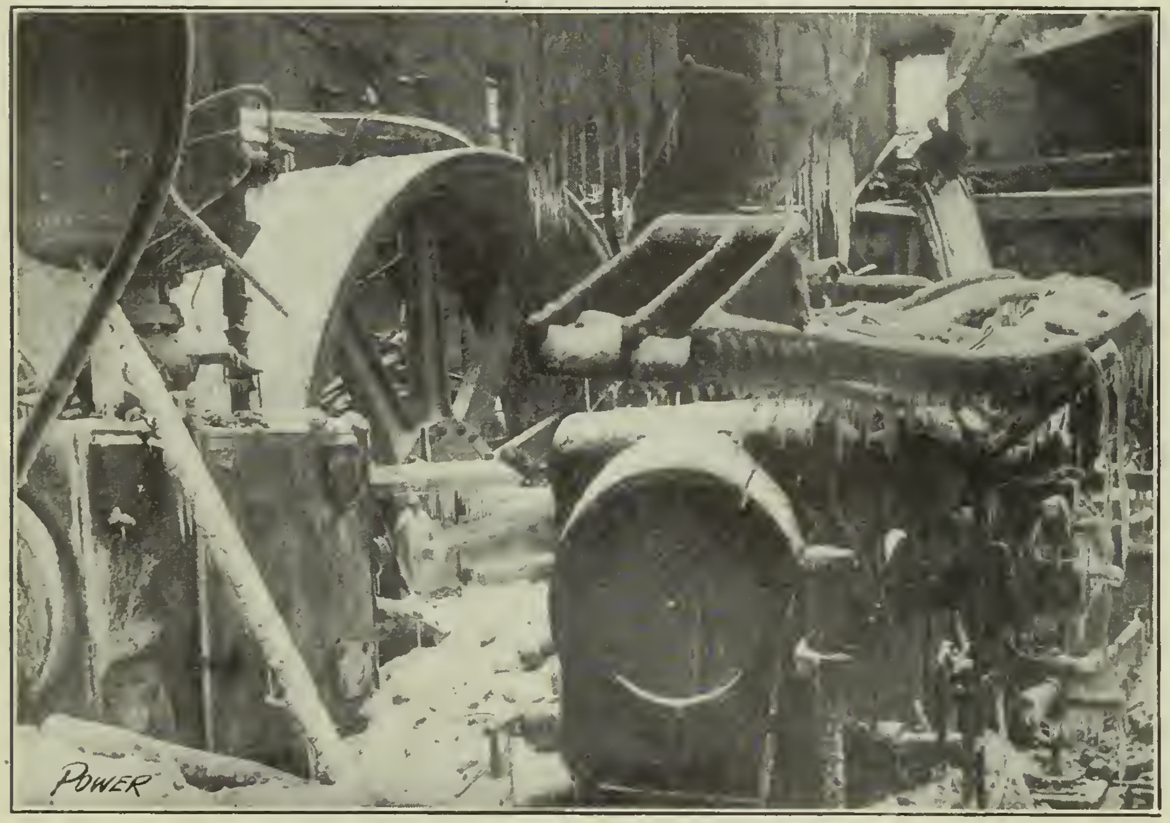


Fig. 1. One of the Corliss Engine Units

Minneapolis Power House Burns

About 6:45 a.m., Friday, January 6, fire broke out in the engine room of the Main street station of the Minneapolis General Electric Company and rapidly reduced the generating side of the station to a mass of scrap. The fire, as near as can be ascertained, originated in the northeast corner of the building near the incoming feeders from the other stations which operated in parallel with this plant, and was the probable result of a short-circuit of some of the electric wires at this point.

In escaping from the fire two men were injured, one of them seriously but not fatally. The floor and roof of the building furnished most of the inflammable material and this, falling on the machinery, had the effect of concentrating the heat. Massive engine frames were in many cases cracked like glass, and it is estimated that the machinery is practically a total loss.

The plant contained one 1000-kilowatt direct-connected unit, two 1200-horsepower and one 700-horsepower belted Corliss machines, and a 1500-kilowatt Curtis turbo-generator. It operated also two waterwheels of approximately 2000 horsepower capacity, and contained one 1000-kilowatt motor-generator, which formed a connecting link between this station and the others in the system.

Notwithstanding the complete destruction of the engine-room side of the house, the boiler plant, containing ten 350-horsepower Stirling boilers, was not injured. A substantial fire wall separated the two parts of the building and it was due to this fact that the boiler room escaped.

Some extremely good work was done by the Minneapolis General Electric Company in making temporary connections whereby normal conditions in the lighting service were resumed. The city was without lights on the night of Friday, but, the following night, lights were burning as usual except in the case of about 1000 open arcs which had been supplied from the Main street station, using old-type Brush dynamos. These will be out of service until they can be replaced by magnetite arcs.

Fig. 2. Remains of the Building

An Industrial Plant Boiler House

By Warren H. Miller

The details of design of boiler house and water softening plant. Fire-tube boilers were selected because of low steam pressure and the hardness of the water. Simple coal and ash handling arrangement. Concrete blowoff sump.

While this boiler house was primarily designed for the sole purpose of making and distributing steam, it has many features of interest and value to those engaged in the design of combined boiler and power houses for industrial plants. About larger manufacturing establishments, comprising big acreage and many buildings, the conditions are considerably different from those of the big city power houses, where ground space is limited and where the ash must be shipped away in gondola cars. For the latter type of plant some sort of conveyer for coal, and elevator for ash are the standard details, but for an industrial-plant boiler house, both can be replaced by simpler and cheaper devices. Probably the most economical way in which to serve coal to the boilers is to haul it in the cars up a trestle of about 5 per cent. grade and dump it into a bin which permits it to flow out in front of the boilers by natural slope, which, for buckwheat, is 33 degrees. Similarly, the easiest way in which to dispose of the ash is to collect it in cars in an ash trench in front of the boilers and haul the string once a day, dumping the ash on low or swampy ground about the works. Such a trench can be made very cheaply of concrete with manholes at each boiler, and steel dump cars can be gotten just about long enough to space one in front of each boiler. Following out these ideas, the boiler house, a cross-section of which is shown in Fig. 1, was designed. It will accommodate either fire- or water-tube boilers of 250 horsepower size. While the water tube is shorter by nearly three feet it needs this amount of extra room in the back alley because of the rear caps, etc.

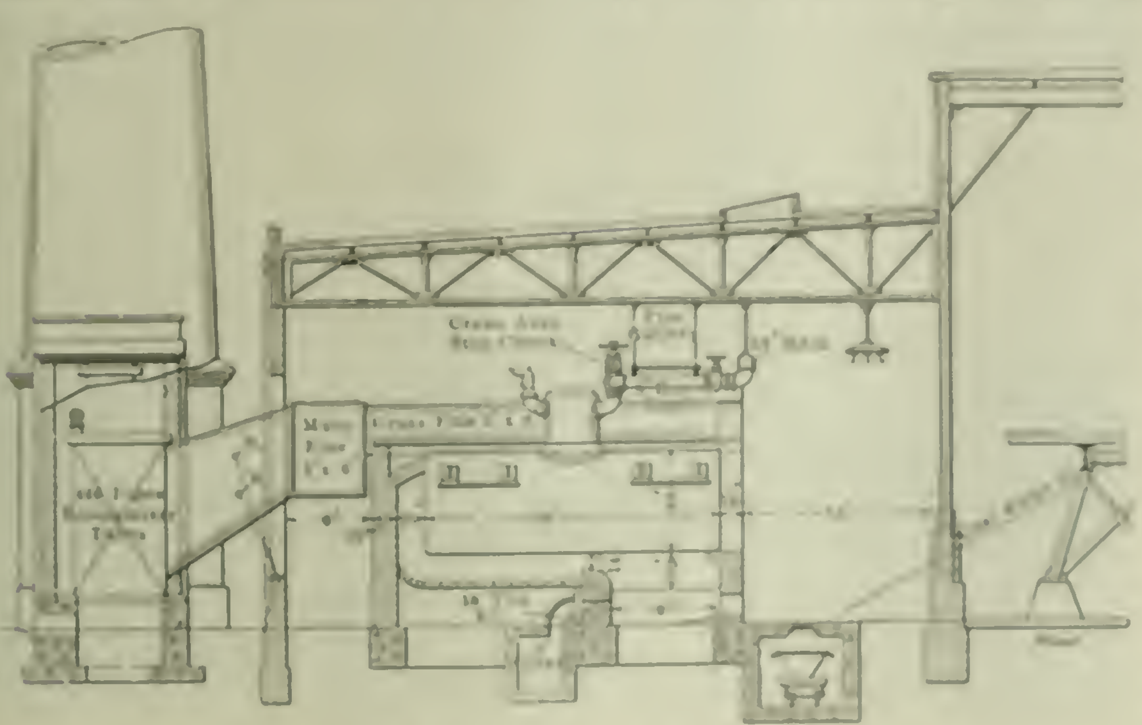

Fig. 1. Cross-section of Half of Boiler House

Coal Trestle

The trestle is a structural-iron affair with 24-inch I-beam stringers. It was adopted after much argument because of uniformity with other trestles about the works, but there is no question but that a concrete trestle would be cheaper and more durable. It has often been the experience in using iron bents in coal bins that they rust quickly from the sulphates in the coal unless dug out and repainted at least once a year. The all-steel trestle costs about $10 a running foot and the concrete pier trestle, with steel I-beam stringers, costs a little over $8 per foot. The hight of the top of the rail on the trestle should not be over 13 feet; the distance from the center line of the trestle to the face of the wall should be 11 feet. The bin walls were made by raising the foundation piers 7 feet above grade and making a retaining wall of them. Each pier was 5 feet wide with an intermediate wall 1 foot wide carrying no column. This arrangement left two doors in each bent 3 feet 8 inches wide. A 3-inch channel was cast vertically in the face of each concrete pier, thus giving a slide for the doors, so that the amount of the coal slope can be adjusted at will. The pressure of coal is very considerable, and it becomes a live load whenever a car is dumped; the descending coal produces a great shock. It is capable of bulging an ordinary 8-inch brick wall if dumped against it to any hight, or bending 4x12-inch yellow-pine bin boards, if the span is over 8 feet between posts.

The floor of the bin is of concrete, smooth finished and pitched each way to a gutter running along the boiler fronts, which also catches the hose water from wetting down ashes. Another scheme for draining the coal bin is to build a blind drain of brickbats laid in a trench running down the center of the bin. This drain is covered by the floor, except for a square opening in the center of each bent. This opening just holds four bricks laid loose. Such a drain will dispose of all rain water which may get into the coal, and will never have to be dug up like a tile drain when laid under concrete.

Ash Handling

The ash trench is 6 feet by 5 feet 2 inches in cross-section, with a 7-inch reinforced-concrete roof and 9-inch plain walls, made by setting up interior forms and pouring concrete between them and the sheer walls of the excavation. The roof was poured before the wall forms were struck, in order to avoid the liability of the earth pressure bulging the walls in. The 30-pound rails of the 36-inch industrial track are laid on sills in the cement. The dump cars used were manufactured by Wickham & Mayer; each is of 2 cubic yards capacity and cost about $80. Using a 2-foot spacing link, their length is such as to place one of them in front of each boiler, with a spare in each of the two alleys. Each car stands directly under a cast-iron 24-inch street manhole, cast in the concrete roof of the ash trench. After the fires have been cleaned, the heap of hot ashes and clinkers is wet down with the hose, the manhole cover lifted with a slice bar and the ashes hoed into the cars below. Each car will hold three cleanings and constitutes both ash bin and conveyer and is far cheaper than either. For 18 cars, serving as many boilers, cost only $1200. They are hauled at 7 o'clock, morning and evening, by the work's electric storage-battery locomotive. The approaches to the ash trench are down 3 per cent. grades from the street level, one straight and the other curved on a radius of about 60 feet. A six-ton locomotive can haul five cars up such a grade, and a ten-ton can take 8 or 12 of them up.

Boilers

The boilers were chosen fire-tube because of the low steam pressure, 80 to 100 pounds, and because of the hardness of the feed-water supply which contains over 18 grains of solids to the United States gallon. There was no hope of softening this below four grains each with the best water-softening equipment that could be devised, because the water was one of the "impossible" variety, such that by the time enough lime and soda have been put in to make all the impurities soluble, there is so much in that the boilers foam to a degree beyond all safety for the engines. While evaporation, capacity and economy of upkeep are, in the long run, about equal with fire- and water-tube boilers of first-class make, the cleaning account of the former is undoubtedly much smaller, being only a three days' job for three men in a 250-horsepower boiler, whereas the water-tube of the same size takes five men a little more than a week. It is the writer's belief that the water boiled is the most important consideration of all. About 90 per cent. of all the accidents and repairs about boiler plants are primarily due to the water and its quality, and yet it is often the last thing considered. The boilers cost about $26,000 for sixteen, against $41,000 for an equal number and grade of water-tube. They are 84 inches in diameter and 20 feet long; the shell is 7/16 inch thick; the joints are triple-riveted butt-strap. The main steam outlet is 8 inches in diameter; the feed, 2 inches; the surface blow, 2 inches; the bottom blow, 3 inches, and the equalizer 2 inches. Each boiler has two 4-inch pop safety valves. The boilers are set in batteries of four so as to have one 5x3-foot cross-connection flue to each pair of boilers. Since, if one boiler were let down and opened, the draft of the other boiler would be broken, dampers were put in by running a dividing plate from the front wall a short distance down the flue, thus parting it in halves; in the passages thus formed the dampers were swung.

Flues and Economizers

The main flue is 5x6 feet in section throughout. It was possible to keep to this size by placing the chimneys in the center of each side of the boiler house, with the economizers on each side of the chimneys. The arrangement of the boiler house is eight boilers on a side, with foundations for four futures. The flue is built for the entire twelve with a dead damper beyond the eighth boiler which can be closed while the future boilers are being connected in. As two boilers are directly opposite the economizer entrance, no section of the main flue is used by more than four boilers at once, whether direct into the chimney or indirectly through the economizer.

The economizers are for six boilers each, but, at present, four feed through one economizer and four down the flue into the other. The location of the four economizers on opposite sides of the chimneys and entirely outside of the boiler house is an arrangement often used by the writer because of the numerous advantages it affords. It costs little if any more than the arrangement of locating the economizer above the main flue, or of backing it up against the back wall of the boiler house, and it gives not only free access to the economizer on all sides, but also plenty of light and air in the alley behind the boilers.

It would seem that few outside of the firemen on the job really appreciate how valuable light and ventilation actually are. Here are located all of the blowoff valves and cocks, surface blowoffs, equalizers, back-cleanout doors and flue-cleanout doors, and, if the boilers are water-tube, here also are all of the thousands of tube caps, which must be cleaned, replaced and tested. If this alley is a dark tunnel and a sweatbox, as is the case if the rear wall is left blank and the economizers backed up against it, these things will be looked after and repaired by the light of a few lanterns or kerosene torches, and will be one of the "meanest" jobs about the boiler house. But, with the economizers outside, there are light and air in the tunnel; there is room about the economizer itself to take out a cracked header or a defective tube, and there are air and light overhead to handle the scraping mechanism and to clean the blessed thing whenever it needs it, which is about every six months at least, and the job takes about two weeks of steady work. As to difference in cost, wide and massive foundations for boiler-house wall, requiring special concrete forms, are avoided; the solid brick wall of the boiler house, which would have to be faced with firebrick, is replaced with window frames and a 12-inch panel wall which is cheaper, and, in addition, one side of the economizer may be covered with the sectional coverings which come with the economizer, so the difference in cost will not be very great—far less than the real advantages that it gives in the work of making steam.

Chimneys

The chimneys, 9 feet in diameter and 125 feet high, are built of radial brick; have common-brick bases which extend up as far as the economizer tops, and are lined with firebrick for 30 feet from the bottom. The flues enter each side, and the direct bypass from the main flue to the chimney enters the brick neck, joining the chimney with the economizer houses on each side of the chimney. Competitive bids were received on reinforced-concrete and radial-brick chimneys. The latter type was chosen in spite of the lower cost of the former. The appearance of the concrete stack is hardly in its favor, as it is impossible to avoid the effect of separate rings caused by each successive batch of concrete, and these rings spoil the unity and column-like appearance which is the chief beauty of a chimney. The durability of the concrete chimney is also probably less than that of the radial-brick, but this remains yet to be proved, as the oldest concrete chimney in America, to the writer's best knowledge, is not over ten years, and is lined from top to bottom with firebrick, making it more expensive than a radial-brick chimney. While a number of poorly built concrete chimneys have had to be taken down, there should be no hesitation in using them at the present time, if price is the first consideration. The radial-brick chimneys for this plant cost about $2700 each. The economizers cost $13,000, erected, for four containing 440 nine-foot pipes each. Their capacity is 1250 horsepower with feed water at 180 degrees and flue gases at 410 degrees. The foundations, setting and houses, made by carrying up the walls above the economizer tops and putting on a roof, cost under $5000 for the four, including the electric drive.

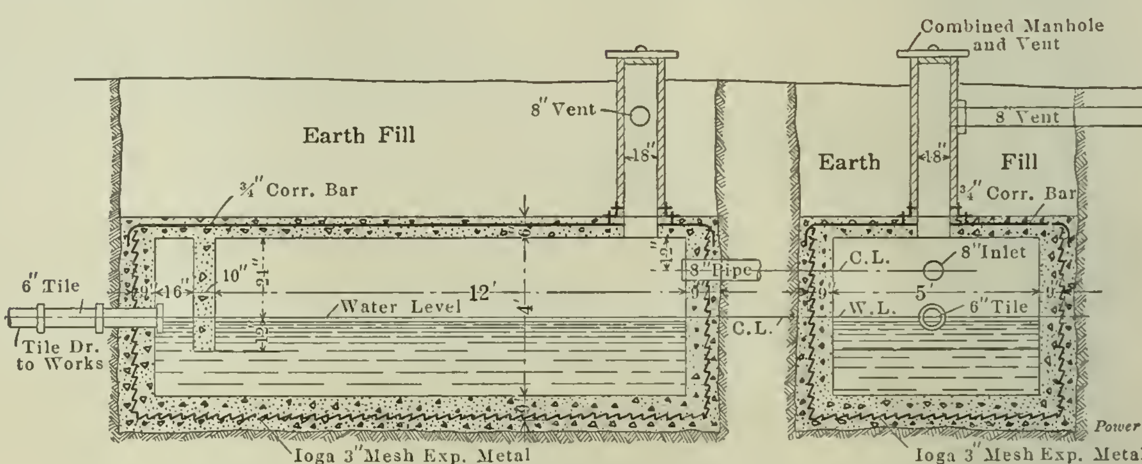

Fig. 2. Details of Reinforced-concrete Blowoff Sump

Grates

The coal burned is buckwheat anthracite, containing much slate, costing about $1.10 a ton and containing 20 per cent. ash. To burn it a pinhole grate and fan blast are required. Two three-quarter-housing, bottom-discharge, Sturetvant 8x12-foot fans supply the blast through reinforced-concrete air ducts, with openings in the bridgewall into the ashpit, controlled by cast-iron swing blast doors. One of the fans is driven by a Sturtevant 10x12-inch heavy-duty fan engine, running at 150 revolutions per minute and the other by a 40-horsepower induction motor. Either fan will furnish the blast for all of the boilers, so as both steam and electric drive are available, it is almost impossible for the fan equipment to be shut down.

Auxiliaries

The fans, engine, motor and three large 15 and 10½ by 18-inch, duplex, boiler-feed pumps are all located in one house under the care of a water tender, who also looks after the water-softening plant adjacent. The arrangement is very simple and compact, and is made possible by simply putting in a relief valve from the boiler-feed discharge main into the suction main. Each fireman tends water for his own boiler by his stop checks, and the feed pumps are run just a little above the intake of all the boilers that may be on. They use about 300 gallons per minute. Any excess that they do not use is discharged back into the suction through the relief valve.

Water-softening Plant

The water-softening plant, like many properties of this company, is characterized by the utmost simplicity. If you reduce water softening to its simplest terms, you need two tanks for combined treating, agitating and settlement, two filters to remove any solid particles not settled out, and a pump to move the water. In this plant, treating 300 gallons of water per minute continuously, there are two iron tanks 20 feet in diameter by 30 feet high, with a 10-inch electrically driven centrifugal pump with a 10-horsepower motor, situated between the two tanks. This pump fills them alternately, taking 20 minutes to do it, adds the softening compound with a single turn of the motor, agitates by sucking from the top of the water level and delivering into the bottom for one hour. The tank then settles for three hours and is ready for use. A 6-inch connection, 2 feet above the bottom, is opened into one of the filters into which the water enters by a pocket in the side, and overflows at the top. The water then passes down through alternate 12-inch layers of sand and excelsior to a hole plate a foot above the bottom of the filter, which is 6 feet deep by 12 feet in diameter. From here the boiler-feed pump sucks the filtered and softened water for steaming purposes. As there are two tanks and two filters, the water in one is always being used while that in the other is being treated and settled. Seven tankfuls per a 24-hour day is the total available output. It is the simplest possible water-softening apparatus. An extra 20x30-foot tank was added later to provide extra settling and storage capacity. This tank is also used as a reservoir for preliminarily heating the feed water to 100 degrees by passing it through the gas-engine water jackets in the power house. The water itself is of villainous quality, containing 18 grains of solids per a United States gallon, and requiring the unusual proportions of 120 pounds of soda and 70 pounds of lime per tank. Only treated water can be used in the gas-engine water jackets or otherwise they would immediately scale up.

Fig. 3. General View of Boiler House, Fan House and Water-softening Plant

Steam Distribution

The problem of distributing the steam to the various departments is solved by the usual "ring," crossing over the boiler house at each end by four 10-inch extra-heavy bends. A division gate valve, with Crane drip pockets duly trapped, is set at each four boilers, with a 10-inch outlet rising from a tee at each division valve. These lead out to the three main process departments and to the power house (for steam spares, exciter and air compressors). The connections from the boiler drums to the steam main consist of 8-inch extra-heavy pipe bends set horizontally and plain 8-inch angle valves coming into the main from the underside—a good flexible arrangement, and one that is self-draining for anything but wet, foaming steam. In the pipe gallery is also run the 6-inch feed-water ring with its direct connections from feed pumps and bypasses through the economizers. Out of the power section is also taken the 6-inch connection for the boiler-house auxiliary plant and the 6-inch connection for the mechanical shops. The 6-inch connection to the auxiliaries is set in a corner of the ring between a big department section and the power section, and protected by a special division valve, so that, in case of trouble with the power section, it can be carried by the departmental section.

Blowoff System

The blowoff system consists of a 2-inch surface blowoff and a 1½-inch equalizer pipe for each boiler, together with a 3-inch bottom blow. The latter are of the Hancock type, which have the very commendable feature of a protruding pilot on the valve disk, which pilot fits inside the seat ring so closely as to push back any pipe scale or hard scale that may be coming through just as the valve is closing. The steam of the blowoff can still get past the pilot and scour the seat clean before the disk comes down on it, a long-felt want, as more blowoff-valve seats are ruined by small particles of scale getting under the disk just as it closes than by any other cause. In addition to this a 3-inch iron, straight-way asbestos-packed cock is put on the blowoff ahead of the valve. It is always open except just before opening the valve, when it is closed, the valve opened and then the cock. The reverse order is followed in closing the blowoff.

A screw ell is put on between the cock and the valve to give it swing, and as the valve is of the angle type, flanged, it can thus be easily removed for repairs without disturbing the main. The latter is of 6-inch extra-heavy pipe with extra-heavy fittings, the whole main being kept above the concrete floor of the rear alley so as to be easily reached in case of clogging or other trouble. The meanest job in existence is digging up a leaky blowoff main full of hot steam and hard fouling, and in this plant it was kept entirely above board. The blowoff main leads by an 8-inch bull-head tee and connection under the economizer to a concrete blowoff sump, often used by the writer in industrial plants.

As this muddy and scaly blowoff water is at 350 degrees, nearly a third of it flashes into steam to restore the thermal equilibrium the instant it passes the blowoff cock and its temperature falls to a little above atmospheric, or 212 degrees. The volume of steam thus released amounts to about [illegible] cubic feet in blowing down a single gage, and as this is a whole lot of steam, it will not do to turn it into the tile drain system of the works, down a sewer, up a downspout or any other place where it is sure to do harm. The heat of this blowoff water is also so great as to crack drain tile for 60 to 100 feet of its length, and this in time would cave in because of the weight of the earth above and clog up. Therefore, if there is a number of boilers to blow down, and there is no empty swamp or ditch to blow into, a large sump is a necessity. It should be always half full of cold water so as to cool down the incoming blow by mixture, and it should have a vent for the escape of the blowoff steam and a trap to prevent any of the steam from getting into the tile drain system of the works. Such a sump, of reinforced concrete, costing from $200 to $300, is shown in Fig. 2. It is absolutely effectual in performing the functions outlined above and has been used a great deal in various boiler-plant installations by the writer. The steam vent should not be less than 8 inches for 250-horsepower boilers, blown one at a time, as, at that, the pressure developed in the sump is three or four pounds per square inch. If the sump is buried near the economizers, the best lead for the vent is up into the neck between the economizers and the chimney, so that the waste steam goes up the chimney.

Structural Features

The roof truss, of the Warren girder type, is rather light for hanging heavy piping subject to waterhammer shocks, heavy pipe galleries, etc. The writer would have preferred the Pratt-Howe truss, with diagonals in tension all the way across, and reversed at the gusset taking the pipe hangers, but accepted the truss shown in deference to the fetish for "standardization" which possessed the works management. The roof construction is also standard for this works, consisting of I-beam purlins spaced about 5 feet, so that notched 2x4-inch hemlock joists could be laid in between the purlins and give support for a flat board centering. The reinforcement of ½-inch rods is laid both ways across the upper flanges of the I-beam purlins. Then the concrete roof is poured 4 inches deep and finished with an asphalt and gravel roofing. In two weeks the centering can be struck by simply knocking the joists out from the lower flanges of the I-beam. All of it can be used over again.

The hight of the bottom of the roof I-beams of the coal-bin monitor should be 22 feet above the top of track rails on the coal trestle. This hight is needed, especially in smaller plants, for the way train in collecting empties often backs a box car up the trestle. As the runway of this car will be 13 feet 6 inches, all of 7 feet is needed above for clearance. The total hight will thus be 35 feet from the floor. As the roof trusses over the boilers need not be over 22 feet from floor to bottom of truss chords, and the trusses will be about 5 feet 6 inches deep, there will be 7 feet of monitor window space available, lighting both bin and firing alleys, and also obviating the necessity of skylights. These latter are always more or less of a nuisance, but the broad band of vertical sashes along the monitor will give ample light and need never leak down on the firemen below. If every third sash is replaced with a louver, as was done in this house, good ventilation is obtained for locomotive smoke, ash, dust, etc. The walls are of red brick, laid up with red mortar, with 24x16-inch pilasters and panels of 12-inch red brick. The window sills, lintels, water table and copings are of reinforced concrete, smooth finished, and the economizer* houses and fan house were worked up in the same architectural construction.

Electrical Lighting

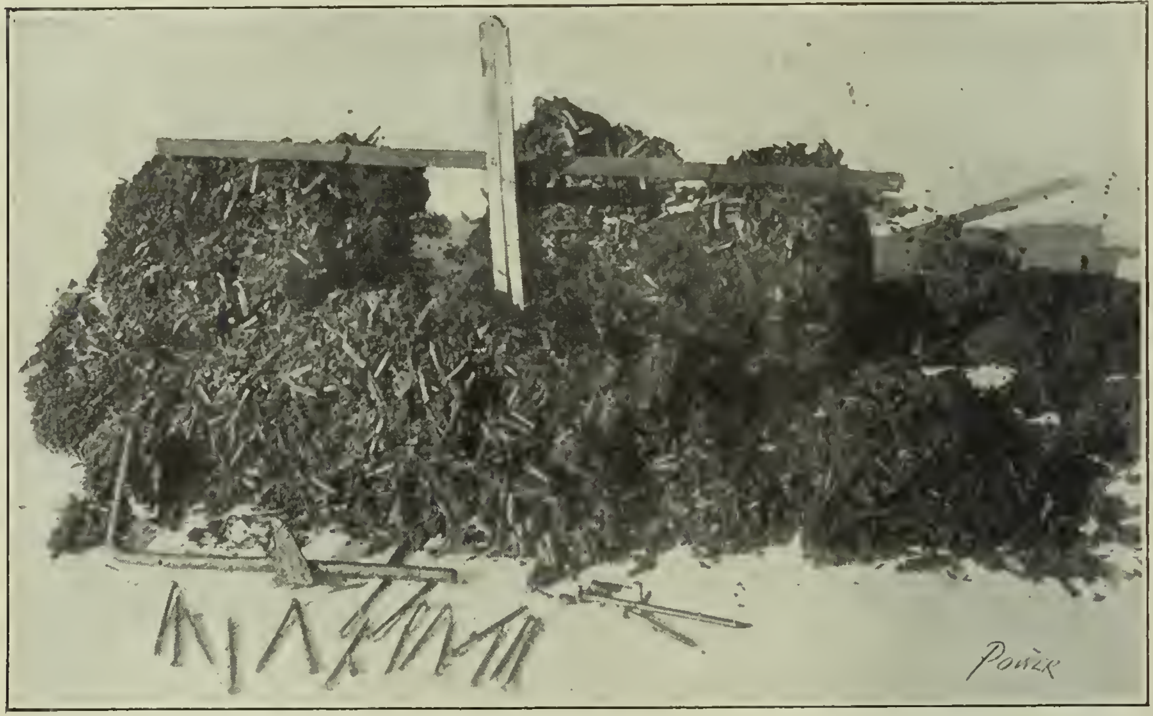
The lighting takes 60 amperes with metallic-filament lamps. There is a row of Harter slag-glass four-light clusters with enameled-steel shades, ½-inch conduit stems, 3-inch black iron canopies and sheet-iron outlet boxes with canopy covers. The clusters hang in the center of the firing alleys from the bottom chord of each roof truss. They are connected by ¾-inch galvaduct conduit, running along on forged hook clamps on the bottom flanges of the purlins just above, and a ¾-inch condulet tee gives outlet at each truss. Each alley has two circuits each way from the center, alternate clusters being in each circuit. The whole is controlled by a two-wire, eight-circuit ironclad switch and cut-out box. There is also a separate circuit of four lamps in each rear alley, so that this subway will not be in Stygian darkness all night, and also to give connections for portables when cleaning out and scaling boilers. Along the pipe gallery runs a third circuit with a lamp at each water column, lighting water gage, steam gage and try cocks. All of these lamps were originally tungsten filament, taking a total of 30 amperes, but they all perished in a short time, in spite of their stable position, and were replaced by the more durable metallic filaments.

*See Power, July 27, 1909.

Junk Shuts Down Large Pumping Engine

By R. C. Turner

The half bushel of iron borings, rods, nails and other junk shown in the accompanying photograph were found riding on top of the piston in the low-pressure cylinder of the large triple-compound vertical pumping engine installed in the water works at Atlanta, Ga. The cylinders are 36, 64 and 90 inches in diameter, and when running condensing the pump has a capacity of 20,000,000 gallons in 24 hours.



Fifty-nine Pounds of Junk Taken from Low-pressure Cylinder

The machine has been in commission about six months but has been in operation only about half of the time. On December 1, the head on the intermediate cylinder cracked in three places and had to be replaced by the manufacturers. After this repair was made, the pump operated for about ten days when valve trouble developed on the low-pressure cylinder. The steam valves are of the poppet type and are located in the heads. After opening up this cylinder one of the valves was found to be stuck and the stem badly bent.

It is supposed that the ports in the head of the intermediate cylinder had not been blown out properly when the casting was made, and that most of the junk came from this source. It is indeed surprising that the pump continued to operate as long as it did.

Increasing the Capacity of Boilers

By H. R. Callaway

> *To meet the demand for boiler units of greater capacity it is suggested that the output of a horizontal water-tube boiler may be increased to approximately 300 per cent. by increasing the length of the first pass, and providing a large combustion chamber, with sufficient draft to enable a thick enough fire to be carried.*

Among the many factors to be considered in the design of a central station is the provision for as large a capacity as possible per square foot of ground area. This is particularly important when the station is to be located in a large city where ground values and taxes are high.

In the engine room great economy has been effected by the development of the steam turbine. Although the point most often advocated in its favor is its economy of steam consumption as compared to the reciprocating engine, the turbine's superiority is much more marked in the matter of space saving. Unfortunately, as yet there has been no parallel development for the boiler house, and if economy of space is to be attained in this part of the power plant, it must be accomplished with the present boiler equipment. To this end a great many plants have been designed with the boilers arranged in two and even three tiers, but it is impossible to go any further in this direction.

In view of these facts, it is evident that the logical way in which to increase a station's capacity is by forcing the boilers to handle much greater overloads than have yet been attempted. In some cases as high as 200 per cent. of rating has been developed with water-tube boilers operated by mechanical stokers and with forced draft, but with the present design such a rating cannot be attained in everyday operation.

In looking over the field of boiler equipment with this purpose in view, natural-draft outfits of all descriptions and also hand-fired boilers are at once eliminated. The possibility of forcing a boiler to 250 or 300 per cent. of rating with natural draft or with hand firing is remote. The amount of coal burned per square foot of grate for, say, 300 per cent. of rating, would probably amount to between 100 and 125 pounds per hour, and obviously no fireman could handle any such amount as this. Even if coal could be shoveled fast enough, it would be necessary to open the doors frequently, with a corresponding loss of efficiency through the introduction of cold air. Furthermore, in order to obtain a rate of combustion as rapid as this, it would be necessary to carry a very thick fire, and no chimney could furnish sufficient draft to burn coal at this rate unless the flue temperatures were very high, in which case the efficiency of the unit would be low and the object of forcing the boilers would be defeated. Therefore, in order to maintain such a high rate of combustion, forced draft and some method of mechanical stoking are essential.

As already mentioned, as high as 200 per cent. of rating has been obtained with ordinary settings. In certain tests in which this figure was reached a 650-horsepower Babcock & Wilcox boiler was fired by a gravity underfeed stoker with forced draft. Although the boiler was designed to deliver 650 horsepower, the baffling and combustion chamber being proportioned for this load, a rating of 1200 horsepower was reached with only a small drop in over-all efficiency. A set of curves plotted from these results show conclusively that a much higher rate could have been attained if the combustion chamber had afforded sufficient space in which to completely burn the hydrocarbons. There seems to be little doubt that the stoker could have been operated at a much higher rate with very little, if any, drop in the efficiency, but the boiler was undoubtedly taxed to its limit and the conclusion seems to be that alterations in boiler design would enable the same unit to be forced to an even greater extent. In the unit under consideration the length of the first pass along the bottom tubes was 7½ feet out of a total length of 18 feet of tube. It might be practicable to increase this length to 9 feet, thus obtaining a 20 per cent. greater area of cross-section for the first pass.

In order to provide a larger combustion chamber the boiler might be raised two feet higher, which, in this case, would have given a 40 per cent. volumetric increase to the furnace. At 1000 horsepower the velocity of the gases through the tubes, although varying to some extent at different points, approximated 24 feet per second throughout. At double this horsepower, which would correspond to slightly more than 300 per cent. of rating with the same proportions of air and coal burned, and assuming that the efficiency remained nearly constant, the velocity of the gases would be about double, or 48 feet per second. If, however, the area of the first pass were increased as previously mentioned, this figure would be cut 20 per cent., giving a velocity at the entrance to the first pass of 40 feet per second. The second and third passes would of necessity be decreased in size, thus tending to produce a greater velocity in this section of the boiler; but, on the other hand, it has been well demonstrated that an increase of velocity of the gases is productive of an increased rate of heat transfer through the boiler tubes, in which case the gases would be cooled at a higher rate and their volume correspondingly diminished. Accordingly, the velocity at the back end of the boiler would probably drop to nearly the same rate as that obtained in the first pass.

Assuming that the increased rate of heat transfer was not proportional to the increased velocity in the first pass, the effect would be to make the middle and upper tubes of the first pass do a greater proportion of the work of evaporation than is the case at present. It is well established that between 75 and 80 per cent. of the evaporation in water-tube boilers of this type takes place in the first pass, and it is probably true that one-half of this amount is contributed by the two lower rows of tubes. In view of this, an increase in temperature in the upper part of the first pass would surely result in the upper tubes of the first pass and all the tubes in the second and third passes doing more nearly their proper share of the evaporation. If the velocity of the gases were greatly increased, as would probably be the case throughout the boiler, and the heat transfer increased, at least to some degree, it is scarcely likely that the flue temperature would be raised enough to seriously affect the efficiency of the unit. The increased velocity and greater volume of gas would increase the resistance offered by the tubes but this could be taken care of by a stronger draft.

In order to evaporate water at such a rate and consequently burn coal so rapidly, the fuel bed would probably have to be between 4 and 6 feet thick, which would make it necessary to have a greatly increased draft in any case. A fuel bed 3 feet thick has been successfully carried by the type of stoker used in the tests referred to with a draft of from 2 to 3 inches and there is no reason to doubt that one considerably thicker could be maintained. It would require experiment to determine with any degree of accuracy how great a draft would be required, but probably 8 to 10 inches of water would answer.

In Professor Nicolson's researches on heat transfer with increased velocity of the gases, he advocates draft-gage pressures of 20 inches of water, but these would be utterly impracticable as it would be impossible to keep the coal on the grates with such a heavy pressure. In the tests mentioned it was found that while the temperature of the combustion chamber varied very little under different load conditions, the temperature at the middle of the first pass varied, roughly, 200 degrees between normal rating and 100 per cent. overload. As this rise in temperature at the middle of the first pass was proportional to the rise in load throughout the test, it is reasonable to assume that the same law would hold up to 300 per cent. of rating. In this case, the temperature at the middle of the first pass would be 400 degrees higher than when the boiler was operated at 650 horsepower. This added temperature would make it necesary for the upper part of the first pass to do considerably more work, and it is scarcely probable that the temperature in the second pass would be much higher than under normal conditions.

It seems, on the whole, quite feasible to so arrange a boiler that it will absorb economically the heat evolved from coal burned at such a high rate. Then the problem would be to burn the coal with a good enough economy to make this excessive overload worth while. The impossibility of doing this with hand firing is obvious, and the stoker which will accomplish the desired result must not only furnish the coal at this tremendous rate but must also coke it thoroughly before it becomes ignited, in order that the hydrocarbons and other volatiles may be distilled off and pass through the zone of maximum heat in order to be completely consumed. Otherwise, smoke will result and with it a loss of efficiency.

The necessarily intermittent operation of hand cleaning with its checking of the fire could not be permitted, so the stoker, to meet these conditions, must be of the self-cleaning type and the ashes must be removed without the admission of cold air. As the whole object of the scheme herein outlined is rapid and continuous operation, the importance of automatic cleaning of the stoker grates is evident.

The phase of this problem, which is not only the most difficult but also the most important aside from the stoker design itself, is that of securing the proper proportions of air and coal. As the amount of coal fired per hour is increased, the amount of air should be automatically controlled in such a way as to increase proportionately; that is, if the allowable amount of excess air has been determined upon for the coal used, it should be possible to so arrange the mechanism of the stoker that this ratio of excess air is maintained constant regardless of the load conditions. This is a problem the solution of which has not heretofore been reached for these extreme conditions because such overloads as those considered have not been tried.

Design of Steam Power Plants

By William F. Fischer

Factors to be considered when designing a power plant, including the selection of a site, the construction of foundations and building and utility of general layout.

Location of Plant

After the available capital has been determined, one of the first questions to be decided is the location of the plant; this depends upon several factors. In order to avoid danger from floods, the plant should be located at a suitable elevation above high-water level. The ground should be nearly level with ample room for future extension, coal storage, outbuildings, etc.; and as all extra blasting, piling and concrete-foundation work involve a considerable expense a site is desirable where excavations can be made readily at minimum cost. Where firm hard-pan, clay, gravel or rock is found within a few feet of the surface and where only slight grading is required, the cost of foundation work may be kept within a reasonable figure. Piling on soft or marshy ground is necessarily expensive, and causes more or less anxiety as to the security of the structure.

There should be an abundant and never failing water supply for boiler feed and condensing purposes, and this water, especially that for boiler feeding, should be pure and, if possible, free of cost, except for pumping. A water-side location is preferable, with a pumping head not over 18 to 20 feet.

The fuel supply must be absolutely reliable and should be delivered to the premises, at the lowest rates attainable by rail or boat, in order to prevent the additional expense of carting. In certain sections of the country it is not well to depend altogether upon river transportation, as there may be seasons when the river is either too low or too swollen, making navigation difficult or impossible. It is well to make arrangements, if possible, with the nearest railroad to run a spur to the plant or, better still, the plant may be located near both a railroad and a waterway.

Sufficient storage capacity is essential so that a full supply of fuel may be procured during the season of lowest prices. By this practice much money may be saved. As an extra precaution this storage capacity should be sufficient for the winter load or to carry over a period of any long strike that may occur at the coal mines or on the transportation lines.

The cost of removing ashes from the plant, whether by rail, water or cart, is another factor to be considered.

An important factor governing the location of the plant is the ease with which power may be transmitted from the generating source to the point of demand. In the case of electric-light and street-railway plants, the most desirable location is, undoubtedly, the electrical center of the entire district to which power and light is supplied, providing the location is convenient in the other respects heretofore mentioned.

Another point to be considered is the fire risk. In this connection the surroundings should be investigated with a view to ascertaining the liability of fire from adjacent buildings.

Type of Plant

If there is a probability of the plant being enlarged in the future, the best arrangement is to place the engines and boilers back to back in parallel rows with a division wall between, separating the engine and boiler rooms. With this arrangement the steam piping is direct and the main steam header may be made comparatively small and be divided into units by placing valves at proper intervals. Then part of the header can be shut off whenever necessary without interfering with the successful operation of the station. Where the engine and boiler rooms are placed end to end the steam main may be inadequate if additional engines are added at one end and additional boilers at the other. Also, to accommodate the additional units the plant must be extended in both directions, thus greatly increasing the cost.

As a rule, the boiler-room floor is on a level with the outside ground, and the engine-room floor, especially where large engines are used, is usually from 6 to 10 feet above the boiler-room floor, with a basement beneath it. Where the engine-room floor is on a level with the outside ground, it is necessary, where no basement is provided, to build a pit for the condenser and construct pipe trenches for the exhaust steam and circulating-water pipes. Where large engines are employed it may be necessary to construct a pit for each flywheel. Such pits, however, ought to be avoided wherever possible, as the vibrations of the engines tend to cause the concrete lining to crack and allow water to enter the pit. Pipe trenches should also be avoided, for the pipes are not as accessible as when suspended from overhead beams in the engine-room basement.

In large plants a basement is usually provided under the boiler room for the accommodation of pumps, blowers, air ducts, etc. The boilers in such cases are usually equipped with ash spouts, leading to the basement where the ashes are emptied directly into ash cars or conveyers.

Where land is cheap, very little consideration is given to compact arrangements, but where land is expensive, it is sometimes necessary to place the boilers on two or more floors, one above the other. An example of this kind may be seen at the Metropolitan street-railway power station at Ninety-sixth street and East river, New York City, where the boilers are placed on three floors, one above the other.

The Building

The building should preferably be of fireproof construction, the walls being of brick, concrete or stone, and the interior faces finished smooth or painted. The finished wall may be painted or calcimined with cold-water paint, although in some large stations glazed tile is used.

No wooden ceiling or sheathing should be permitted in power-plant construction. However, brick walls with steel trusses supporting a wooden roof covered with tar and gravel, or with some fireproof material, is the practice in many of the smaller stations. Metal roofings should be avoided as they entail a cost for painting and maintenance not incurred with a slate, tile or concrete roof; but in all cases a tile roof laid in cement or concrete is to be preferred.

In the smaller stations the roof trusses and tracks for traveling cranes are frequently carried directly by the brick walls of the building, but in the larger stations these are always supported by steel columns resting on their own foundations, the walls carrying only their own weight. Concrete floors with a granolithic finish are usually laid around the engine foundations and vitrified brick laid in a bed of concrete is very durable for boiler-room floors on to which hot cinders are frequently raked from the ashpits.

In all cases it is preferable to separate the engine and boiler rooms by a division fire wall. Doors in this wall should be of the self-closing "underwriters' pattern," hung on sloping tracks or hangers. Doors of this type may be placed on one side of each door opening (preferably the boiler-room side), and held open by fusible links, which melt or fuse at a certain temperature. All windows exposed to fire from without should be protected by suitable fireproof shutters. Fire hydrants should be provided at suitable points, both outside and inside the building, with adequate lengths of hose in accessible places and connected at each hydrant ready for immediate use.

The building should be designed to conform to the equipment and in no case ought the mechanical layout to be cramped to suit the building conditions, unless absolutely necessary. Utility is the primary consideration in power-plant design and architectural features secondary. In designing a power plant care must be taken to provide one or more doors of sufficient size to admit the largest piece of machinery, or the largest part of a machine; otherwise it may be impossible to get the machinery in and out of the building.

Ample space is essential around all engines, pumps and similar machinery so that the pistons may be removed without moving the machines from their foundations. A clear space of sufficient width to remove the tubes is necessary in front of each boiler. Where it is absolutely necessary to economize in space in front of the boilers, large windows may be placed in the wall, one in front of each boiler, and of such size as to permit the removal of the tubes. A space 4 to 6 feet wide should be allowed between the backs of the boilers and the nearest wall. This space is necessary in order to get at the blowoff piping and the cleanout doors.

If economizers are to be installed, sufficient space must be provided for their operation, cleaning, repairs, etc. Sometimes, however, separate housings are provided for economizers.

To avoid mistakes, the building plans and specifications should not be completed until all the important points of the mechanical layout are decided upon and approved by the owner or engineer in charge of the work.

Foundations

With but a few exceptions all soils become compressed under the weight of a building, and allow the building to settle a certain amount. Therefore, the main object is not to prevent settling entirely, but to insure its being uniform.

As many soils, such as sand, gravel and clay, may vary greatly within a comparatively small area, it is well to determine its character and bearing power at several different points by borings or excavations. The building code of New York City specifies the following as the maximum permissible loads per square foot for different soils: Soft clay, one ton; ordinary clay and sand together, in wet and springy layers, two tons; loam, clay or fine sand, firm and dry, three tons; firm, coarse sand, stiff gravel or hard clay, four tons, or as otherwise determined by the commissioner of buildings.

Sand, if confined or kept from spreading, will support safely a considerable load, as shown by an experiment made some time ago in France, where clean river sand which was tamped in a trench and kept from spreading supported safely 100 tons per square foot.

When proportioning the foundations in power-plant work, several practical considerations must be taken into account. For example, the allowable pressure on the soil per square foot of area is considerably less for tall chimneys and similar high structures than for low massive structures; for, in the former case, any slight inequality of bearing power and consequent unequal settling might endanger the stability of the structure, while in the latter case no serious harm would result.

All machinery foundations should be constructed absolutely independent of the walls of the building; but where two or more foundations for individual units are within a short distance of one another, they may be bonded together, in which case the combined mass and increased area will render them more capable of withstanding greater strains. If loose rock is found when excavating, it should be removed, and all solid rock, unless absolutely level, should be dressed off in steps with vertical risers and horizontal treads so that the pressure will be exerted everywhere in a vertical direction. Solid rock may support almost any load likely to be imposed upon it, but care should be taken in order that the load per square foot of surface does not exceed one-eighth of the crushing strength of the rock.

Where the soil is of a yielding nature, piling or grillage must be used to support the foundations. Spread foundations of reinforced concrete are frequently used in place of piling where the foundations are spread over a large area, but where the ground is very soft and marshy, piles should always be driven to support the foundations. The durability of piles in ground constantly saturated with water is beyond question, as piles have been found in a perfectly sound condition after the lapse of many centuries. All piles should be driven to rock or hard-pan, or to an even bearing until capable of supporting the loads imposed upon them.

In modern construction, the ground is excavated between the heads of the piles to a depth of one or more feet and the piles capped with a bed of concrete. Steel reinforcing rods may be embedded in the concrete if it is thought necessary to increase the strength of the concrete foundations.

All holes for the foundation bolts should be accurately located by template, leaving sufficient space around the bolts for a slight variation in the location of the machinery. After the machinery is set in place, the space around the bolts may be filled with a cement grouting.

Gas Power Department

Everything worth while in the gas engine and producer industry will be treated here in a way that can be of use to practical men

The New Ajax Engine

The new Ajax gas engine, illustrated herewith, represents a combination of progressive ideas in design and construction derived from long experience in this class of work. The entire Ajax line* has been redesigned and the scope extended to include tandem construction, as indicated in Fig. 1.

The longitudinal and cross-sections, Figs. 2 and 3, show the constructional details of the frame, cylinders and valves fairly well. The front cylinder is fitted to the frame with a liberal flange and neck and is supported on a pedestal which is free to slide on the sole plate. As the front piston serves as a crosshead, it is made longer than the rear piston and the cylinder is also extended forward to provide a correspondingly long bearing surface. The rear cylinder is exactly like the front one except for this forward extension, and the valve cages of the two cylinders are therefore interchangeable. Consequently, in case of any accident which might disable one of the rear valves, the corresponding valve and cage on the front cylinder could be transferred to the rear one and the engine operated with the front cylinder cut out. Or, if spare parts are carried in stock, one valve and cage will fit either cylinder. The damaging of a valve cage is a very remote possibility, but the feature of interchangeability is much like the Texan's gun during the period of regeneration—useless most of the time but more precious than a diamond mine when the occasion did arise.

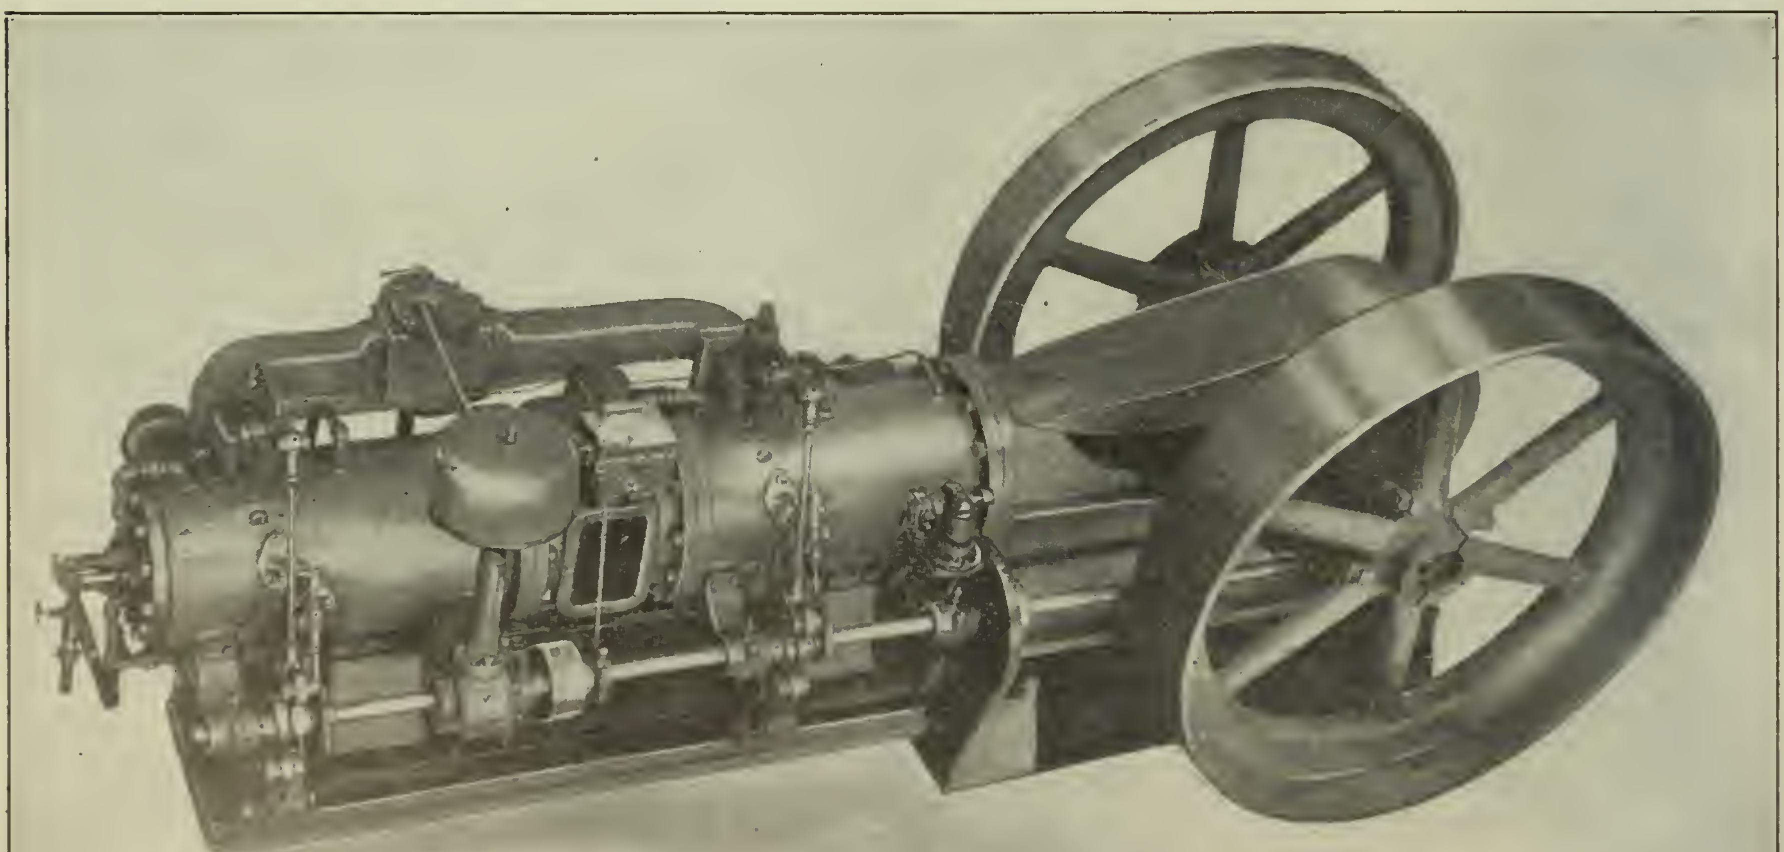


Fig. 1. Tandem Single-acting Ajax Engine; New Type

The rear cylinder is mounted on a pedestal exactly like the front one. The distance barrel between the two cylinders is made with openings large enough to allow the stuffing box in the front cylinder head to be removed without disturbing the general structure. The distance barrel is split lengthwise and attached to the cylinders by bolts (instead of studs and nuts; consequently, it can be taken out entirely, giving access to the rear piston and cylinder and allowing the head of the front cylinder to be removed, without disturbing any of the pipe connections or cam-shaft mountings.

The piston-rod stuffing box is split lengthwise into two equal parts and held together, independently of the pocket in the cylinder head, by transverse fillister-head screws. Fig. 4 illustrates this construction. The half box at the left is

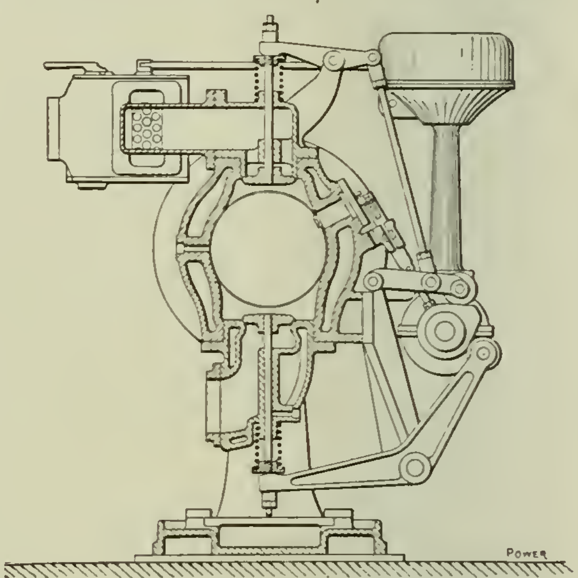

Fig. 2. Cross-section of Ajax Engine

shown with the rings in position. These are of rather unusual construction. Each main ring is made with a circular recess around one edge and a small ring of square cross-section fits into this recess, the two forming a compound ring. Both the inner and outer members are cut into three equal pieces after being turned to size, and the inner ring is doweled in

*Built by the Ajax Iron Works, Corry, Penn.

its recess in such a position that the three cuts in it do not come in line with those in the outer ring. A coil spring around the outside of the outer ring clamps the parts around the piston rod.

The construction of the piston and rod is shown in Fig. 5. The ends of the rod are turned down to form long necks, which are threaded at the ends, and the shoulder where the diameters change is beveled to 45 degrees. This bevel fits a 45-degree seat at the mouth of the hole in the front piston and in a flange which is bolted to the rear piston; this flange, or cap, is shown separately at *F*. The rod and flange are held together by a heavy nut which is held in place by a set screw, and the rod is held snugly in its seat in the front piston by a similar nut. This construction, it will be noted, relieves the screw threads of all stresses due to the working pressures; the only work the threads have to do is to pull the rear piston forward idly during the suction strokes—the beveled shoulders take the thrusts of explosion and compression.

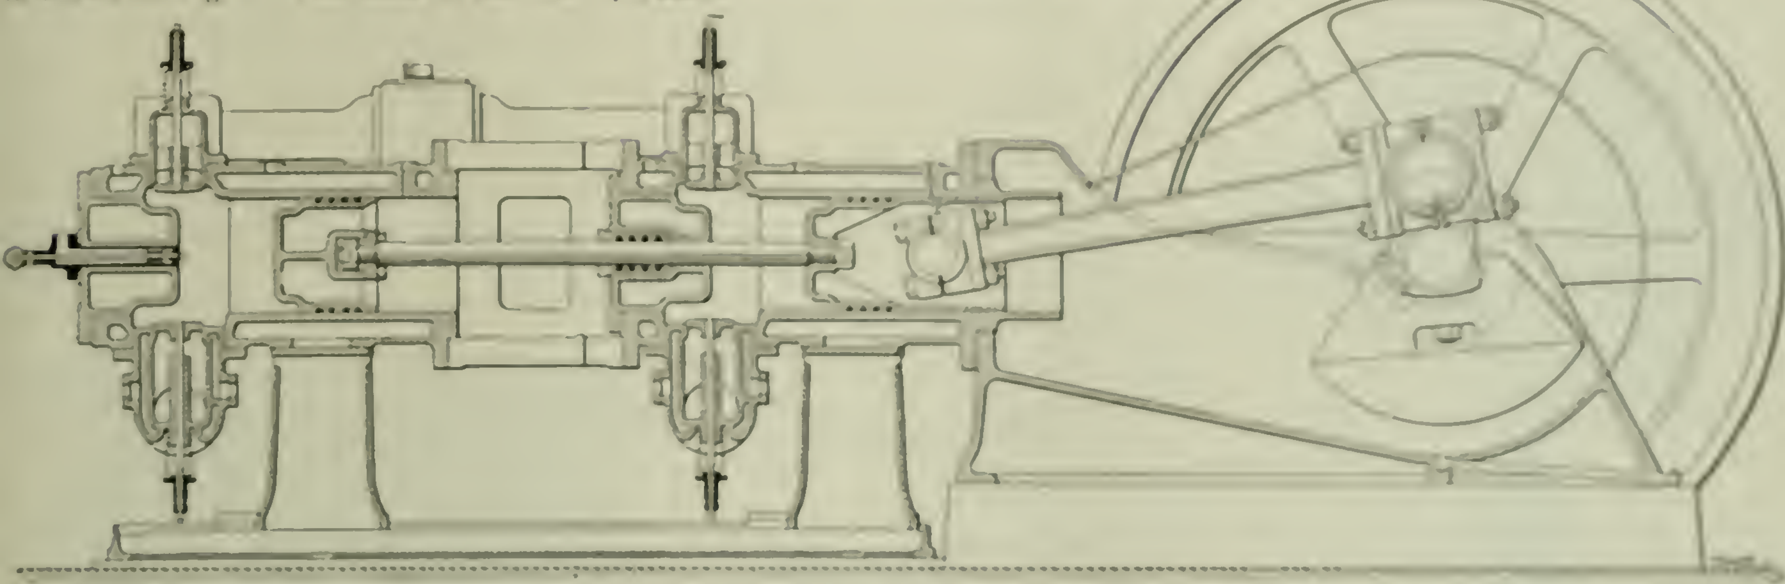

Fig. 3. Longitudinal Section of Ajax Tandem Engine

The connecting-rod construction is so clearly shown in Fig. 3 that description is unnecessary. A practical feature of the crank-pin box is that the two parts are exactly alike and therefore interchangeable. The balancing weights of the crank are fastened to the ends of the crank cheeks by massive studs and nuts, and the nuts are housed in a little pocket in the weight, as shown in Fig. 3.

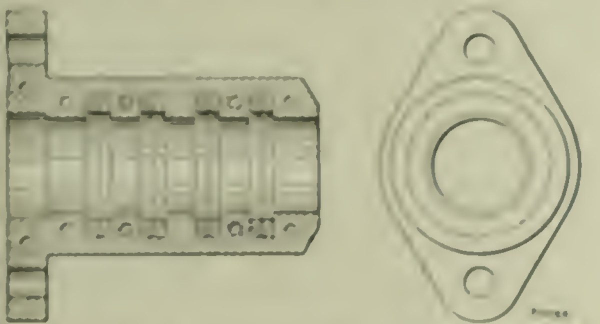

Fig. 4. Piston-rod Packing

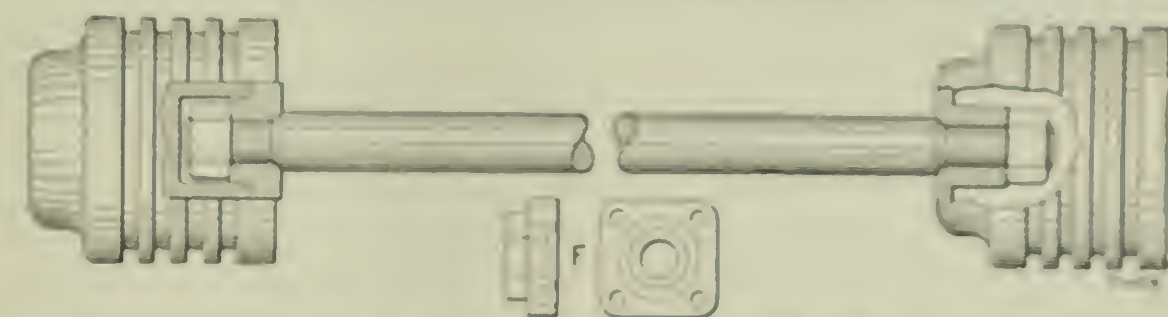

Fig. 5. Ajax Pistons and Piston Rod

The valves are of the ordinary poppet type, with the heads slightly crowned. They are opened by the usual arrangement of cams, rollers, push rod and rocker arms. The exhaust-valve cage is water-jacketed very thoroughly, as Figs. 2 and 3 show, and the walls are of uniform thickness at all points. Fig. 6 shows the inlet and exhaust valve cages, complete with valves and springs. The mixing chamber is located midway between the inlet valves of the front and rear cylinders, as may be seen in Fig. 1, and contains a combined mixing and throttling valve which is controlled by the governor. This valve is of the multiported cylindrical form and is oscillated by the governor to vary the port openings according to the load demands. A plug cock in the gas entrance to the mixing box is adjusted by means of a handle to get the proper proportion of gas to air.

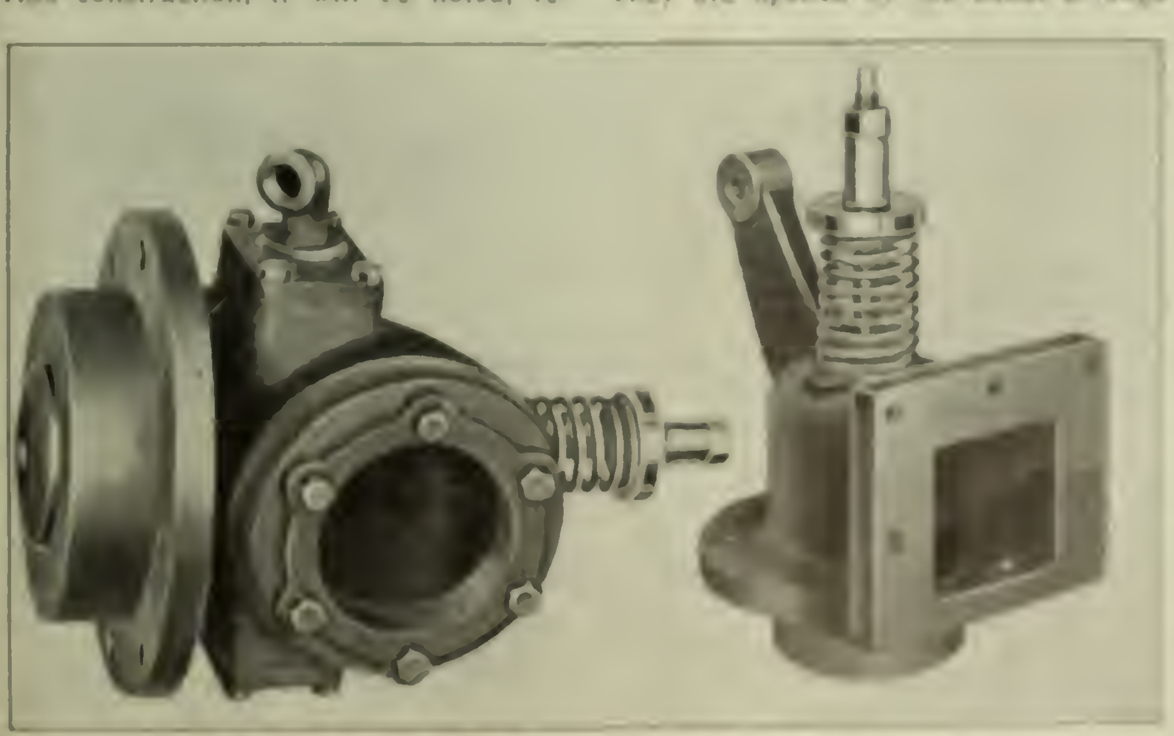

Fig. 6. Exhaust and Inlet-valve Cages and Valves

The governor, Fig. 7, is a modification of the Hartung type and is provided with a thumb-screw adjustment by means of which the speed can be changed while the engine is running. It is gear driven from the cam shaft.

Make-and-break igniters are used and they are of the simple mechanical type, tripped by cams and push rods. Current for the igniters is supplied by a magneto generator, which is mounted on a bracket on the side of the forward cylinder and is belt driven by a pulley on the cam shaft; this arrangement is shown in Fig. 1.

The main features of the engine which reflect care and forethought on the part of the designer are these: The engine frame, which is of the double-wall box type, is provided with an oil groove all around the bottom edge to catch waste oil from the various bearings; the water jacket of the exhaust-valve cage is so constructed that the cooling water enters near the bottom on one side and must

FIG. 7. THE GOVERNOR

pass upward to the top of the valve before it can get out; all wearing parts of the governor run in an oil bath; the mixing and throttling valve is mounted on ball bearings and copious lubrication is provided between the periphery of the valve and the wall of its cage; the cam shaft is divided into sections, coupled together at points corresponding to divisions in the main structure; all of the moving parts are on one side of the engine and all of the piping is on the other side; all

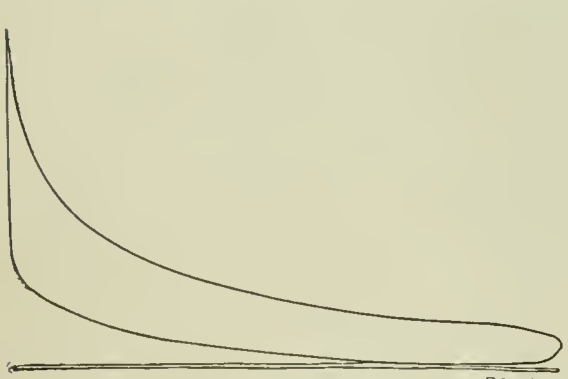

FIG. 8. AN AVERAGE DIAGRAM. SCALE 275 POUNDS AS PRINTED

cams, rollers and pins are hardened; every pair of rubbing surfaces is lubricated, including pivot pins and rocker hubs; the proper settings of the ignition timer and the gas cock for starting and running are marked plainly on those parts; an auxiliary safety attachment on the governor will cut out the ignition current if the speed should go beyond the maximum advisable rate; either cylinder can be cut out of action while the engine is running, leaving the other cylinder to do all the work. This last-named feature is of more value than it might appear upon first thought. In places where an engine has to carry less than half load for a considerable part of the day, cutting out one cylinder during that part of the run effects a very important saving of fuel.

The indicator diagrams, Figs. 8 and 9, are representative of the performance of the engine; they were selected by the writer from a large number of diagrams in preference to some which were more symmetrical but which did not truly represent average performance, as these do.

The engines are built in single-cylinder form for small outputs, single tandem form for medium sizes and twin tandem for the larger outputs.

A Narrow Escape from Gas Poisoning

According to a New York daily newspaper, the night engineer of the Newton (N. J.) Gas and Electric Power Company recently had a narrow escape from death by gas poisoning. The story is to the effect that the engineer, who was alone in the power house, was taking a reading of the gas pressure in the main when he felt the sudden dizziness and weakness in the knees and back which indicate dangerous poisoning by carbon-monoxide gas. Realizing what these symptoms meant, he managed to crawl to the telephone, call up the day engineer and gasp "Help" in the telephone, before he lost his senses.

The day engineer, fortunately, recognized the voice and after getting into as few clothes as he could venture out of doors in he rushed over to the station. He found the night engineer unconscious

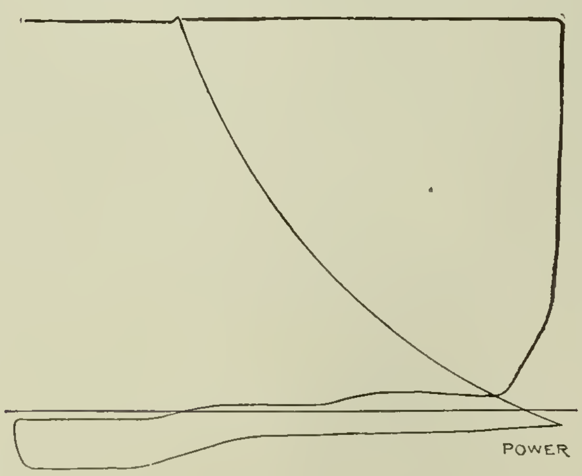

FIG. 9. AN AVERAGE STOP DIAGRAM. SCALE 13.6 POUNDS AS PRINTED

near the telephone, dragged him out into the fresh air and summoned a physician to attend him. Then he had the gas shut off the main that supplies the power house.

After two hours of hard work, the doctor succeeded in reviving the night engineer, and he has entirely recovered from the effects of the poisoning.

LETTERS

Sounds in Gas Engines

A knock in a gas or gasolene engine is often extremely hard to locate, as the same sound can be generated in several ways. A loose flywheel is sometimes responsible; yet it may be that the ignition is advanced too far, or there is pre-ignition from incandescent carbon, short-circuits or an overheated engine due to derangement of the cooling system. Lack of lubrication or using the wrong oil will cause a knock, but it is not such a distinctive sound as something loose or broken. Too rich a mixture or water in the combustion chamber will often cause uneven running which produces a sound that slightly resembles a knock.

Worn bearings will frequently cause an engine to pound in a most alarming way. Care should be taken not to set up a badly worn bearing too much; there is danger of throwing the whole shaft out of line and ruining the remaining bearings.

Sometimes when the compression is not uniform in all the cylinders of a multicylinder engine it appears to have a slight knock while in reality it has not; the cylinders with the better compression give stronger power strokes than the weaker ones, and this causes irregular running which is usually attributed to loose parts.

Hissing sounds are mostly due to loose igniters, loose or broken spark plugs, a cracked exhaust pipe, looseness in the exhaust manifold, open compression-relief cocks or worn gaskets.

The correct amount of good oil in the cylinders and bearings and plenty of hard grease or graphite paste in the gears and on other rubbing parts will prevent wear and the resultant noises.

A. L. BRENNAN, JR.

New York.

The largest installation of Diesel engines yet ordered is that which is being built by Franco Tosi, of Legnano, Italy, engineer, and he has entirely recovered. for the city of Rome. The order comprises two Diesel engines of 1000 horsepower each, and three of 2000 horsepower each, to operate on the two-stroke cycle. The engines will run at 136 revolutions per minute and be direct connected to three-phase generators of 8200 volts. The contract includes the operation of the engines for ten years by the manufacturers. The plant will furnish electricity for the city, pending the development of the water power of the River Aniene, which will not be completed for a couple of years, and probably used as a standby after the completion of the hydraulic works.

Electrical Department

Especially conducted to be of interest and service to the men in charge of the electrical equipment

Through Fire and Water

Electrical apparatus is generally considered to be less rugged than some other classes of machinery, but the accompanying illustrations indicate that it can pass through severe ordeals without irreparable damage. The pictures are those of two Bullock motors taken from the ruins of the *Los Angeles Times* building. After the explosion and fire which recently destroyed the building these motors were removed from the basement where they were lying in five feet of water. The printing presses to which they were attached were completely destroyed and had no value except as scrap iron. The motors, however, were not badly damaged and were practically the only articles of value saved from the ruins. In the adjustment of losses made by the Fire Underwriters Association, 99 per cent. of the total insurance was allowed, the 1 per cent. saving being based almost entirely on the value of the motors. The insulation of the machines was destroyed, but the commutator bars and cores, brush holders, bearings and frames were in good condition.

SIXTY-HORSEPOWER DIRECT-CURRENT MOTOR AS IT CAME FROM RUINS

TEN-HORSEPOWER DIRECT-CURRENT MOTOR AS IT CAME FROM RUINS

The motors attracted considerable attention and excited much comment because of the fact that they were the only pieces of machinery saved from the ruins. The larger motor is a 60-horsepower, 500-volt machine, and the smaller one is a 10-horsepower machine. They are now being rewound in the shops of the manufacturer and will be used to drive new presses in the new building which is soon to be erected.

The Fan Motor in Winter

It is the popular opinion that the range of usefulness of the electric fan motor is limited to the summer months and that its sole utility lies in its application as a means of reducing the temperature of a room or an office. This is not true, however, and slowly but surely the public is beginning to understand that the usefulness of the fan motor is by no means confined to the hot days of summer, and that, paradoxical as it may seem, the electric fan blows hot or cold; and incidentally while it is blowing hot it cuts down the fuel bill. Following are a few of the more important applications of the fan motor to winter use:

The efficiency of the hot-air heating system may be greatly increased by placing a fan motor in the cold-air box to force the air through the registers to all parts of the house. On particularly cold days, when the wind is so strong that it forces the air through the furnace into the rooms without having become heated, a fan motor placed in the cold air box, after having closed the slide which permits air to come in from the outside and opening the slide which lets the air in from the cellar, will cause an appreciable rise in the temperature of the room, without making any increase in fuel consumption.

As is very often the case, the house contains one or more rooms which under certain conditions are difficult to heat. This difficulty can be overcome by placing a fan motor in front of the hot-air register, or over it in case the register is located in the floor. This plan will prove more efficient if the register and fan motor are covered by a box or hood of some kind which will cause the fan to draw air from the pipe only, and not from the room.

Another service to which the fan motor may be applied to advantage in winter is preventing the accumulation of frost on the show windows of stores. The air from the fan motor directed against the glass of the window will keep it practically free from frost. This application of the motor is a boon to merchants who have heretofore lost during cold weather practically all the advantage which their window display would have afforded them.—*G. E. Review.*

An Excessive Magnet Drag

By Richard Clemens

We have at our power plant a 200-kilowatt, direct-current, 250-volt Thompson-Ryan generator, direct connected to a 20x22 McEwen simple automatic engine, running at 180 revolutions per minute. This dynamo has 14 balancing field-magnet coils, with 14 other field coils, making 28 coils in all. When the dynamo was installed we had an experience which may interest some readers of POWER.

The installation of the plant being complete, we began an acceptance test of the engine and generator, using three large barrels filled with salt water as a rheostat to put the load on the generator. The engine was started, and everything seemed to be going very satisfactorily. The voltage stood at 250 with no load, and compounded to 270 as the load was increased up to 700 amperes. After running for an hour or little more, the water in the barrels began to foam and boil over, and in adjusting the terminals to reduce the load, an attendant accidentally short-circuited the generator, which knocked out the circuit-breaker. The engine regulated well, but when the breaker was reclosed the voltmeter showed only 200 volts.

Careful tests showed that the speed was normal, the brush yoke was in the proper position, the rheostat in the field circuit was undamaged and the connections were all sound. Then we began a systematic search for the trouble. We investigated the various connections around the machine, the connections the armature leads; in fact, everything but the right one. The magneto showed no grounds of any kind, or short-circuits. Finally, we tested the polarity of the entire twenty-eight field-magnet coils, not once but several times; but nothing was wrong with the polarity. For two days we kept this up, trying first one thing and then another. We called up the manufacturers, for they had a representative there to see the test, but their suggestions did not remedy the trouble.

On the following Sunday morning I got into communication with an old friend who had been on the road for years and, fortunately for us, he had had a similar experience. He advised us to take the machine apart and examine the dowel pin which holds the field coils in position. This pin is situated right at the bottom of the yoke ring and in order to get at it we had to remove the armature; sure enough we found the pin bent almost to a right angle. The heavy armature current due to the short-circuit when changing the terminals at the water rheostat had reacted on the field magnet with sufficient force to bend the pin and shift the position of the whole ring of coils. We replaced the bent pin with two of larger size, at the same time wedging each coil by placing a liner behind it. When the machine was put together again and driven at normal speed, the voltage went up to 250, and when the various loads were put on, the machine compounded perfectly.

CORRESPONDENCE

"Be Sure You're Right," etc.

The incident related in a recent issue of Power about the sweeper advising the engineer to pull the generator switch instead of using a brake on the engine flywheel reminds me of a somewhat similar scrape the other fellow got into once. In this plant, which is combined hydraulic and steam, we have a little trouble in pulling our peak load with water power alone, and in conjunction have a cross-compound condensing engine driving a 500-kilowatt generator and exciter to tide us over the rush. The main-drive pulley on the line shaft runs on a quill; so does the generator, both being connected by clutches to the main shaft. The exciter is belted direct to the main shaft.

One evening as the peak-load period was approaching, the engineer started the engine and coupled it to the main shaft, and this started the exciter. Overlooking the generator clutch, he went to the switchboard and put the exciter in parallel with the one already in service. Then he closed the generator-field switch, but with all the resistance cut out of the rheostat the voltmeter would not budge. Supposing that the fuses on the transformer were out of business, he proceeded to test them out, but found them all right. He pounded on the voltmeter with his fist until the glass cracked, but the hand still refused to move. By this time the load on the waterwheel had increased until the speed had dropped off so the lights began to get dim, but pulling his hair produced no useful results. The superintendent fortunately arrived on the scene about then and advised him to throw in the generator clutch.

Abe Fout.

Iowa City, Ia.

Identifying Alternating and Direct Current

Referring to H. Priestley's query on this subject, in the December 6 issue, I suggest that by attaching to the socket a plain carbon-filament bulb, turning the current on and holding one pole of a magnet close to the bulb, he can tell what kind of current is flowing in the circuit. The lamp filament will be attracted or repelled (according to which pole of the magnet is used) and will remain in the attracted or repelled position until the magnet is withdrawn, if the current be direct current; the filament loop will vibrate toward and away from the magnet if the current be alternating.

Another simple test, if no magnet is available, can be quickly made by screwing an attachment plug in the socket instead of a lamp and submerging the two terminals of the plug cord in salted water. If the current be direct, one of the terminals (the negative) will gas freely. A lamp should be connected in series with one conductor of the plug cord to prevent accidental short-circuiting.

There are in the market several inexpensive testing contrivances, but when these are not on hand just as positive results can be obtained by the methods described.

Alex. Dolphin.

Jamaica, N. Y.

There are several ways to determine whether the current in a lamp socket is direct or alternating. One way is to hold the poles of a horseshoe magnet close to the lamp bulb. If the current is direct, the filament will be drawn toward one of the magnet poles; with alternating current, the filament will vibrate between the two magnet poles. Another way is to wet a spot on a white pine board and stick the ends of two wires in the wet place about two inches apart, the wires being connected to a plug inserted in the lamp socket. If the board turns green around one of the wires, the current is direct and the wire producing the discoloration is positive in polarity. If there is no discoloration, the current is alternating.

If there are any arc lamps on the circuit it is easy to tell which kind of current is passing. Direct current will produce a blue tinge at the upper part of the arc and a pure white light below it. But this, of course, is not identifying the current at the lamp socket, as Mr. Priestley wishes to do.

An ordinary pocket compass also will indicate the character of the current. It is only necessary to place the compass on a wooden table or box, away from any large pieces of iron or steel, and hold a wire horizontally above the compass, parallel to the normal position of the needle. Direct current in the wire will deflect the needle to one side; alternating current will either cause it to quiver or have no visible effect on it—probably the latter. The wire can be one of two leads from the circuit to an incandescent lamp.

Spokane, Wash.

[The foregoing letters were received before the January 3 issue went to press, but not quite early enough to be printed with the other letters on this subject that were published in that issue.—Editor.]

Static Electricity around Printing Presses

Will some readers kindly suggest through this department of Power the most practical way to overcome the static electricity that causes so much bother around printing presses?

A. W. Fish.

Argos, Ind.

Some figures are given in the annual report of the electricity department of the Manchester Corporation which show the progress made in recent years toward cheapening the engines, boilers and other machinery and plant used in the generation of electricity. For example, the costs per kilowatt erected at Dickinson street, Bloom street and Stuart street stations are respectively $98, $84.50 and $85.50. Most of the machinery at Dickinson street is not that originally erected in 1894. On the basis of the old machinery the cost would have been much higher. A reason for the exceptionally low cost at Stuart street may be found in the two large turbines there, which are considerably cheaper than reciprocating generating sets. Stuart street has also the advantage of large units, which means economy both of capital outlay and fuel and operating costs. Thus the fuel cost per unit generated is 0.288 cent at Stuart street and 0.394 cent at the other two stations. The total operating costs, including repairs, but not capital charges, are respectively 0.428 and 0.690 cent. Distribution, management and capital costs must, of course, be added, the total cost per unit averaging 2.28 cents, and the revenue 2.52 cents. Excluding capital charges, the total cost amounts to 1.22 cents. —*The Engineer.*

Welded Steel Products

The tank shown in the accompanying illustration was made in Germany, and is used for the transportation of compressed Pintsch gas, used for lighting railroad coaches, the pressure carried ranging from 18 to 20 atmospheres. A riveted tank cannot be used for this work, as the constant racking and straining cause leaks which would be very serious in handling an inflammable gas. The tank is made of heavy plates with welded joints and the cost of manufacture is approximately the same as with riveted work, while the resulting product is infinitely superior. Welded work of this character is not a new product, but has been turned out in Europe for the last ten years, extremely complicated shapes being produced, while in the United States there is to my knowledge no concern able to produce work of this kind.

WELDED-STEEL TANK CAR

In Europe, plate welding has advanced to the stage where nothing is too difficult and it is used for the production of seamless cylinders and tanks of any practicable size. The water legs of boilers are readily produced; sulphite digesters, used in paper-pulp mills, of one-inch plate have been made 7 feet in diameter by 30 feet long, and larger. The bodies of buoys to be charged with compressed gas and which serve as floating beacons are another product of the plate-welding process, which is also used for producing corrugated fire boxes and boiler flues with the Galloway tubes welded in place. Steam headers and the military masts for warships, ornamental electric light and trolley poles, are other products, as are seamless tank cars for the transportation of fluids and the rotary kilns for cement mills.

In this country the welding of plates has been guarded as a secret process by the one boiler-making concern which uses this method of manufacture. The process has been closely guarded and the concern has been blindly asleep to the fact that an extension of the process was feasible to other parts of its boiler, and with the proper plant would cost them less than their present riveted work.

Besides, there is no real secret about the process they use.

Over ten years old, and nothing doing yet, in America.

Cleveland, O.

Reinforcing a Cracked Steam Cylinder

A rather novel repair of a transverse crack in the outside shell of a steam-jacketed, high-pressure cylinder of a vertical, triple-expansion pumping engine, working under 180 pounds steam pressure, and carrying this same pressure in the jacket, was carried out as follows:

In this case the heads were secured to the cylinder by means of studs tapped into the cylinder heads, and the problem was to tie the two heads together, with the cylinder between them without shutting down.

First wrought-iron bars of the same diameter as the studs were cut so that the combined length of any two of them was about an inch less than the distance between the projecting ends of a stud in the upper head and the one in line with it in the lower head. These were threaded as shown in the accompanying illustration.

Next some hexagonal iron pieces, of the same size as a United States standard nut for this size bolt, and a little more than twice as long as the hight of a standard nut were tapped to fit the studs and the bars. Finally turnbuckles were made of the same size hexagonal iron and tapped for right- and left-hand threads. Then, after screwing one bar into each end of the turnbuckle far enough to make the total length of the three pieces about equal to the distance between the ends of the studs, and screwing one of the hexagonal iron pieces onto the other end of the bars until the ends came flush with the hexagonal iron pieces, the whole was put in place and the hexagonal iron pieces screwed onto the studs, thereby partly unscrewing them from the bars. This had the same effect as the gaskets as the original ones had. Finally, by turning the turnbuckle, the desired strengthening effect was obtained and the cylinder has not given any trouble since.

METHOD OF STRENGTHENING CRACKED CYLINDER

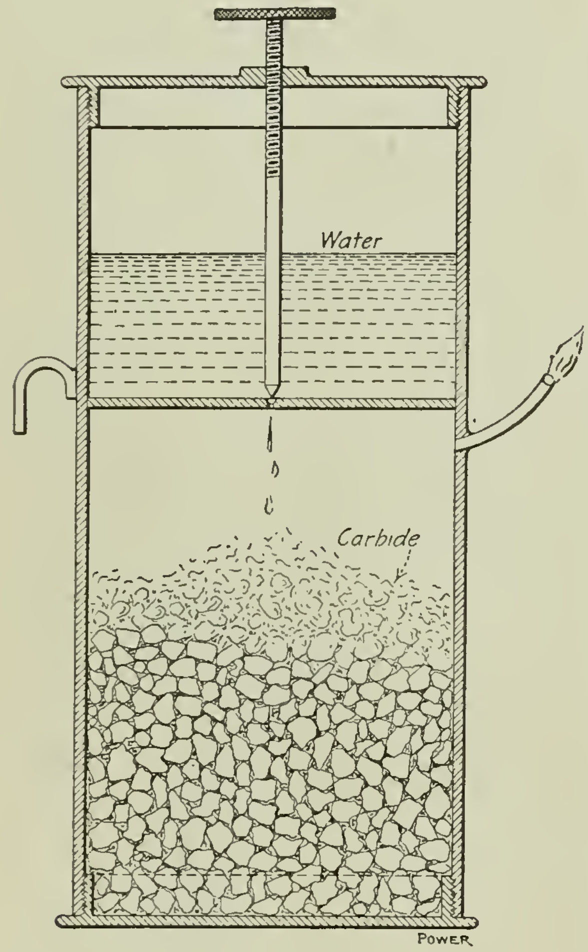
Acetylene Gas Lamp

The accompanying sketch represents a cross-section of a carbide-gas lamp that is very handy around the engine room. It was made from a piece of 1¾-inch brass tubing. The top and bottom caps and water stem were taken from the top of two old glass oil cups, the hole in the bottom cap being plugged. The burner



Section through Lamp

is a small piece of brass pipe taken from an old lubricator, and the hook is a piece of copper wire. The lamp will burn about two hours with one filling of carbide.

An Experience in Boiler Cleaning

On taking charge of an electric-lighting plant, in which were three 72-inch by 18-foot horizontal return-tubular boilers, I found them in bad condition. The best of the three boilers was badly scaled, but was capable of carrying the load alone, except on Saturday night. Either of the other two could carry the load Sunday night and until the lighting load came on Monday night.

The feed water was so bad that a boiler had to be washed after each week's run. Because of these conditions it was the custom to run the best boiler, No. 3, during the week, fire up one of the others to help on the Saturday-night load and carry the Sunday load on it while No. 3 was being washed and fired up again in time for the Monday-night load.

This process required the filling and firing up of two boilers each week, one of which was run but two days, so that its setting was cold each time it was fired. No boiler compound had been used and very little effort had been made to prevent further formation of scale, or to remove the old scale.

I immediately began using a boiler compound and set to work to remove the old scale from the boilers. A careful internal examination of the boilers was made and the assistant engineer was set to work getting off the scale from one of them. He spent an entire day at it and got off scale enough to show he had been at work, but it was hard work and a flue cleaner was purchased and by its aid about 500 pounds of scale was removed from each boiler.

After I had had charge of the plant about a month, boilers Nos. 1 and 2 would carry the load as easily as No. 3 had formerly, but as No. 3 received the same attention it was still the better boiler.

From this time on, the practice of firing up two cold boilers a week was discontinued and the fresh boiler that was cut in for the Saturday-night load carried it alone until the next Saturday night. This gave six days' time in which to cool, clean and repair No. 3 after each run, and as it was the most economical boiler it was used every other week, and a saving was made in several ways.

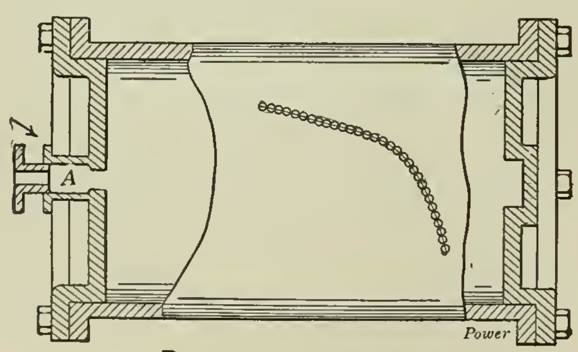
Salida, Colo.

Cylinder Troubles

At one time a cracked cylinder was repaired in the engine room without removing it from the engine frame.

An electric drill was used to drill holes through the crack, which holes were tapped and a copper plug dipped in iron cement screwed into each hole, as shown in the illustration. Then the job was gone over with a hammer and filed smooth both sides.



Plugged Cylinder

An accident revealed a defect in an engine that had escaped detection for some years. The connecting rod was of the marine type, and one morning, when under light load, the heads flew off of the bolts, allowing the connecting rod to drop. It went through the floor, striking a joist on the outward stroke, and buckled the piston rod; on the return stroke the cylinder-head stuffing-box glands were also broken.

The stuffing box shown had not been bored out true with the cylinder, and one shoulder was nearly all on the bottom. There was a brass collar in the stuffing box that had been worn, there was no shoulder, and it had worked nearly into the cylinder.

We rigged up a device through the cylinder with a rod centered at the end of the cylinder and centered with the crank shaft at the other end, and secured a tool to the rod; then a crank was placed on the projecting end of the rod at the cylinder end and the stuffing box was rebored.

After finishing the repairs I noticed an occasional and peculiar knock in the engine which puzzled me for some months. I examined the stuffing box and found that the new throat collar that we had placed in it was a pretty loose fit, and when the piston was on the outward stroke the end packing contracted and the steam forced the collar against the packing. When the piston started on the return stroke the collar came back with a knock.

William G. Walters.

Stratford, Canada.

Valve Stem Broke

In the electric-light and power plant where I am employed as engineer, a boiler-feed pump failed to pump.

After going over the pump and testing the steam valves, I tried the gate valve on the discharge pipe and found it quite loose. Taking off the bonnet, I found the stem broken and the disks stuck on their seats. After removing the disks and replacing the bonnet the pump worked all right. It is these little things that, when found, help to simplify power-plant difficulties.

J. E. Dawson.

Cumberland, Md.

Put Shims under Knock-off Block

I have charge of an 18x36-inch Corliss engine, making 80 revolutions per minute, and the load varies from no load to 200 horsepower.

When the load was all thrown off, the governor would throw the knock-off cams so far back that the cam levers would strike the bolts that hold the springs on the steam hooks and that would cause the governor to jump and the engine to race.

To overcome this trouble I removed the knock-off blocks and cut out liners the size of the block from 1/16-inch sheet iron and drilled a hole in them for the screw and secured them under the blocks. I then readjusted the governor rods, and have had no trouble since. The governor works nicely, and the engine runs just the same with no load as with a full load.

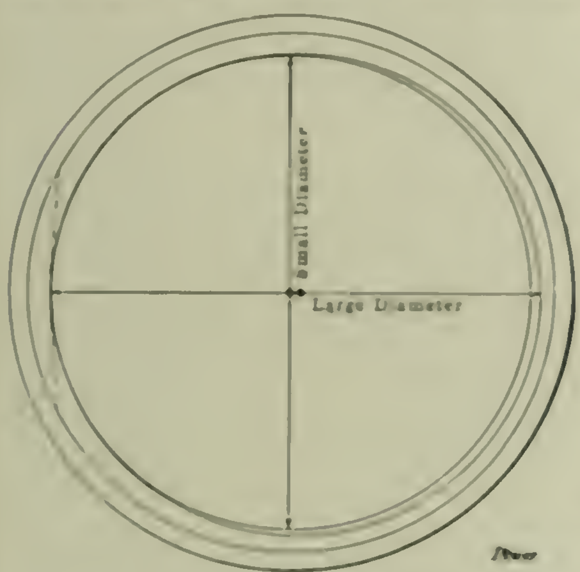
George H. Lee.

St. Louis, Mo.

Truing a Crank Pin

The subject of flat and badly scored crank pins is of interest to most engineers. A crank pin cannot well be taken out and trued up in a lathe, and it, therefore, falls to the lot of the operating engineer to devise some means of remedying the trouble, and the file is usually called into service.

The first thing to know is what size the finished pin is to be. The calipers



Two Sizes of Pin

are put on the flat pin to find its smallest diameter, which will be the largest diameter of the trued-up pin. Most of the wear is found on one side of the pin and consequently if the pin is filed true in the manner suggested, the center of the pin will be changed, thus shortening the piston stroke a little. However, this would not be very noticeable, and in a pin 1/16 inch out the difference in the stroke could easily be taken care of. If the pin were filed all around and the same center retained, the pin would be smaller than it would be if filed, using the new center; see illustration.

A piece of wire should be filed to precisely the same length as the finished diameter of the pin. The crank-rod boxes should be rebabbitted and bored, using the wire as a gage. The boxes should be left as they come from the lathe without any scraping, as one-half of the box is to be used as a templet while filing the pin. A sharp bastard file will rasp off stock pretty fast, commencing at the heaviest part of the cut. One-half of the pin should be roughed down and practically finished before starting on the other side, often using the half box as a templet and filing down the high places untill a good bearing is obtained. The pin must also be filed as square with the crank as possible. Red lead should be used in the templet to mark the high spots when filing and should be used quite sparingly as too much lead will not show a true bearing. The least possible amount applied with the finger to just mark the high places will be enough.

After both sides of the pin have been brought down to a fairly good finish and as round as possible, the pin should be polished with emery cloth held in a clamp, such as is used to polish shafting. This clamp is made of two pieces of 3-inch stock with a section bored out about the size of the pin, and a piece of leather tacked on for a hinge.

The boxes should then be scraped, oil grooves cut, put together and not keyed up too tight at first, until the pin has fitted itself to the box a little. Then key up until a proper adjustment has been obtained.

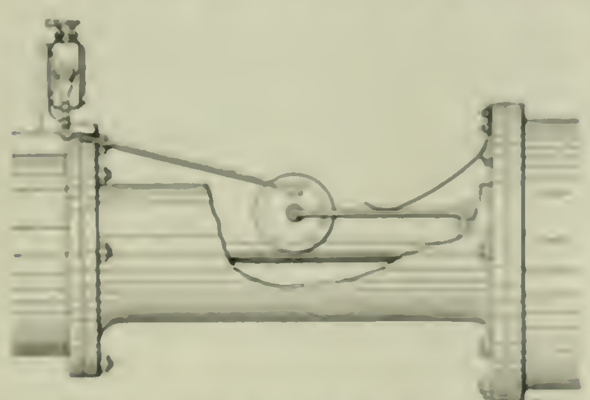
Charles H. Taylor.

Bridgeport, Conn.

Attaching a Force Feed Lubricator to a Pump

A question was put to me recently in reference to attaching a positive feed lubricator to a pump of which the only exposed moving part is the piston rod, the distance between the stuffing boxes being such as to leave no part of the piston rod not passing through the stuffing boxes to which connection can be made to obtain motion for operating the oil pump.

One method would be to put a grooved roll on the top side of the rod, and keep



Lubricator Attached to Pump

the roller in contact with it by means of a spring, the motion for the lubricator to be derived from the roller. The accompanying sketch gives an idea of the plan I would suggest. The roller should be made of some material that will make a good frictional contact with the piston rod, and also withstand the heat.

George J. Little.

Passaic, N. J.

Cemented Cracked Pipe

A [illegible]-inch cast-iron pipe was used as an intake from the river to the condenser-pump house. It was built in the form of a siphon and a piece 12 feet long cracked about half way around at the junction of one end and the flange.

The surface was cleaned with muriatic acid, washed with water and dried. Then an iron cement was applied and allowed to stand four hours. Although the line has a 12-inch vacuum, it has since given no trouble.

Kansas City, Mo.

Measuring an Indicator Diagram

A fairly accurate method of measuring the area of indicator diagrams, when a planimeter is not at hand, is shown in the cut, and works out as follows:

Extend the exhaust line AC, and at the point A, which is the intersection of AC with a vertical line drawn through the end of the diagram, fasten a pin through the paper to hold one end of a thread.

The other end B is placed in such a position that the sum of the areas D and E is as near equal as possible to that of the areas F and G.

After this position has been obtained to the satisfaction of the eye, another pin is placed at the point B, the thread wound around it and the operation is again performed at C until the area of H is equal to the area of C.

In this manner the original diagram is supplanted by a triangle ABC of approximately the same area, which can be calculated by the following formula:

Position of Thread on Diagram

When AC equals the base and BK the altitude

$$Area = AC \times \frac{BK}{2}$$

After a little practice very close results may be obtained with this method, rough though it may seem.

Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

Two Hundred Horsepower Horizontal Boilers

I notice in the issue of December 13 an inquirer wants to know if horizontal tubular boilers are made in sizes of 200 horsepower. I know of two plants equipped with boilers of this size, 78 inches in diameter by 20 feet long, and containing 2000 square feet of heating surface.

I have had charge of four units of the above dimensions since their installation six years ago. The shells are built of 17/32-inch sheets in three courses: have quadruple-riveted double-strap joints and are designed for 150 pounds pressure.

The repair bills on the four amounted to $18 in that time. This cost was for having the fire seams calked on the inside as they showed a slight disposition to leak at this point.

The only other defects that have shown up are three or four fire cracks at the fire seam. These have not been serious enough to need more than calking.

As regards economy, we are not fixed for making accurate evaporation tests but believe they will hold their own with the water-tube type.

Our only objection to them is the curvilinear seam over the fire. At this point we have $1\frac{1}{16}$ inches of metal between the fire and water which is too much even if the boiler is kept free from scale. There has never been the slightest tube leakage. We were told that 4-inch tubes 20 feet long would give us no end of trouble by sagging, but nothing of the kind has occurred. So far as repairs are concerned we feel that no type of boiler could show a much better record. They have had the best of care and the feed water has passed through a purifying process before entering the boilers.

From my point of view it is a most short-sighted policy for steam users to supply their boilers with water containing scale-making impurities when there are at least a dozen concerns making purifying apparatus that will remedy the trouble. Bad water in a boiler makes for poor economy in the use of fuel and high repair bills.

Some things that boilermakers do are hard for me to understand. One thing is, for instance, they put 6-inch steam outlet nozzles on a 200-horsepower boiler and the same size on a 150-horsepower. I suppose I am about the only engineer who ever put a steam-engine indicator on a steam drum or header. I was trying to find out if the pressure in the drum pulsated with the engine. Also, I had a slight suspicion that the pressure was greater in the boiler than in the drum.

J. O. Benefiel.

Anderson, Ind.

Treatment of Subordinates

Several of the articles recently published in Power bearing on the treatment of help in the power plant were very fine. I have always found that a man, perhaps by good fortune, promoted to a place of authority, who takes advantage of his position by being tyrannous with those under him, very soon gets up against trouble. An assistant can ward off lots of annoyances for the chief engineer and he will if treated right. When a man treats his subordinates considerately they take an interest in their work, if they are the right kind of men, and will be on the alert to keep things about the plant in the pink of condition. If they do not show a desire to do this with fair treatment, they should be discharged. One does not have to put on a "big air" or look over the tops of the men's heads in order to hold a place as "boss." Often, this seems to be necessary to those who occupy places which they are not fitted to fill. Sometimes a man has a subordinate who could fill his place just as well or better than he does. In such cases the man "higher up" is usually extremely jealous. I remember a remark that was made to me one time some years since by a man of this type. He said, "You should not tell those young fellows all you know, for they will soon know as much as you do." I did not tell him that that would not be much. I reasoned that while the young fellows were learning, I could be doing likewise. I think that one should always show as much consideration as possible to those who are seeking information, so long as they are men of the right character.

I believe in good men—they are just a bit scarce—a good set of men means a good organization which not only means success for the chief but success for the plant. I tell you, boys, your subordinates can do a lot toward your holding your job; the fact cannot be disputed. The man who wants to learn should always be shown as he may make a mark some day which will reflect no discredit to the one who started him off.

It is often remarked that some men cannot stand good treatment. This is true and when such a one is discovered it would be well to let him find another occupation; the engine room is no place for him—what I want is a man that I can reason with, and treat in the right way. A man that has to be driven is not the kind that goes to make up a good organization. I want help from the coal bunker to the switchboard that will take interest each in his particular part of the work.

C. R. McGahey.

Baltimore, Md.

The Double Entasis

In Power for January 3, my attention was specially attracted to the chimney of the Queen Lane filter plant, that is, to the "pot-bellied" appearance of the shaft. There is nothing in mechanics, mathematics or beauty that justifies that shape, and it seems to me that the man who can make a thing that is dead wrong look better than one that is right, or nearer right, should have his taste cultivated. Mathematicians tell me that increasing the area to meet increased load would result in a concave, rather than a convex outline; anyway, the convex cannot be right. It is plain that the reason why chimneys are built larger at the bottom than the top is because there is more weight to be carried at the bottom than at the top, and the wind pressure must be withstood. It needs no figures to show that increasing the size above the bottom adds nothing but weight and wind-pressure area, neither of which is wanted.

I do not know but that the "swelled" columns are so common that people may have learned to believe that they look best. With a plain taper one, like the one mentioned, and one concaved like some of the Constantinople shafts, I am sure few, if any, would select the convex one as being the best looking.

John E. Sweet.

Syracuse, N. Y.

Chimney Problem

Referring to L. G. Watry's chimney problem in the December 27 issue, most of the hot gases will pass up the larger opening, and the chimney with the smaller opening will not be of much service.

The best thing to do is to divide the smoke box in half, which would make a separate stack for each boiler.

Another way would be to cut out stack No. 2 and build an addition to stack No. 1 and use this stack only, which is capable of producing enough draft for both boilers.

MIKE FUKER.

Chicago, Ill.

Does the Crosshead Stop?

I have been much interested in reading the discussion of the question, "Does the Crosshead Stop?" I would like to ask a question. If the crosshead does not stop for its return trip, what becomes of it, or, in other words, where does it go?

If a person is running a race and has to return over the same ground, he must stop for the fraction of a second as he turns to retrace his steps.

E. M. COBURN.

St. Johnsburg, Vt.

Boiler Efficiency of 82.36 per Cent

There is an error in the report of the boiler test in the issue of November 29, in which an efficiency of 82.36 per cent. is claimed, and if, as was stated, a bonus was "paid immediately after the completion of the official tests" on the basis of "$1000 for each per cent. efficiency above the contract requirements of 65 per cent.," or $17,360, then the Government paid several thousand dollars more than was justly due. It is well known that it is practically impossible to obtain from a water-tube boiler of the inclined-tube type, with an ordinary furnace, in which the tubes are directly above the fire, hand firing and soft coal, an efficiency above 76 or 77 per cent. Any higher figure indicates that an error was made either in the test or in the computation of the results. The errors that may occur in the test are the following:

1. Error in the calorimetric determination of the heat value of the fuel, giving too low a result.

2. "Stealing of coal" by the fireman.

3. Error in weighing the coal or the water.

4. Leaks of water from the boiler.

5. Error of judgment in estimating the quantity and condition of the fuel on the grate at the beginning and end of the test.

It does not appear from the record of the test that any of these errors were made. The heat value of the fuel per pound of combustible, 15,683 B.t.u., is within the range of what is found generally with Pocahontas coal, which runs usually between 15,600 and 15,900. The error in the figure given is not likely to be more than 1 per cent. There is also a possible error of 1 per cent. in the weight of water fed to the boiler, as it was weighed in tanks when very hot (the official record giving the temperature as 183.57 degrees), and must have lost some weight by evaporation from the surface of the three or four tanks and as it flowed from an upper tank to a lower one. These are only minor errors, but they may possibly account for $2000 of the bonus. The great error, however, is in the computation and it amounts to not less than 6.5 per cent., corresponding to $6500 bonus.

According to the record, the water evaporated under actual conditions per pound of coal as fired was 10.30 pounds. The weight of water fed was 129,218 pounds and the weight of the coal fired was 12,545 pounds. The coal contained 1.70 per cent. moisture, and the ash and refuse was 2.36 per cent. of the dry coal, making 12,006 pounds of combustible. The average feed-water temperature was 183.57 degrees, the steam pressure, 188.00 pounds, gage, and the superheat 98.70 degrees. Using the Marks-Davis steam tables, these figures give a factor of evaporation of 1.1391, which multiplied by 129,218 gives 147,192. The official report gives 157,312, a difference of 10,120 pounds, or 6.8 per cent. error. The economic results as reported and as corrected are as follows:

Equivalent Evaporation from and at 212 Degrees	Reported	Corrected
Per pound of coal as fired	12.[illegible]	11.[illegible]
Per pound of dry coal	12.[illegible]	11.[illegible]
Per pound of combustible	13.[illegible]	12.[illegible]

The efficiency, corrected, is calculated as follows: The calorific value per pound of the dry coal, as reported in POWER, being 15,202 B.t.u., and that of the combustible 15,683.8 B.t.u., the efficiency of the boiler is

$$12,283 \times 970.4 \div 15,683.8 = 75.86$$

per cent.

The efficiency of the boiler, including the grate is

$$11,040 \times 970.4 \div 15,202 = 73.81$$

per cent.

The reported efficiency, 82.36 per cent., is 8.55 greater than this, showing an error of

$$8.55 \div 73.81 = 8.6 \text{ per cent.}$$

as compared with 6.8 per cent. error in the equivalent evaporation from and at 212 degrees.

The capacity developed in the test is

$$147,192 \div (8 \times 34.5) = 533.3$$

horsepower

instead of 570 horsepower as reported, and the water evaporated from and at 212 degrees per square foot of heating surface,

$$147,192 \div (8 \times 4070) = 4.51 \text{ pounds}$$

instead of 4.82 as reported.

In all cases where a very high efficiency is reported as the result of a boiler test it is well to check the figures by making an approximate heat balance.

We have not sufficient data for a complete balance, but an approximate one may be made from the following:

Heating value per pound combustible, 15,683 B.t.u.
Probable analysis of the combustible, 91C, 5H, 4(O + N + S)
Air per pound combustible for maximum economy, say, 21 pounds
Dry gas per pound combustible for maximum economy, say, 22 pounds
Specific heat of gas, 0.24
Temperature of flue gases, 471 degrees; of fire room, 90 degrees
Specific heat of water vapor, 0.48
Moisture in coal, referred to combustible, 1.84 per cent.
Moisture in air at 90 degrees, assuming 60 per cent. saturation, [illegible] pound

Heat absorbed by the boiler per pound combustible, corrected figures, 12.283 × 970.4	11,[illegible] B.t.u. =	7[illegible] per cent.
Heat lost in the dry gases, 22 × (471 − 90) × 0.24	2,0[illegible] B.t.u. =	12.[illegible] per cent.
Loss due to moisture in coal, 0.0184 × (212 − 90) + 970 + (471 − 212) × 0.48	2[illegible] B.t.u. =	0.1[illegible] per cent.
Loss due to moisture in air, 21 × 0.0[illegible] × (471 − 90) × 0.48	1[illegible] B.t.u. =	0.[illegible] per cent.
Loss due to moisture formed by burning hydrogen of the coal, 0.05 × 9 × (212 − 90) + 970 + (471 − 212) × 0.48	548 B.t.u. =	3.49 per cent.
	14,294 B.t.u. =	91.[illegible] per cent.
Loss due to radiation, to C burned to CO, to unburned hydrocarbons and to fuel lost through the grates	1,389 B.t.u. =	8.[illegible] per cent.
Total	15,683 B.t.u. =	100.00 per cent.

The corrected efficiency, based on the combustible, of 75.86 per cent., is a very satisfactory and creditable result, but it is not more than might be expected from such a boiler with Pocahontas coal, when the "high percentage of CO_2 (12.46 per cent.) was obtained by close supervision of the draft." The figure indicates not only that the setting was in good condition, but that the firing was good.

It is difficult to understand why a bonus was offered for each per cent. of efficiency above 65 per cent. That figure would be an exceedingly low result for any good type of boiler using Pocahontas coal, hot feed-water and with expert firing. The difference between 65 and 75 per cent. means a bonus of $10,000. Why should the Government offer to pay such a large bonus for a performance that is no higher than might reasonably be expected? Why should a bonus ever be paid on the performance of a standard apparatus, such as a water-tube boiler with an ordinary grate, when the dimensions, heating and grate surface, etc., are all specified in the contract? Unless the price of the boiler without the bonus was lower than the ordinary or normal price it appears that the Government is "out" the whole amount of the bonus, $6500, on account of an error in computation of the results of the test, and nearly $11,000 on account of an error of judgment in drawing the specifications and contract.

William Kent.

New York City.

Automatic Nonreturn Valves

I noticed an inquiry from Louis J. Corilla in the December 20 issue in regard to "Automatic Nonreturn Valves."

For the past three years I have had charge of forty 10-inch and ten 4-inch valves of this type and have never noticed a failure to close. Several times in this time one has failed to open, but the trouble is always due to a gummy deposit on the plunger of the valve, which can easily be cleaned off by simply removing the valve bonnet and using cool oil and fine sand paper. They do not chatter, neither do they wire draw the steam. As for their value, I simply state that there should be a law making their use compulsory in plants of any size. We have had several tubes blow out, but we did not know anything about it in the engine room until it was all over. In one plant of four water-tube boilers I was shut down once by a feed pipe breaking off at the drum where we had no nonreturn valve. I also know of a 5000-kilowatt plant being completely shut down two times for the want of these valves. The only thing to guard against is this gum on the plungers, and two hours per year per valve will take care of this.

E. H. Lane.

Kansas City, Mo.

Accumulators for Furnace and Boiler Capacity

In the editorial, "Accumulators for Furnace and Boiler Capacity," in the November 29 issue, we read the following:

"It has been one of the first precepts of a boiler room to keep the pressure constant, but it is a question if the boiler pressure cannot be allowed to vary through a considerable range with less damage to the over-all efficiency than would result from the constant manipulation of the damper and the slice bar necessary to hold it constant. At the pressure ordinarily carried, a considerable pressure drop will produce a comparatively insignificant change in the initial temperature, and it is the temperature range which affects the efficiency!"

For one, I am sorry that the writer of the paragraph just quoted did not go a little more into detail relative to constant boiler pressure and its attending advantages or disadvantages as the case may be; therefore, I am in hopes that this writing may bring out some more points along this line.

In the first place, just what are we to understand by "the over-all efficiency"? Second, what would be the allowable variation in boiler pressure? Third, if a considerable variation is permissible, it seems to me the allowable range would be governed somewhat by the nature of the steam in use; that is, saturated or superheated.

The temperature of saturated steam at 130 pounds gage, 145 pounds absolute, is 355 degrees and the total heat in the steam above 32 degrees is 1190 heat units. With a gage pressure of 115 pounds, 130 pounds absolute, the temperature is 347 degrees, and the total heat in the steam above 32 degrees is 1187 heat units. We note by these figures that with a drop of 15 pounds pressure there is a drop of only 8 degrees in the temperature of the steam and a loss of only 3 heat units. Now, if in these two cases the steam is flowing through a superheater and is getting 100 degrees of superheat in the first instance, it seems to me that in the second case the cooler steam—even though a large number of pounds may be passing in a given time—will take up sufficient additional heat units, not only because the temperature of the steam is lower but also because the temperature of the hot gases circulating is increased, due to the stronger draft made necessary by the increased demand for steam, to make the final temperature of the steam the same in both cases. If these statements are correct, it would seem that a variation of at least 15 pounds in the steam pressure would not affect the final results when superheated steam is used.

It would seem, too, that with saturated steam and a variation of only 8 degrees, the economy would be affected but little, if any; yet, my experience is not in accord with the theory stated, as the following will show:

In a certain power plant, running 16 hours per day, two firemen were employed, working eight hours each; one would carry the steam pressure at or near 110 pounds throughout the entire eight hours, with but little need for the use of the slice bar, the damper being handled by a regulator. The other man, working his shift under precisely the same operating conditions as to load, length of time, etc., would have the steam pressure anywhere from 90 to 110 pounds, would use the slice bar much more than the other man did and burned 500 pounds of coal more; and it made no difference which shift this man worked, the results were the same.

Now, while looking into the matter a little further and from another viewpoint, we will grant the statement, as probably correct, that the "over-all efficiency is not affected by a considerable variation in the range of boiler pressure!" However, it seems to me that there are other conditions, aside from the effect on the efficiency, produced by permitting a considerable variation in the range of the boiler pressure, which are not favorable to continuity of service and which should make it desirable to carry the pressure as nearly uniform as possible. Of course, the intervals of these variations will determine somewhat the deleterious effects produced.

It is well known that with every change in steam pressure there is a corresponding change in the contour of the boiler, the effect being more marked in the lap-seam boiler than in the butt-joint type, with detrimental results in the latter case as well as the former. Then, too, with the fluctuation in the steam pressure, there must be a variable furnace temperature, with more rapid deterioration of furnace walls and boiler, due to excessive contraction and expansion, than would be otherwise if the temperature were more uniform.

I am well aware that it would be a hard matter to determine the effects produced by some of the conditions mentioned above; however, I am desirous of bringing out the ideas of others along this line, for I believe it will be beneficial to those of us who, as yet, have a great deal to learn.

Handling Men

I was interested in J. M. Row's letter on the above subject which appeared in a recent issue. It contains some sound general advice, and, if followed, no doubt it would result in financial benefit to both employer and employee. I wish to say here a few words about the different systems of handling help, and, as fairly as I can, compare the results obtained. The three plants discussed are each of about 5000 kilowatts capacity.

The first is a plant, one of a chain, supplying power for street-railway service. It is in charge of a chief engineer who has under him three assistants, three oilers, five firemen, four cleaners and coal passers and one repairman and his helper. The salary of the chief is fair, but that of the rest is low. The main duty of the assistant is to watch the switchboard, keeping the voltage steady, throwing in the circuit breakers when they come out, and reading the wattmeter and to note the temperature of the feed water hourly. He does no repair work and must not be absent from the switchboard even to start an extra engine, which is done by the oiler. In fact, his work is simply that of a switchboard tender, a job which could be very satisfactorily filled by a bright fireman. Yet the assistant engineer must hold a first-class engineer's license. The repair work is looked after by a repairman of steam-fitting experience only, under the direct supervision of the chief. His hours correspond to those of the chief's, except that he is subject to calls at all hours of the night. As these, however, are extra time for him, naturally he is called to attend to those things only which are absolutely necessary to keep the plant running.

The condition of the plant as to orderliness and cleanliness is above reproach, and the casual visitor would readily believe that this is a model plant. The steam pipes from the boilers to the engines and their auxiliaries, however, pass through a basement tunnel, which cannot be seen from the engine-room floor, and, indeed, its dimensions are barely discernible even when fronting it in the basement; but its presence is positively made known by the large number of steam leaks. It stands to reason that one ill-paid repairman and a helper, plus the chief engineer, who, of course, cannot be expected to do more than supervise the work done, cannot possibly maintain a station of this size in sound condition. Consequently, the whole equipment from the governors of the engines to the blowoff valves suffers. Yet no man can point to anything that is very much out of repair. It is, no doubt, needless to say that it is not one single piece of apparatus in a large plant that is the cause of low economy, but the combined total of a lot of little things, each of which may be only a little bit out. And here are the figures to prove this in the case of this station:

Average number of pounds of coal consumed per kilowatt per hour, 3.6; labor per kilowatt per hour, 0.11 cent; cost of fuel and labor per kilowatt per hour, 0.6752 cent.

Yet this station has all the help necessary to maintain it in first-class condition, if the system of managing the help was changed only slightly, as is proved by the next case.

This plant is another street-railway power station, of about like equipment and capacity. It is operated by a chief engineer and two assistants, four oilers, eight firemen and five coal passers. Out of this gang, ordinarily, there are available for repairs and cleaning up, about five men. The chief engineer's wage is fair; that of the rest of the men is good. When the assistant engineer comes on his watch he finds written on a sheet of paper a list of the repair work necessary to be done that day. All the spare help report to him, and it is his duty to divide the work among them according to their abilities. He sees that all do their portion properly, and that each uses the required stock to the best advantage and without waste. It is surprising the amount of repair work that can be done in a few hours by the men, who soon become highly trained. Jobs that 90 per cent. of other power houses would send for outside help to do, are here thought very little of. Of course, they have all the necessary tools, such as drill, lathe, shaper, etc., to do their work with. The result is highly efficient apparatus, but not a very good-looking plant. By the latter is meant that the visitor will find the paint scratched off nuts and the surrounding metal, and, here and there, a chunk of asbestos covering off some of the steam lines. But he will find no leaks, either steam or water, nor will he see any clattering apparatus, which has to hustle to make good. The log-book figures for this station are as follows:

Pounds of coal per kilowatt per hour, 2.5; labor per kilowatt per hour, 0.16 cent; cost of coal and labor per kilowatt per hour, 0.552 cent. The coal costs 20 cents per ton more at this station than at the other.

Taking all of the figures, such as cost of repairs, etc., this station delivers the same amount of work as that in the first case, at a saving of $175 per week.

The next case is that of an electric-light station which is seven years older than the two samples considered above, but outstrips both in economy of operation. It is presided over by a chief engineer who, after giving much intelligent thought to the handling of his help, developed a system which, in my estimation, is nearly perfect. It is never essential for him to ask, "Who did this, or who did that job?" And none can evade responsibility by stringing that oft repeated excuse, "The other fellow don't do it." He has all of the men in competition with one another, and he has a method of rewarding those who try to do their best, without showing favoritism to any.

To describe the system fully in this letter would take too long, and to attempt to describe it briefly would not do it justice. Suffice it to say now, that his method is somewhat similar to that used in the second case, but, in addition, every man has a certain task for which he is held responsible. For instance, one assistant engineer is responsible for the general good behavior of one engine; he must see that the boxes are properly keyed up, all lost motion in the valve gears taken up, etc. Again, one oiler, though he must look after and keep clean all running apparatus, is responsible for the bright work on one engine only. It will easily be understood that one assistant tries to keep his engine running as well as, or better than, the other's engine, and that one oiler tries to outshine the other. This competitive system, carried from assistant engineer to coal passer and directed by a tactful chief, who knows how to maintain it, works wonders, as the following figures prove:

Pounds of coal per kilowatt per hour, 2.34; labor per kilowatt per hour, 0.13 cent; cost for coal and labor per kilowatt per hour, 0.5319 cent.

WILLIAM POWELL.

The Chief and His Subordinates

There often seems to be a feeling of resentment on the part of the chief when he is approached by an assistant who is striving to rise to a higher place in his chosen profession. During my short career as an engineer I have found but one chief who was willing to explain things in detail.

I well remember an experience with one of those men who do not have time to listen to the operating engineer's suggestions.

The plant consisted of one 150- and two 100-horsepower tubular boilers, carrying steam at 120 pounds gage pressure; one 18x42-inch Corliss engine; one 100-kilowatt alternating-current and one 2000-volt direct-current series arc machine, belted to a line shaft.

I found the flues half full of soot and after a little talk with the fireman was able to get him busy with the flue cleaner. Then, I rigged up a device for blowing the flues and had them blown morning, noon and night. When the fireman found that I was working for his interests, conditions began to improve, insofar as our end of the plant was concerned.

The chief never found fault with me at any time, for if he had I would have looked for another job right away. I am always willing to listen and want to learn all that I can, and it is the height of my ambition to be a chief and if ever I attain that position, I will spare no effort to be worthy of the trust placed in me.

Blowoff Piping

In the issue of POWER for December 20, I noticed a letter by Edward Hamilton describing the blowoff arrangement in his boiler plant. That this arrangement is a satisfactory one is due to the manner in which the blowoff pipes are protected from the heat, and to that only, as a little consideration will show that his so called circulation pipe in no way affects the result. If the connection is made as shown in the sketch that accompanied his letter, that is, into the steam space of the boiler, all the circulation that such an arrangement would give would be that due to the condensation of the steam in the small riser, which would be of no practical value.

Had this pipe been made the full size of the blowoff connection and then carried into the boiler above the first row of tubes and below the water line, the results would be different.

A Method for Getting High CO_2

Orosco C. Woolson sends in the following belated discussion of the paper upon "Combustion and Boiler Efficiency," presented to the recent meeting of the American Society of Mechanical Engineers, by Edward A. Uehling.

To secure practical benefit from any CO_2 recorder it is necessary not only to have the apparatus properly installed, but to have its readings correctly interpreted, taking into account potent conditions which might exist, abnormal or otherwise, and which would prove a puzzle to many, and even to an expert should he be lacking in a keen appreciation of such conditions.

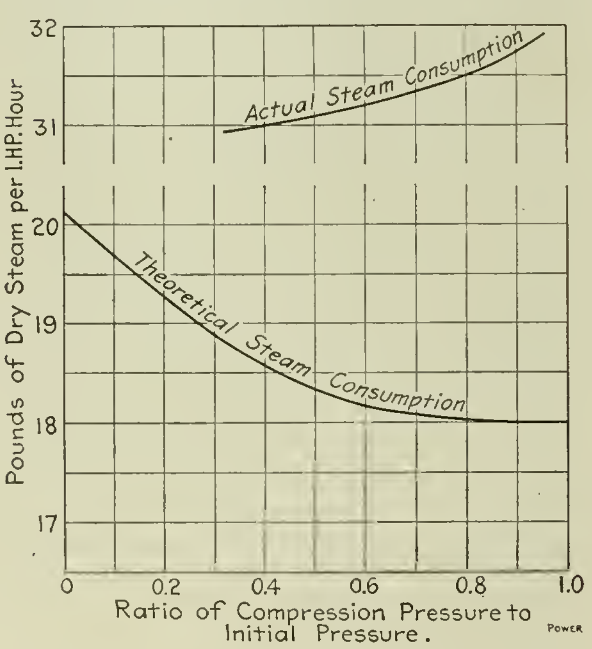
To get at the business end of the question so that results shall show on the right side of the ledger is, in my estimation, a difficult thing to accomplish, and unless some other explanation can be offered for so many CO_2 recorders being out of business in different power houses, I am forced to the conclusion that we are attempting to establish a too refined apparatus for determining what is required to obtain the greatest value from our boiler plants except for expert testing.

I have an invention of my own which I have tried for some years to put into everyday practice. I have secured no patent on it, yet I will magnanimously permit any member in good standing in the society to appropriate it, to wit:

Say to your chief engineer, "Bill! the longer I live the more I find, by gracious, out and I find, by gracious, that it's time to raise your salary and I am only astonished that I did not find this out before, but don't think, Bill, this is philanthrophy on my part. I am going to make a CO_2 recorder out of you at about $300 per year, but I want you to save me $600 a year in fuel by devoting more of your time to the boiler room. Your assistants are quite capable of watching those automatic cutoff and turbine engines with their fine adjustments go around, but you know as well as I do that the fire room is lacking that careful and intelligent adjustment which it should have to secure the highest degree of 'actinism' possible, and, Bill, if you don't get on to that word, actinism, just look it up, for it's part of my CO_2 invention, and I want you to study up and produce for me the greatest actinic value that bituminous coal can accomplish. And, by the way, let me say this to you, don't let me catch you in the fire room with your coat off doing the work I am paying others to do, but you just use your brains that I pay for and notice whether the firemen, or, more properly speaking, the furnace tenders, keep their fire doors closed continuously or whether they are up to the same old trick of their youth of jerking the fire door open every time they walk up to the boiler. You have noticed, Bill, that that fire door is provided with a large peep hole that will admit of surveying the interior of the furnace all right, and, inasmuch as I paid for that hole, I want you to get the money's worth out of it; otherwise my CO_2 invention will record a minus mark against you. Now, Bill, you get busy and do as I suggest and the extra salary is yours at the end of the year and I shall be saving money myself. One thing more, Bill, if you find after careful investigation you think it would be better, all around, to build a trestle alongside of our boiler house sufficiently high to admit of spouting the coal direct into the magazines of those furnaces instead of dropping the coal clear down to the fire-room floor, for the sake of lifting it up again to feed the furnaces, just let me know, and we will see if we can't accomplish still further good results; but, as I remarked before, you get busy on the boiler room and you will find that what Mr. Uehling says is beginning to be recognized as essential for good results, is true."

Compression in the Steam Engine

The *Sibley Journal* for December contains a contribution by Prof. R. C. Carpenter upon the subject of "Compression in the Steam Engine." The article is in the nature of a review of what has been done to settle this controversial question and contains the results of a test conducted by the author several years ago upon the high-pressure cylinder of a triple-expansion Corliss engine at the Sibley College experimental laboratories.



THEORETICAL AND ACTUAL STEAM CONSUMPTION

Three sets of runs were made at a vacuum of about six inches with constant pressure at the throttle, constant cutoff and varying compression, the degrees of compression being 42.8, 66.3 and 87.2 per cent. of the admission pressure. The steam consumptions on these runs were respectively 31.03, 31.3 and 31.7 pounds per indicated horsepower-hour. The increase in the water rate with increased consumption is here so slight as to have very little effect upon the economy of the engine, but, nevertheless, it is opposite to what a theoretical treatment of the subject would indicate.

The accompanying chart shows the actual steam consumption as plotted from the tests and the theoretical steam consumption of the engine working without cylinder condensation. The slopes of these curves are opposite, although the theoretical curve shows a very slight improvement in economy after the ratio of compression to initial pressures passes 60 per cent. The discrepancy is undoubtedly due to losses the exact nature of which is not well understood and, as Professor Carpenter remarks, "It is evident that further investigation is necessary to find out what is the matter with our theory."

It is proposed to make further investigations along this line in the laboratories of Sibley College with a view to throwing light upon the discrepancy between the predicted and the actual results, which information should go far toward settling the controversy which is now being waged between the adherents and the foes of compression.

In the annual report of *Lloyd's Register*, recently issued, reference is made to the use of internal-combustion engines for marine purposes. With this type of engine there is considerable difficulty in effecting the reversal of the direction of rotation of the engine, and when these engines are used for marine purposes the astern motion of the screw has usually been obtained by the use of toothed-wheel gearing. Comparatively recently there has been a development in the Diesel oil engine for marine work. A two-stroke cycle has been successfully adopted, and the reversal is effected in the engine itself, the crank shaft being directly coupled to the screw shaft. The Diesel oil engine is now being fitted to three fairly large vessels being built on the Continent under the supervision of the surveyors of *Lloyd's Register*. One set is being constructed on the older principle of the four-stroke cycle with single-acting cylinders, and will be of about 450 indicated horsepower. Another set is being made on the two-stroke cycle, also single acting, and is intended for a twin-screw vessel, the power being about 900 indicated horsepower on each shaft. The third set is being made on the two-stroke cycle double-acting system, each cylinder providing two impulses per revolution; this also will be fitted in a twin-screw vessel, the total power being about 1800 indicated horsepower. In each of these cases the engines will be directly coupled to the screw shafts. A set of internal-combustion engines is being constructed under the society's survey in this country for a vessel of about 260 tons.

CIRCULATION STATEMENT

Of this issue, 31,000 copies are printed.

None sent free regularly, no returns from news companies, no back numbers. Figures are live, not circulation.

Contents

PAGE

Notice!

The publishers of the paper called *Steam* have written us protesting against the statement on the first page of the year that POWER was made up of a lot of papers, including one called *Steam*, and asking us to place the matter right before our readers, which we are glad to do here and now.

POWER bought its rival, named *Steam*, a long time ago and carried the name as part of its own title for more than eight years.

The new paper calling itself *Steam* took that title—which it had a legal right to do—but this cannot prevent us from truthfully making the statement we did.

Certainly we can hardly be expected to apologize because our esteemed contemporary used a second-hand name that we had dropped.

Conservation of New York State Water Powers

The recent proposal of Governor Dix to abolish the New York State Water Supply Commission and the renewed activity on the part of the New York Board of Trade toward the flooding of a portion of the State forest preserve again bring to the front the important question of conserving the water powers of the State. According to official reports the water power now in use in New York State, excluding the Niagara and the St. Lawrence rivers, which are international streams, amounts to six hundred and twenty thousand horsepower, while the surveys show that there is eight hundred and eighty thousand horsepower still undeveloped. The principal reason for over half the total available water power of the State being undeveloped is the uneven stream flow; many streams which overflow their banks and waste millions of gallons into the sea every spring, shrink to mere rivulets during the dry summer months. Therefore plants located on such streams would require auxiliary steam equipments having a capacity nearly equal to the maximum power demand.

In 1907 the Water Supply Commission was created, and after three years of careful investigation submitted plans and recommendations for the construction of four great storage reservoirs to be located respectively on the Genesee, Sacandaga, Raquette and upper Hudson rivers, in addition to several smaller ones. By means of these reservoirs the stream flows could be regulated, resulting in a reduction of the great pecuniary damages caused by the periodic recurrence of floods and affording a constant flow for power purposes. It was proposed that the State issue bonds to the extent of twenty million dollars for the construction of these reservoirs and that they should be entirely under State control, the use of the water being leased for terms of fifty years to consumers at nominal charges which would be sufficient to produce a revenue to the State. A bill to this effect was introduced in the legislature but powerful influences were exerted to bring about its defeat. The power users were willing to pay an assessment sufficient to meet, in fifty years, the interest and sinking-fund charges on the bonds, but they insisted upon the right to use the water without charge and in perpetuity after the State had been reimbursed for its outlay.

Later the power users induced the legislature to pass a bill granting their demands through an amendment of the "River Improvement Act" but Governor Hughes vetoed it. The next step in this direction was an amendment to the constitution, introduced by Assemblyman Merritt, which provided for the flooding and the construction of storage reservoirs in the forest preserve, but this was worded so as to ignore any revenue to the State from the power development. This amendment must be approved by another legislature and then submitted to popular vote before it can become effective, but it is hoped that its shortcomings will have been recognized before that time arrives.

A comprehensive development of the available water powers would, undoubtedly, be a great boon to the manufacturing industries in western and northern New York. At the same time, the interests of the people at large make it imperative that such developments must be entirely under State control and produce a fixed revenue besides. This is especially important in view of the fact that water-power privileges, amounting to two hundred thousand horsepower at Niagara Falls alone, were given away to private individuals before the State awoke to the necessity of changing its policy. One of the strongest arguments in favor of State control is that it would place the water at the disposal of anyone willing to pay for it, and thus guard against monopolistic control, provided the *proper form of contract* and impartial administration are applied.

While it is conceded that the best interests of the State demand the adoption of a policy as herein outlined, the extent to which actual construction should be carried on at present demands careful consideration. Certain groups of individuals are advocating its immediate application to all the undeveloped water powers of the State; this would include the clearing and flooding of several hundred thousand acres of State forest lands. Yet there is no guarantee that a large part of the power thus made available would be used in the near future, and the people of the State would be carrying the burden of expense until such time as the utilization of all the power would make the investment self-supporting. This phase of the subject is important in view of the fact that New York City would bear nearly three-fourths of the expense and would be only remotely benefited by the results. Therefore, it is expedient that for the present, storage reservoirs be built only where there are prospects for the immediate sale of the power produced.

The Proof of the Pudding

Suppose you were the owner or manager of a mill and upon the recommendation of your master mechanic had put a device upon your boilers which produced a large saving in coal. If tests made and reported by the master mechanic were criticized as nonsensical and impossible, if engineers and physicists proved by figures that no such results were attainable and scientists demonstrated scientifically the fallacy of the principle upon which it were based—but if your coal bills were less week after week and month after month, what would you say?

You would be apt to say that "The proof of the pudding is in the eating" and to give the inventor or the vendor of the device an enthusiastic letter of recommendation.

And it is by such a process as this that the enthusiastic and sincere indorsements which inventors and vendors of devices which contravene all the laws of physics and the principles of mechanics are obtained.

In a big New England mill, some of the boilers were equipped with a device which was supposed to decompose steam by the heat of the furnace and to add its hydrogen to the available fuel. The master mechanic tested it and reported an evaporation of over sixteen pounds of water with a pound of combustible. Engineers denied the possibility of any such a performance. Those who knew demonstrated that it cost more than it was worth to produce the hydrogen, but the treasurer said, "Here are the only figures that interest me," produced his diminished coal bills and ordered more of the devices.

What are the facts?

Here was a battery of fifteen 175-horsepower boilers, aggregating 2625 horsepower, connected to a six-foot chimney one hundred and seventy-five feet high, good, by any formula ordinarily used, for only about half that capacity. These boilers are mulling along with an insufficient air supply, doing only sixty-odd per cent. of their rated capacity, with the furnaces piled full of coal and producing gas to be sent off unburned up the chimney. This device with its steam jets is put on, the master mechanic, after "lots of trouble," gets his firemen trained to fire as directed, and behold—the diminished coal bills.

Of course, the boilers are not evaporating anything like 16.69 pounds of water per pound of coal. The master mechanic is evidently not a trained testing engineer and has fooled himself. Of course, the decomposed steam, if it really is decomposed, is of no net value as fuel.

The diminished coal bills do not establish a contravention of well known natural laws nor prove the value of a device based upon an evident fallacy. They simply do prove that the efficiency of the boiler plant has been improved and that could have been done by any change which secured an adequate draft and the same amount of drilling of the firemen, and at a cost considerably less than ten dollars per horsepower.

Smoke and CO_2 Recorders

If the smoke which comes out of a smokestack were only as heavy as it is black, and would fall down in chunks on the head of the fireman who made it, firemen would lose no time in inventing some kind of device to warn them when such an eruption was about to occur.

We have steam gages on our boilers so we may not get the pressure too high and do us an injury. We have water glasses to warn us not to get the water too low, and now we want some simple apparatus to determine the percentage of CO_2 in the products of combustion and to determine their temperature so that we may be warned against the production of black smoke. Of course, we have the CO_2 meter and the pyrometer at the present time, but the cost, the delicacy and the unfamiliarity of the ordinary operator with either the instrument or the deduction of applicable knowledge from its indications have hindered the wide use of such apparatus, especially in small plants. Still, the day may come when the fireman will look to his CO_2 gage and his pyrometer as confidently and intelligently as he does now to his water glass and steam gage.

In a recent test of great importance, because it was to determine the suitability of a certain boiler for use in battleships of the United States Navy, Lieutenant Commander Dinger, one of the board of naval officers in charge of the test, in referring to the use of the CO_2 meter, said:

"The fireman soon became very much interested in the results of the gas analysis, and realized the value of so firing as to maintain as high a percentage of CO_2 as possible. This interest manifested itself very early in the tests, in the decreased density of the smoke escaping from the stack."

The foregoing remark in regard to the decreased density of smoke is of particular interest at the present time while cities all over the country are laboring to prevent smoke by the use of ordinances.

Compression as a corrective of clearance losses is gradually losing its hold. Prof. R. C. Carpenter in an article on "Compression" in *The Sibley Journal* says: "I have reached the conclusion that the loss of work caused by compression may in practice offset the gains which would otherwise be produced. The reason why the practical engine shows no improvement in economy with increase of compression is not clearly known. There is need for investigation and research of a high order before general laws or conclusions can be stated."

He quotes Professor Jacobus who, in a paper presented to the American Society of Mechanical Engineers, said: "The experiments prove that for either equal amounts of work produced or for equal points of cutoff the cushion steam in an engine should not in general be compressed as high as the initial pressure in order to obtain the best economy, but to some lower pressure, thus verifying conclusions arrived at by theory."

According to the official estimates of the Department of the Interior, the available water power in Canada is capable of developing more than twenty-five million horsepower annually; which, if produced from coal, would represent a consumption of approximately five hundred and fifty million tons per annum. This is excellent data for those individuals who are looking forward with so much apprehension to the time when the coal supply shall have been exhausted.

The pioneers of the air are sacrificing their lives freely in the cause of future navigation in the ocean of space, says the daily press. That is no reason, however, why an engineer should screw down the safety valves on his boiler to keep it from blowing off steam.

It is better that an engineer should know all about a safety valve than enough about hyperbolic logarithms to get by the examiner.

Inquiries of General Interest

Lap Crack

What is a lap crack in a boiler?

P. C. V.

It is a crack in that part of the sheet that laps over the other and extends along near the line of rivets.

Braces in Heine Boiler

Has the Heine boiler any braces and, if so, where?

B. H. B.

There are braces extending across the opening from the drum into the water legs and the flat surfaces of the water legs are supported by staybolts.

Mud Drum Nipples

If the nipples between the headers and the mud drum of a water-tube boiler are renewed and leak after repeated rolling, what can be done to stop the leaking?

M. D. N.

Get a mechanic who knows how to do tube expanding intelligently.

Advantage of Butt and Strap Joints

If a double-riveted lap seam has an efficiency of 75 per cent. and a double-strap and butt joint has the same strength, what is the advantage of the butt joint over the other?

B. S. J.

In the boiler with a lap seam the shell is never round, and as the pressure tends to make it round the sheet bends near the lap, and the repeated bending which takes place at every change of pressure, however slight, finally cracks the sheet. In the boiler with the butt joint the shell may be made round at the start and no change of pressure will alter its shape and start a crack. It is believed that no boiler having a double-strap butt joint has ever exploded.

Pump Compression Valve

If the compression valve on a duplex pump is closed, what effect does it have?

D. C. V.

The compression valve controls a passage between the steam and the exhaust port in the cylinder and when closed prevents steam from flowing from the steam port to the exhaust through this passage after the piston has covered the exhaust port. Thus considerable steam is trapped in the cylinder and compressed, shortening the stroke of the piston.

Questions are not answered unless accompanied by the name and address of the inquirer. This page is for you when stuck—use it

Factor of Safety and Water Pressure

If, with a factor of safety of 5, a boiler has a working pressure of 150 pounds, how much cold-water pressure will it stand?

S. W. P.

With a factor of safety of 5, the calculated strength of the boiler would be 750 pounds, and the effect of internal pressure would be the same whether produced by steam or water. If tested by hydrostatic pressure, it would be carried to 50 per cent. above the working pressure, or, in this case, to 225 pounds.

Hunting of Engine Governor

What is the probable cause of "hunting" by a Corliss engine governor?

H. E. G.

Undue friction between the moving parts; too heavy oil in the dashpot, or oil on the belt making it slip.

Position of Eccentrics

With two eccentrics on a Corliss engine, the steam eccentric moving in the direction of rotation to open the valve and the exhaust eccentric in the opposite direction to open the exhaust valves, what will be their relative positions on the shaft?

P. O. E.

Both eccentrics must rotate in the same direction with the shaft. If the steam eccentric is directly connected, it must be set 90 degrees plus the angular movement necessary to overcome the effects of the lap and lead of the valves ahead of the crank in the direction of rotation. If the exhaust eccentric is indirectly connected to the valves, it must be set 90 degrees minus the lap and lead of the valves behind the crank.

Pounding in Low-Pressure Cylinder

In starting up a cross-compound Corliss engine there is a pound in the low-pressure cylinder which seems to be all over the cylinder. But when it is up to speed with the load on, it runs quietly. The same thing happens in shutting down after the load is thrown off. What causes the pound?

P. L. C.

It is probably caused by too high compression. When starting, the receiver pressure is low and the excessive compression in the cylinder forces the inlet valves from their seats and at the end of the stroke they fall into position with a bang. When the receiver pressure rises it holds the valves to their seats during compression and the engine is quiet.

Lap of Steam Valve

What is lap in a slide valve, and what is the object in giving lap?

L. S. V.

Lap is the distance the edge of the valve extends or laps over the port when it is in the middle of its travel. Lap is given for the purpose of cutting off the flow of steam to the cylinder before the stroke of the piston is completed, thus using steam a part of the stroke expansively.

Pressure in Water Main

If a standpipe 80 feet high is full of water, what will be the pressure in the main?

P. W. M.

A column of water one foot high will exert a pressure of 0.433 pound at the bottom. If the top of the water in the standpipe is 80 feet above the pressure gage, it will show a pressure of

$$0.433 \times 80 = 34.64 \text{ pounds.}$$

Reciprocal of 3.1416

In getting the circumference of a circle I saw a man divide the diameter by a number instead of multiplying. What was this number and how did he get it?

R. O. P.

He used the reciprocal of 3.1416; that is, he divided 1 by 3.1416 and obtained 0.3183 which he used as a divisor. Multiplying one number by another will produce the same result as dividing the first number by the reciprocal of the second. For instance,

$$4 \times 3.1416 = 4 \div 0.3183$$

Reciprocals are frequently used to avoid division as multiplication is a shorter and easier process. For instance, it is desired to divide 32 by 2.5. The reciprocal of 2.5 is 0.4 and

$$32 \times 0.4 = 12.8$$

is shorter than long division.

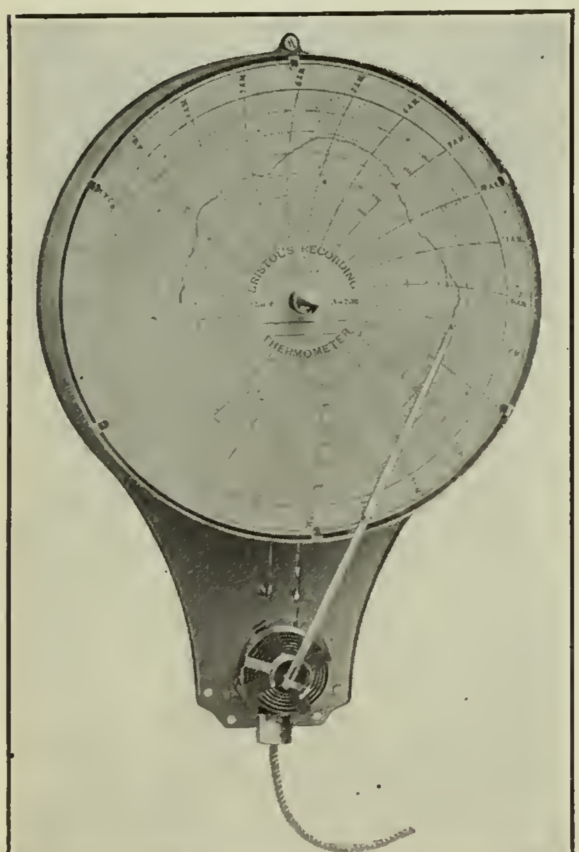
Bristol's Compensated Gas Filled Recording Thermometers

During the last fifteen years, Bristol recording thermometers have been constructed in various different forms, depending for their operation on the expansion of a liquid, the expansion of the vapor of a liquid or the expansion of a gas. These thermometers have been used for ranges of temperature up to 800 degrees Fahrenheit, but the model equipped with flexible connecting tube between the sensitive bulb and recording instrument and depending for its operation on the expansion of a vapor or a



New Bristol Recording Thermometer

gas has not until recently been adapted for recording the lower ranges of temperature.

A new compensated gas-filled recording thermometer has recently been developed for recording the lower ranges of temperature, such as atmospheric temperature, temperatures of water, temperatures of brine in refrigeration systems, etc., and found satisfactory in numerous tests. These thermometers are equipped with a patented compensating device which automatically corrects for changes of temperature at the recording instrument.

The thermometers are equipped with a sensitive bulb and flexible capillary connecting tube and a patented pressure tube, the sensitive bulb and flexible connecting tube and spiral pressure tube all being filled with an inert gas under pressure. Changes of temperature at the sensitive bulb cause corresponding changes in the pressure of the confined gas and these changes in pressure are measured and recorded by the recording instrument. The sensitive bulb is usually about 10 inches long and 3/4 inch in diameter and the volume of gas contained in this sensitive bulb is very large in proportion to the volume of gas contained in the fine capillary connecting tube between the sensitive bulb and the recording instrument, thus making the error due to changes of temperature along the connecting tube negligible.

The important new feature of this thermometer is the patented compensating attachment for the spiral pressure tube, since a thermometer equipped with this compensator gives the same readings or record when the temperature at the recording instrument changes as it would if the temperature at the recording instrument remained constant. The need for such a compensator can be illustrated by the application of a recording thermometer for recording temperature of brine in a refrigeration system. The temperature of the atmosphere at the point where the recording instrument was installed might change, although the temperature of the brine at the point where the sensitive bulb was installed remained constant, and a recording thermometer for brine temperature should, of course, be so constructed that it would be affected only by changes of temperature at the sensitive bulb.

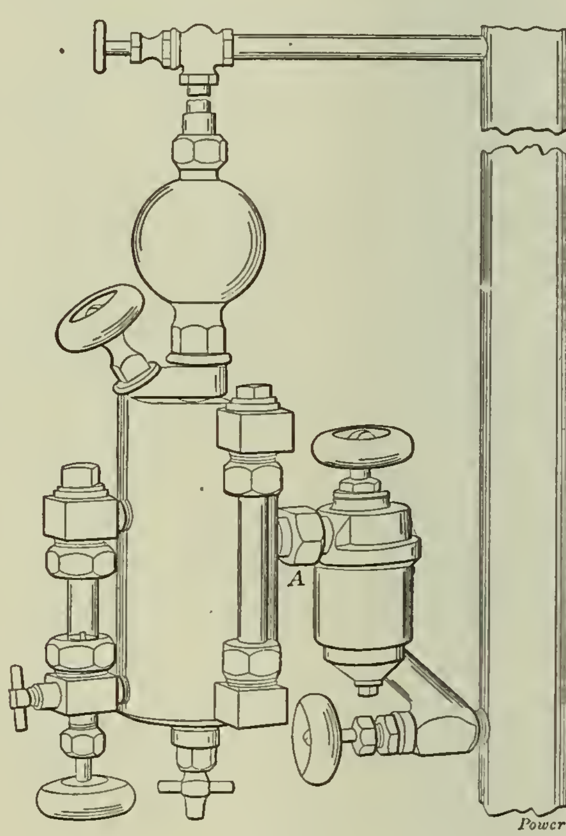
This instrument is manufactured by the Bristol Company, Waterbury, Conn.

If the wood handle has been broken from a monkey wrench, a serviceable substitute can be made by slipping a piece of hose over the wrench, then filling the hose with babbitt.

Graphoil Lubricator

The illustration shows the manner in which this lubricator is attached to a hydrostatic lubricator. The index connection *A* of the lubricator is made in various ways, so as to fit the connections of the different makes and sizes of oil lubricators.

The shutoff valve of the hydrostatic



Graphoil Lubricator

lubricator is dispensed with and the vertical and horizontal vapor pipes are changed slightly in length.

When used in connection with mechanical or simple systems of lubrication, the oil pipes are connected to the inlet connection *A* of the graphoil lubricator. This device is made by C. C. Stilwell & Co., 1215 Filbert street, Philadelphia, Penn.

A curious accident interrupted the operation of the Hudson & Manhattan power station a short time ago. The fine soot and dust from the back connections had been discharged and allowed to accumulate in the fan room beneath the boilers, and had been drawn by the fans into the air ducts and deposited as a coating of carbon upon their inside surfaces. In some unexplained manner this carbon took fire, and urged by the blast of the fans developed such a heat that the ducts were twisted all out of place, and the entire draft-producing mechanism of the station put out of business.

Features of Plant at Kodak Park Works

From the description of the oil-storage system used at the Kodak Park works embodied in the article under the above caption in the January 17 issue, the form of oil report shown herewith was inadvertently omitted.

Isolated Plant Movement Permanently Organized

A fair start in the movement toward rescuing the isolated plant from the invasion of the central station was made at a meeting held Monday evening, January 16, at the United Engineering Societies' building, 25 West Thirty-ninth street. The attendance was large and represented the interests of the manufacturers and supply men, the consulting engineers and the operating engineers. It was voted to make the organization permanent and a committee was appointed to draw up a constitution and by-laws, the object of the organization being to collect facts and data through mutual coöperation and thus make possible a concentrated effort to advance the interests of the isolated plant.

It was suggested that the membership be divided into two classes, members and associates, the former to be made up of those who would receive the greatest pecuniary benefit from the campaign, such as manufacturers and consulting engineers, and the latter to include the operating engineers and property owners. While the latter would have equal representation in the movement, they would not be called upon to subscribe so heavily as the former. This contention is justified by the fact that the majority of engineers already pay dues in a number of organizations, and making the dues in this one light, would attract a larger membership of operating engineers.

At the next meeting, to be held in the same rooms on January 30, the constitution will be acted upon and permanent officers elected.

NEW PUBLICATIONS

The second edition of BULLETIN No. 4 of the Canadian Department of Mines is just out. The title of this work is "Investigation of the Peat Bogs and Peat Industry of Canada during the Season of 1909-10." The author is Aleph Anrep, Jr., peat expert for the Canadian government.

Reports are given on various peat bogs located in the eastern section of the Dominion, including the bog at Alfred, owned by the government. A complete description of the peat plant at the bog, together with numerous illustrations, is also given.

The bulletin is accompanied by eleven plates illustrating the Alfred bog and the equipment of the peat plant.

DYNAMO BUILDING FOR AMATEURS. By Arthur J. Weed. Published by the Norman W. Henley Publishing Company, New York, 1910. Eighty-three pages, 5x7½ inches; 64 illustrations. Price, cloth $1; paper 50 cents.

The problem of designing and building a 50-watt direct-current dynamo is taken up in detail, dimensioned working drawings are given for each piece of machine work and all important operations are illustrated. With the exception of three small castings, all the parts can be made on a small foot lathe.

The treatise should prove both instructive and useful for the amateurs and students in manual-training schools as this little machine embodies the same principles as found in larger machines. When used as a motor in connection with a set of batteries it will drive a small drill press, lathe or sewing machine.

OBITUARY

Charles Hill Morgan, prominent as a mechanical engineer and manufacturer, died at his home in Worcester, Mass., January 10. Mr Morgan was born at Rochester, N. Y., Jan. 8, 1831, of New England parentage. His father was a mechanic and from him the son received that love of machinery and mechanical engineering which has been one of his most remarkable characteristics.

His first invention of note was a system of designing and constructing cam curves for looms. In 1868 he was made general superintendent of Washburn & Moen Manufacturing Company, and for eleven years was one of the company's directors. During his service with this company he improved the continuous rod-rolling mill, designed and originally constructed by George Bedson, of Manchester, Eng.

Nine years after the construction of

CHARLES HILL MORGAN

the Bedson mills, a third mill from new designs furnished by Mr Morgan was built on the Belgian and continuous plans. This mill, the result of Mr. Morgan's studies, was known as the combination mill. The third improvement was the invention by Mr Morgan of an automatic rod reel of the pouring type.

This was completed and gave a successful test in March, 1880. The automatic "laying" reel, now in common use in nearly every rod mill in the world, was the joint invention of Mr. Morgan and F. H. Daniels, another inventor of Worcester.

After 13 years of continuous service with the Washburn & Moen Company, Mr Morgan resigned his position as general superintendent in 1887. He had previously founded the Morgan Spring Company, which came into existence in 1881, and now devoted his entire attention to its development. From the manufacture of steel springs only, the scope of the business was enlarged into a general wire-mill business.

Four years later, in 1891, the Morgan Construction Company was incorporated to manufacture rolling-mill equipment and wire-drawing machinery. The work of Mr. Morgan and his associates in this company has been most successful and their designs of machinery have been widely adopted.

Besides his executive work, Mr. Morgan found time to become interested in the Worcester Polytechnic Institute, with which he has been connected in an official capacity for many years. He was, up to the time of his death, a trustee of the corporation, as well as being one of the active workers on the shop committee of the Institute.

He became a member of the American Society of Mechanical Engineers in 1881, the year following the society's establishment. He served as manager from 1884 to 1887, and was honored by an election as president of that society for the term 1899-1900. He was also a member of the American Institute of Mining Engineers.

While an engineer of exceptional ability and wide-spread influence, he has always been unassuming and never made the least effort to obtain recognition. He had a large circle of friends in Europe, where he spent much time in travel. In 1900 Mr. Morgan was elected to honorary membership in the Société des Ingenieurs Civil de France, and he was for years a member of the British Iron and Steel Institute.

His principal monument is the large number of young men he has helped. He was never too busy to see a young man and none ever left his presence without being richer and stronger in ambition and courage.

NEW INVENTIONS

Printed copies of patents are furnished by the Patent Office at 5c. each. Address the Commissioner of Patents, Washington, D. C.

PRIME MOVERS

GAS ENGINE. Henry K. Holsman, Chicago, Ill. 980,263.

INTERNAL COMBUSTION ENGINE. Henry L. F. Trebert, Rochester, N. Y. 980,366.

ROTARY ENGINE. William Birrell and James Birrell, Carbonado, Wash. 980,402.

GAS ENGINE. Otto J. Kirchen, Hancock, Mich. 980,423.

HYDRAULIC ENGINE. August Sundh, Yonkers, N. Y. 980,449.

ROTARY CYLINDER EXPLOSION ENGINE. Clyde J. Coleman, New York, N. Y., assignor to Rockaway Automobile Company, Rockaway, N. J., a Corporation of New Jersey. 980,491.

INTERNAL COMBUSTION ENGINE. Joseph S. Cortelyou, Brooklyn, N. Y. 980,494.

STEAM TURBINE. Ellis F. Edgar, Woodbridge, N. J. 980,504.

ROTARY INTERNAL COMBUSTION ENGINE. Eric Harald Ewertz, Wollaston, Mass. 980,506.

INTERNAL COMBUSTION ENGINE. Olof Ohlsson, Södertelje, Sweden. 980,552.

TURBINE. Joseph Knight, Holyhead, Anglesey, England. 980,644.

WATER WHEEL. Frederick Overfield, Cornwall, N. Y. 980,666.

WATER WHEEL. William C. Turner, Casey, Ill. 980,708.

ROTARY ENGINE. Paul Glamzo, New York, N. Y., assignor of one-half to Anton Razutocitch, Brooklyn, N. Y., and one-fourth to Baltrus S. Yankaus, New York, N. Y. 980,771.

INTERNAL COMBUSTION ENGINE. Otto Kraus, New York, N. Y., assignor to Kraus Engine Company, a Corporation of New York. 980,801.

BOILERS, FURNACES AND GAS PRODUCERS

FIRE GRATE. Ebenezer Hall-Brown, Kelvinside, Glasgow, Scotland. 980,247.

GRATE. James Walp, Allentown, Penn., assignor to Clara C. Walp, Allentown, Penn. 980,370.

GAS PRODUCER. Charles F. Miller, Pittsburg, Penn., assignor to the Westinghouse Machine Company, a Corporation of Pennsylvania. 980,660.

POWER PLANT AUXILIARIES AND APPLIANCES

LUBRICATING SYSTEM. Leon Alleman, Rochester, Penn. 980,178.

PUMP VALVE. John J. Ballard and Frank W. Parsons, Newark Valley, N. Y. 980,184.

WATER-LEVEL REGULATOR. Joseph E. De Bisschop, New Britain, Conn. 980,214.

SELF-CENTERING SHAFT PACKING. Edmund H. Farquhar, Schenectady, N. Y., assignor to General Electric Company, a Corporation of New York. 980,231.

PIPE COUPLING. John N. Goodall, Portsmouth, N. H., assignor, by mesne assignments, to Goodall Manufacturing Company, a Corporation of Maine. 980,245.

TURBINE BUCKET. Ernst Kallberg, Berlin, Germany, assignors to General Electric Company, a Corporation of New York. 980,283.

DRAFT REGULATOR. Theodore G. Meas, Lansing, Mich. 980,317.

OIL-CAN INDICATOR. Charles Scurlock, Pasadena, Cal. 980,348.

HOSE CONNECTION. Ira H. Spencer, Hartford, Conn., assignor to the Spencer Turbine Cleaner Company, Hartford, Conn., a Corporation of Connecticut. 980,355.

BLOWOFF VALVE. Anthony Nicholas Anderson, Albany, Ga., and Frederick W. Frank, Wilkes-Barre, Penn. 980,392.

GOVERNING MECHANISM FOR ELASTIC FLUID TURBINES. John G. Callan, Nahant, Mass., assignor to General Electric Company, a Corporation of New York. 980,487.

JOURNAL-BOX LUBRICANT DEVICE. Charles B. Coon, Evanston, Ill. 980,492.

DEFLECTOR FOR OIL BURNERS. Frederic A. Curtis, Toledo, Ohio, assignor, by mesne assignments, to the Steel Mantle Light Company, Toledo, Ohio, a Corporation of Ohio. 980,497.

TURBINE BUCKET. Edwin W. Rice, Jr., Schenectady, N. Y., assignor to General Electric Company, a Corporation of New York. 980,563.

VALVE. Walter E. Barnes, Malden, Mass. 980,585.

METALLIC PACKING. Charles O. Bullock, Cleveland, Ohio, assignor to the H. W. Johns-Manville Company, Cleveland, Ohio, a Corporation of New York. 980,594.

MEANS FOR LUBRICATION OF WRIST PINS. John K. Campbell, Hartford, Conn. 980,597.

ROD PACKING. Parmer Dorsey, Hutchinson, Kan. 980,617.

WATER-LEVEL CONTROLLER. Forest A. Ray, Boston, Mass. 980,675.

STEAM TRAP. Charles E. Squires, Cleveland, Ohio. 980,694.

MOUNTING FOR FURNACE DOORS. George H. Cushing, Westfield, Mass., assignor to the H. B. Smith Company, Westfield, Mass., a Corporation. 980,764.

BOILER FURNACE. Gustav De Grahl, Wilmersdorf, near Berlin, Germany. 980,772.

FIRE DOOR FOR BOILER FURNACES. Gustav De Grahl, Zehlendorf, near Berlin, Germany. 980,773.

ELECTRICAL INVENTIONS AND APPLICATIONS

SYNCHRONOUS DYNAMO ELECTRIC MACHINE. Jens Bache-Wiig, Edgewood Park, Penn., assignor to Westinghouse Electric and Manufacturing Company, a Corporation of Pennsylvania. 980,183.

ELECTRIC SWITCH. Arthur C. Eastwood, Cleveland, Ohio, assignor to the Electric Controller and Manufacturing Company, Cleveland, Ohio, a Corporation of Ohio. 980,221.

ELECTRIC SIGNALING APPARATUS. Roy A. Wilhite, Indianapolis, Ind. 980,380.

MOTOR-CONTROLLED SWITCH. Alfred James Barlow, Tottenham, England, assignor of two-thirds to Electromotor Equipment Company, Ltd., London, England. 980,475.

ENGINEERING SOCIETIES

AMERICAN SOCIETY OF MECHANICAL ENGINEERS

Pres., Col. E. D. Meier; sec., Calvin W. Rice, Engineering Societies building, 29 West 39th St., New York. Monthly meetings in New York City.

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

Pres., Dugald C. Jackson; sec., Ralph W. Pope, 33 W. Thirty-ninth St., New York. Meetings monthly.

NATIONAL ELECTRIC LIGHT ASSOCIATION

Pres., Frank W. Frueauff; sec., T. C. Martin, 31 West Thirty-ninth St., New York.

AMERICAN SOCIETY OF NAVAL ENGINEERS

Pres., Engineer-in-Chief Hutch I. Cone, U. S. N.; sec. and treas., Lieutenant Henry C. Dinger, U. S. N., Bureau of Steam Engineering, Navy Department, Washington, D. C.

AMERICAN BOILER MANUFACTURERS' ASSOCIATION

Pres., E. D. Meier, 11 Broadway, New York; sec., J. D. Farasey, cor. 37th St. and Erie Railroad, Cleveland, O. Next meeting to be held September, 1911, in Boston, Mass.

WESTERN SOCIETY OF ENGINEERS

Pres., J. W. Alvord; sec., J. H. Warder, 1735 Monadnock Block, Chicago, Ill.

ENGINEERS' SOCIETY OF WESTERN PENNSYLVANIA

Pres., E. K. Morse; sec., E. K. Hiles, Oliver building, Pittsburg, Penn. Meetings 1st and 3d Tuesdays.

AMERICAN SOCIETY OF HEATING AND VENTILATING ENGINEERS.

Pres., Prof. J. D. Hoffman; sec., William M. Mackay, P. O. Box 1818, New York City.

NATIONAL ASSOCIATION OF STATIONARY ENGINEERS

Pres., Carl S. Pearse, Denver, Colo.; sec., F. W. Raven, 325 Dearborn street, Chicago, Ill. Next convention, Cincinnati, Ohio.

AMERICAN ORDER OF STEAM ENGINEERS

Supr. Chief Engr., Frederick Markoe, Philadelphia, Pa.; Supr. Cor. Engr., William S. Wetzler, 753 N. Forty-fourth St., Philadelphia, Pa. Next meeting at Philadelphia, June, 1911.

NATIONAL MARINE ENGINEERS BENEFICIAL ASSOCIATIONS

Pres., William F. Yates, New York, N. Y.; sec., George A. Grubb, 1040 Dakin street, Chicago, Ill.

INTERNAL COMBUSTION ENGINEERS' ASSOCIATION.

Pres., Arthur J. Frith; sec., Charles Kratsch, 416 W. Indiana St., Chicago. Meetings the second Friday in each month at Fraternity Halls, Chicago.

UNIVERSAL CRAFTSMEN COUNCIL OF ENGINEERS

Grand Worthy Chief, John Cope; sec., J. U. Bunce, Hotel Statler, Buffalo, N. Y. Next annual meeting in Philadelphia, Penn., week commencing Monday, August 7, 1911.

OHIO SOCIETY OF MECHANICAL ELECTRICAL AND STEAM ENGINEERS

Pres., O. F. Rabbe; acting sec., Charles P. Crowe, Ohio State University, Columbus, Ohio. Next meeting, Youngstown, Ohio, May 18 and 19, 1911.

INTERNATIONAL MASTER BOILER MAKERS' ASSOCIATION

Pres., A. N. Lucas; sec., Harry D. Vaught, 95 Liberty street, New York. Next meeting at Omaha, Neb., May, 1911.

INTERNATIONAL UNION OF STEAM ENGINEERS

Pres., Matt. Comerford; sec., J. G. Hannahan, Chicago, Ill. Next meeting at St. Paul, Minn., September, 1911.

NATIONAL DISTRICT HEATING ASSOCIATION

Pres., G. W. Wright, Baltimore, Md.; sec. and treas., D. L. Gaskill, Greenville, O.

POWER

NEW YORK, JANUARY 31, 1911

THERE is a right and a wrong way of doing most everything. In fact, there often are several wrong ways of doing a given thing.

Usually, the discovery and use of the *one* right way only come after considerable study, experience and practice.

What a masterpiece of skill is necessary to dock successfully a great ocean liner of perhaps twenty-thousand tons displacement. Yet, the feat is accomplished every day in the year without anyone making a particular "noise" about it. The reason that the operation is successful so often is that the men intrusted with the task know the right way in which to do it as the result of years of training.

In the power plant there are a thousand and one operations, both simple and difficult, for the performance of each of which there is one *right* way.

Bring a barbarian into a plant and set him to work tightening up a one-half inch cap screw, for instance. If the screw happened to be a bit rusted and he could not turn it easily with his fingers it is only natural to expect that he would take the biggest wrench in the place to it, rather than put a "bit" of oil on the threads, start it right and use a suitable sized wrench to turn it home.

The barbarian is accustomed to accomplishing things by brute strength rather than by the use of intelligence.

The equipment under the care of some engineers lasts for a remarkably large number of years and gives efficient service during all of the time. On the other hand, the same kind and grade of equipment under men of another type has but a brief and riotous career full of wastefulness.

The reason for this is that the engineers of the former class use intelligence and care in operating the machine, not abuse and neglect. They see to it that each machine is amply lubricated and kept at least decently clean. Further, they make repairs promptly and thoroughly, realizing that "a stitch in time saves nine" and that "a thing worth doing is worth doing well."

And it pays—in the longevity of the apparatus and the uniformly good service which it gives.

Make the means selected for doing a given piece of work fit the purpose. Use efficient methods—efficient from every point of view, if possible.

In other words, use intelligent, civilized methods, not barbaric ones.

A 120,000 Horsepower Plant in France

By A. Grandjean

The St. Denis station supplies light and power to the city of Paris under several different phase and voltage conditions, as well as furnishing direct current for the railways. To meet these requirements several novel arrangements are made in the electrical equipment. The coal handling apparatus also embodies some notable features.

One of the largest and most important power plants in France is the St. Denis station of the Electrical Society of Paris. This is situated on the banks of the Seine between the towns of St. Ouen and St. Denis, and, in addition to supplying light and power to the greater part of Paris, also delivers about 20,000 horsepower to the Metropolitan railway of that city. At present the total output is 100,000 horsepower, but after the additions, which are now in the course of construction, have been completed, the station will have a capacity of 120,000 horsepower.

From Figs. 1 and 4 it will be seen that the general layout of the plant is somewhat different from that ordinarily met with. Owing to the large area available it is spread out considerably, the building covering approximately 160,000 square feet, and by having the coal bunkers in separate buildings, the hight of the boiler house is made much less than is the usual practice.

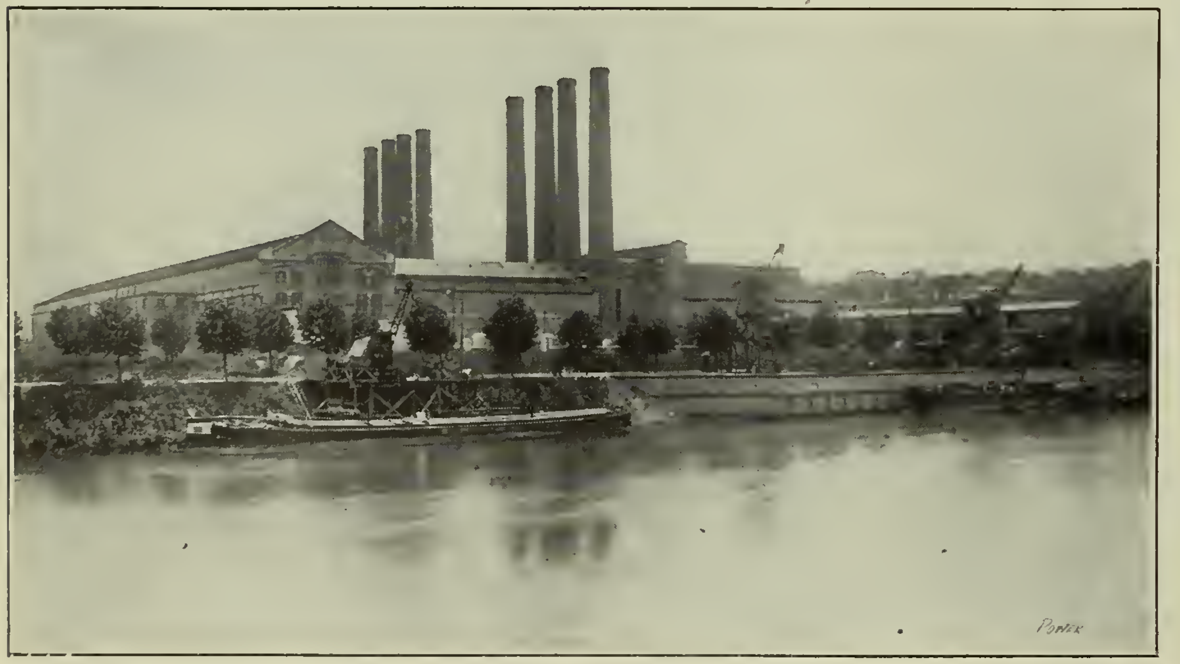

Fig. 1. Exterior View of Plant

Coal-handling Apparatus

One of the most interesting features of the installation is the means for handling coal. This is brought by scows direct from the collieries to a concrete wharf, in front of the power house. Two electrically operated traveling cranes, see Fig. 3, with clam-shell buckets pick the coal from the scows and deliver it into automatic weighing hoppers, one attached to each crane. And from each hopper it is discharged onto a conveyer, running parallel to and over the crane track. At the end of this conveyer the coal passes through a transfer hopper and is elevated to a second conveyer, running at right angles to the first and passing between the boiler houses and the coal bins of each group. This second conveyer consists of a roller chain carrying pivoted steel buckets,

Fig. 3. Method of Unloading Barges

which are hung so as to always remain in an upright position, regardless of the direction in which the chain is traveling. Each bucket is provided with a cam by means of which it may be tipped at any point in its travel. Passing over and under the aisles between each two rows of boilers and extending over and under the coal bins is a third conveyer, by which coal may be transferred from the second conveyer to the bin or to the hoppers over the boilers, or can be delivered directly from the bins to the hoppers. This ar-

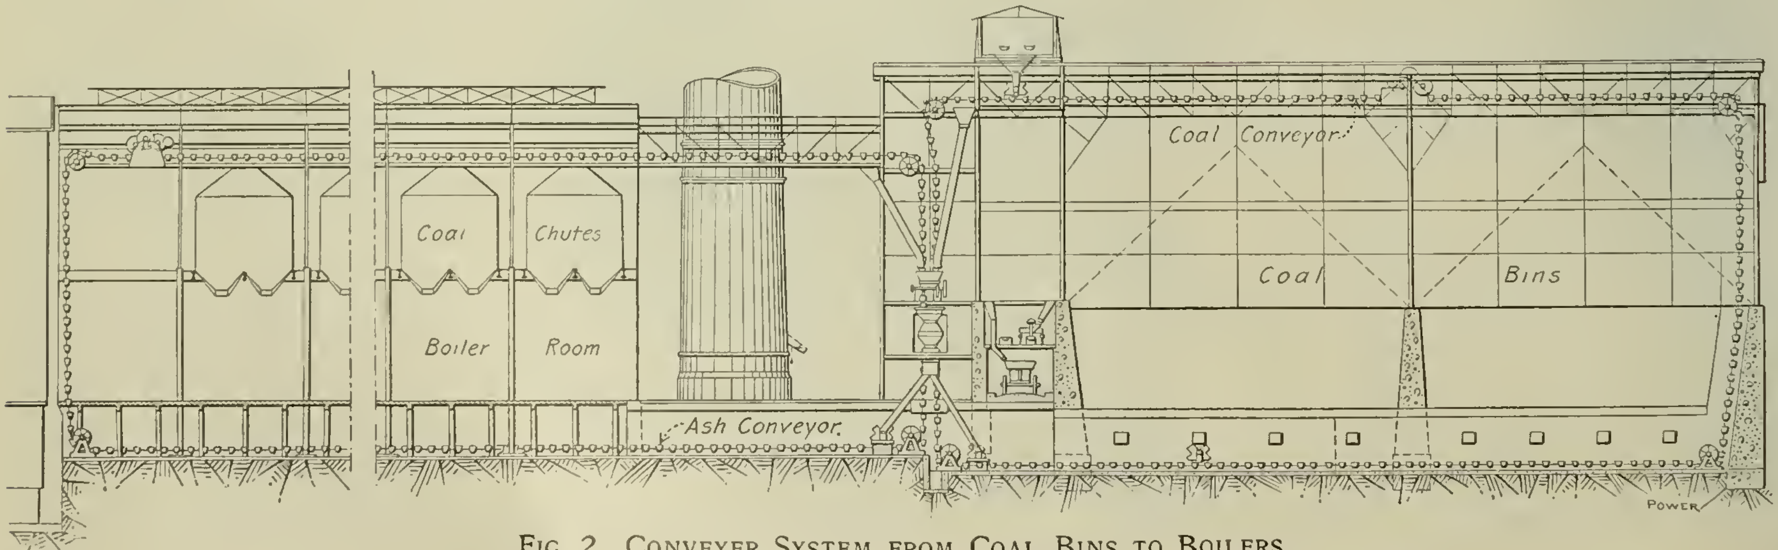

Fig. 2. Conveyer System from Coal Bins to Boilers

rangement is shown in Fig. 2. Fig. 5 is a view of the conveyer over the boilers. This conveyer in passing under the boilers is also used to carry away the ashes and discharge them into dump cars. The system has a capacity for handling 40 tons of coal per hour and, when unloading, only three men are required to each scow, one man operating the crane and two men to guide the buckets. From the time the coal has been delivered by the buckets, no further handling by hand is required. The total length of conveyer at the plant amounts to nearly 8000 feet.

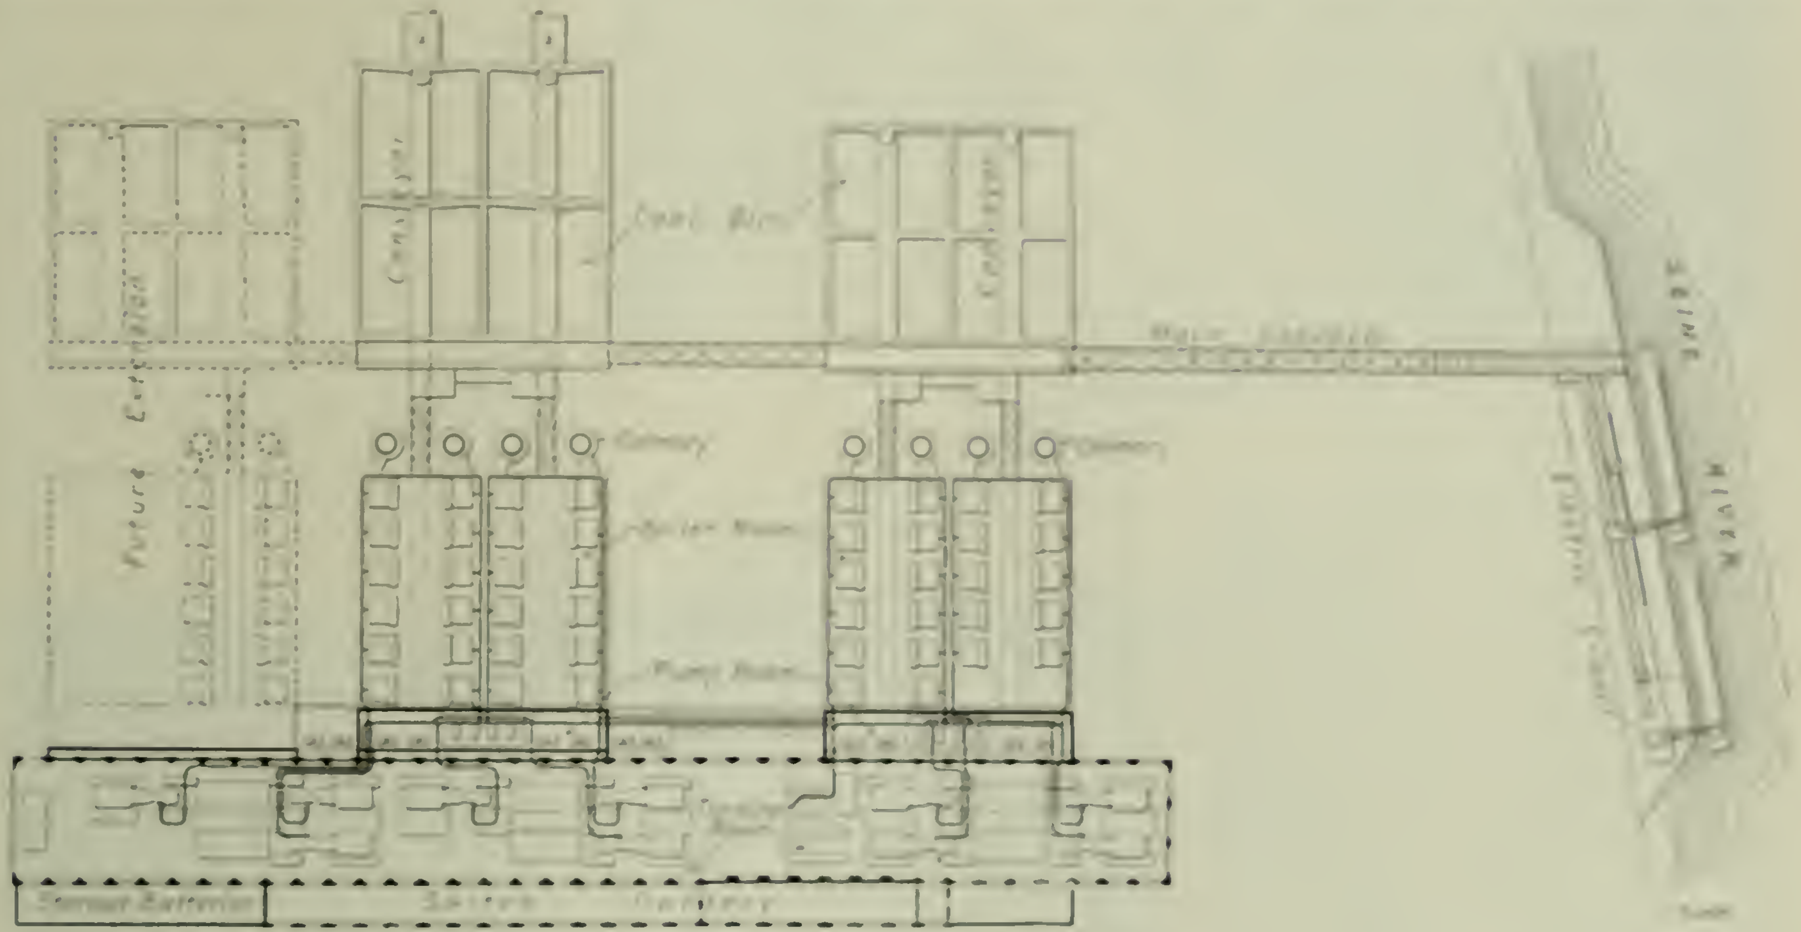

FIG. 4. GENERAL LAYOUT OF PLANT

Boilers

At present there are forty-six 450-horsepower boilers of the Babcock & Wilcox marine type, arranged in batteries as shown in Fig. 4; but when the additions now under way are completed, the number will be increased to 58. Chain-grate stokers are employed, two to each boiler, and, in addition to the draft furnished by the 180-foot chimneys, this is supplemented in four of the batteries by a forced-draft system. The feed water is heated by Green economizers located over the boilers, and Babcock & Wilcox superheaters attached to each boiler are capable of raising the temperature of the steam to 662 degrees Fahrenheit, the superheaters being arranged so that the temperature may be varied through a range of 100 degrees. Fig. 7 shows a sectional elevation through one of the boilers and Fig. 6 a view of one of the boiler rooms.

Piping and Auxiliaries

The turbines are mounted in groups, thus greatly simplifying the piping layout. Steel piping is employed for all high-pressure steam and riveted sheet-iron pipe for the exhaust steam. The condensing water is fed from the condensers by submerged pipes working on a siphon, so that the work of the circulating pumps is reduced.

The surface condensers are located below the turbines and the pump room is situated between the boiler room and the turbine room. The circulating pumps are of the vertical centrifugal type, driven by motors, and the air pumps are of the three-cylinder plunger type, also driven by motors.

FIG. 5. CONVEYER OVER BOILERS

FIG. 6. VIEW OF THE BOILER ROOM

Main Units

Some complication arose from the fact that three-phase alternating currents at about 10,000 volts and 25 cycles were required for traction purposes; two-phase

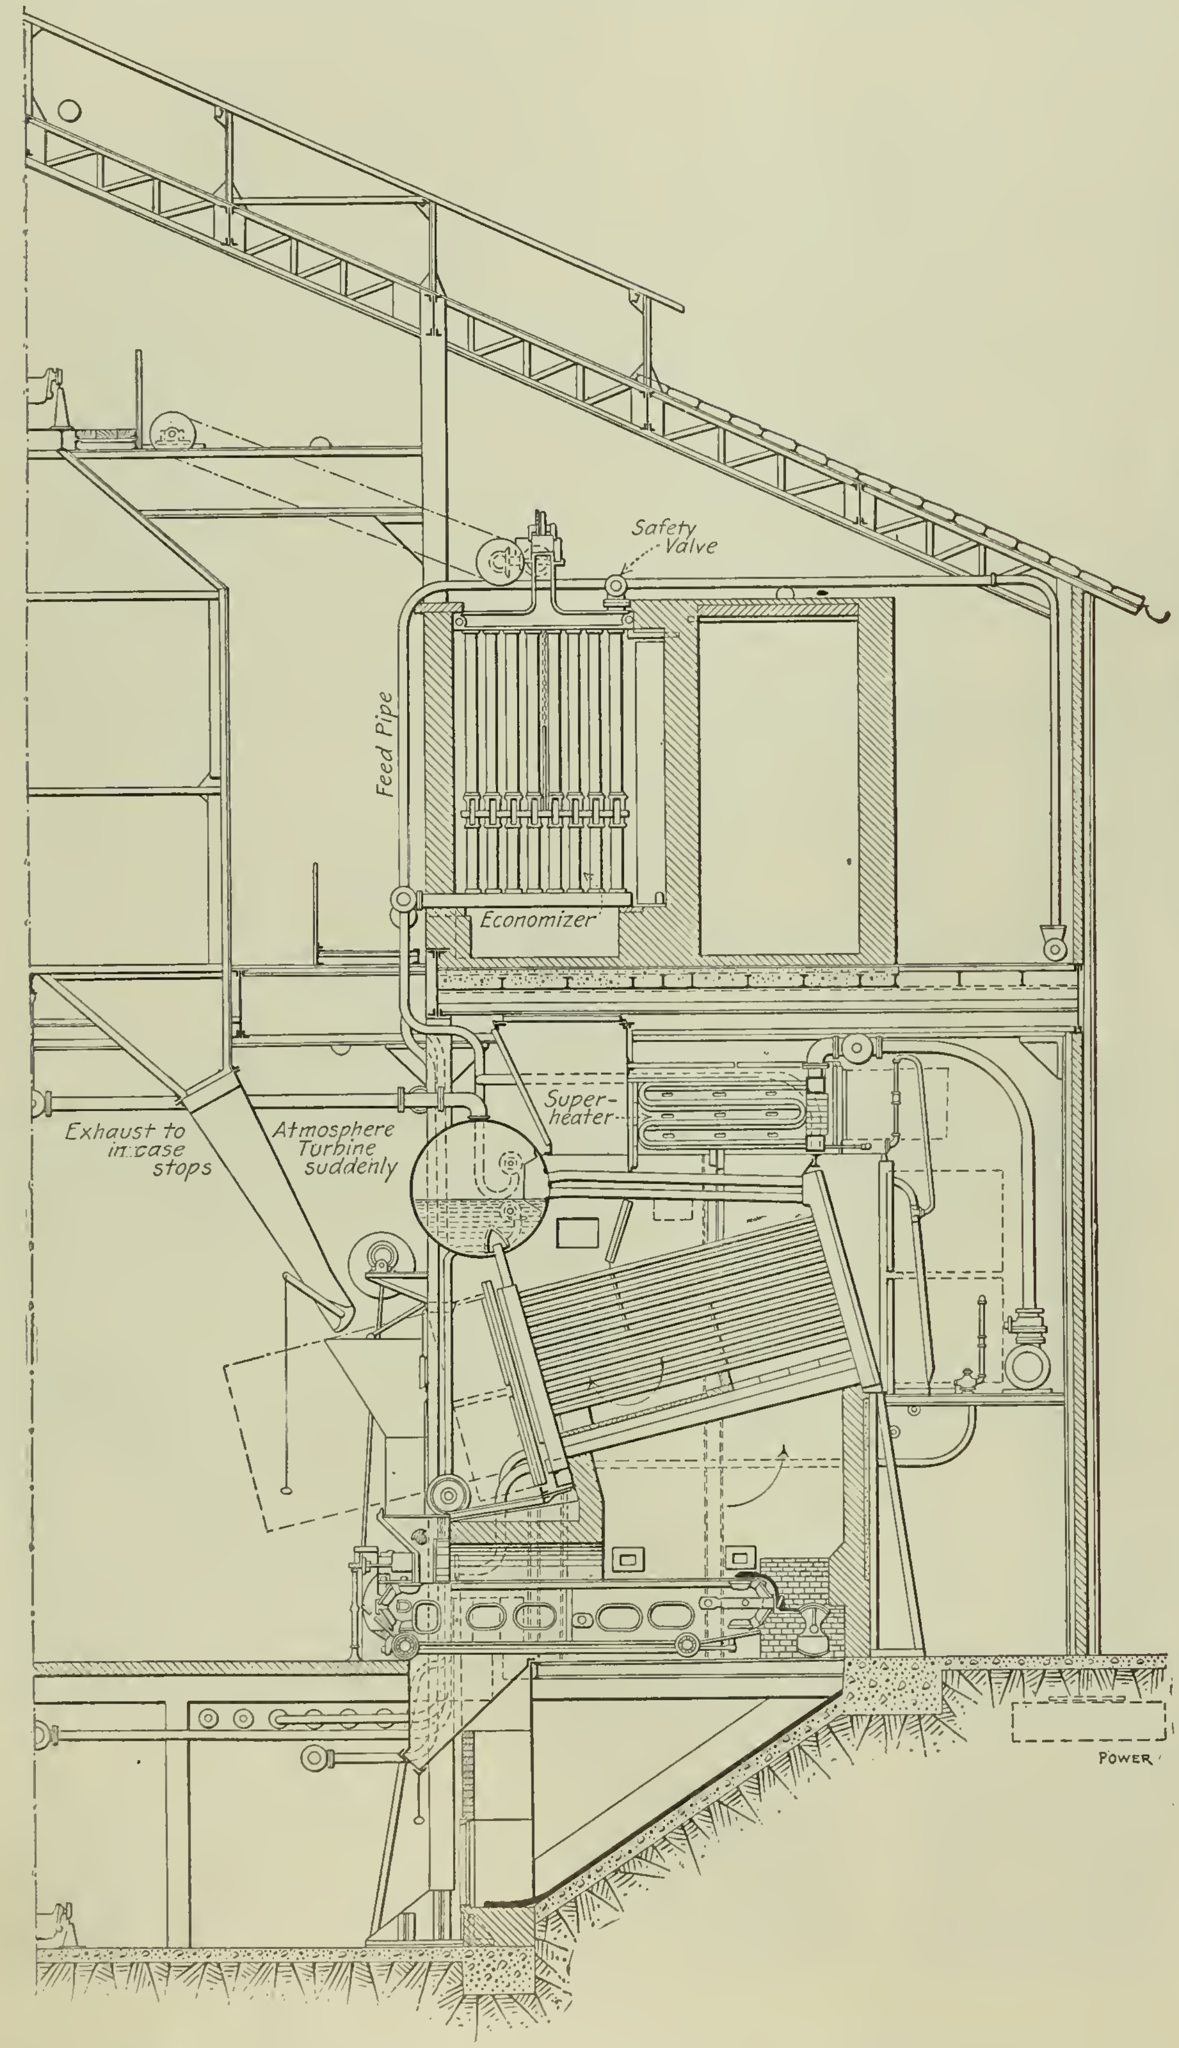

Fig. 7. Section through Half of Boiler Room

42-cycle currents at 12,300 volts for lighting; three-phase currents at 6000 volts and 42 cycles for distributions to the suburbs; direct current at 230 volts for plant service, and direct current at 550 volts for certain other traction purposes. To meet these various classes of service the following units were installed:

Four three-phase turbo-generators of 5000 to 6000 kilowatts capacity.

Four two-phase turbo-generators of 5000 to 6000 kilowatts capacity.

Two turbines, each connected to two alternators, one of which is a two-phase, 42-cycle, 12,300-volt machine and the other a two-phase, 25-cycle, 10,150-volt machine of 5000 to 6000 kilowatts capacity.

One two-phase, 25-cycle, 10,150-volt turbo-generator of 10,000 to 14,000 kilowatts capacity.

Two two-phase motor-generator sets, each of 750 kilowatts capacity, taking alternating currents at 12,300 volts and delivering direct current at 220 volts.

Two motor-generator sets of 750 kilowatts capacity, taking three-phase current at 10,150 volts and delivering direct current at 220 volts.

Two motor-generator sets of 375 kilowatts capacity, taking three-phase currents at 10,150 volts and delivering direct current at 220 volts.

One 375-kilowatt, 230-volt direct-current turbo-generator.

One storage battery of 1300 ampere-hours capacity and another of 3000 ampere-hours capacity.

Fig. 8. Switch Compartments

Two motor-generator sets for charging the storage batteries.

Two 6050- to 12,300-volt static transformers, each of 1000 kilowatts capacity.

The speed of the three-phase machines is 750 revolutions per minute and that of the two-phase machines is 835. Each turbine is provided with a Parsons speed regulator which maintains a practically constant speed in spite of the varying load, especially on those machines supplying the electric railways. The admission of steam is automatically cut off as soon as the speed of the turbine reaches 15 per cent. above normal.

In addition to the foregoing there is a special reversible motor-generator set consisting of two synchronous motors coupled together, one being fed with three-phase current at 10,150 volts and 25 cycles and the other with two-phase current at 12,500 volts and 41⅔ cycles. The three-phase motor has six poles and the two-phase motor, ten poles. As

$\frac{25}{41.66} = \frac{6}{10}$ it will be noted that both motors run at the same speed, that of 500 revolutions per minute. Therefore, it is possible, by using either of the machines as a motor or a generator to transfer available power from the three-phase machines to the two-phase circuits or *vice versa*, up to the limit of the capacity of the machine, which is 1500 kilowatts. A view of the main turbine room is shown in Fig. 9, at the right of which may be seen a large lathe used for turning down the commutators.

Switching Equipment

The high-tension switching apparatus is housed in a reinforced-concrete structure which adjoins the main turbine room. All the switch barriers and slabs are of concrete and every precaution has been taken to insure against fire. Fig. 8 is

Fig. 10. Gallery Containing Remote-Control Benches

Fig. 9. Turbine Room

a view of the oil switches, showing the track that has been provided for convenience in handling them. In the upper part of this building are located the desks containing the remote-control apparatus; these are shown in Fig. 10. The long desks on the right are for feeder control and the small ones on the left, overlooking the turbine room, are for controlling the machine switches. Each row is separated into two sections, one for two-phase and the other for three-phase currents.

On the desks are mounted signal lamps showing the position of the switches and the operation of the rheostats, these lamps being supplemented by a warning bell. With this arrangement the control of the entire high-tension switching equipment is placed under the direction of one operator. The high-tension busbars are divided into groups, the leads from each two generators connecting through oil switches to a pair of generator busbars; each pair of busbars is connected through an oil switch to a pair of feeder busbars which, in turn, connect through other switches to the feeders. These switches have time-limit control, which automatically cuts out a feeder, group or machine in the event of a short-circuit. The several sections of both the generator and the feeder busbars may be connected in parallel, the former by remote-control oil switches and the latter by disconnecting switches. This arrangement permits any section being isolated for the purpose of making repairs.

Along the side of the turbine room and raised slightly above the floor is the low-tension switchboard containing the excitation control and the various instruments. A pedestal located in front of the switchboard and opposite each unit carries a Siemen's apparatus with the wattmeters, voltmeters, ammeters and emergency interrupter for each machine. This board and the pedestals are shown in Fig. 11.

The operating force consists of three shifts of twenty men each, in addition to an engineering and superintendent's staff of eleven.

The Metropolitan Street Railway Company, of Kansas City, will install a 15,000-kilowatt, maximum rating, Curtis turbine and base condenser next summer.

Vacuum for Reciprocating Engines

By John H. Ryan

The experience of a refrigerating man with a young engineer who thought he could better the economy of his engine by increasing the vacuum to 28 inches.

Several years ago the firm by which I was employed built an ice plant in the Southern fruit belt, most of the output being used in refrigerating cars. As coal was expensive in that locality, the plant was designed to operate as economically as possible. The ice machine consisted of two single-acting compressors, driven by an 18 and 36 by 48-inch cross-compound Corliss engine, the flywheel of which was used as a main driving pulley for running, through a jack shaft, the plant auxiliaries. These consisted of a boiler-feed pump, a circulating pump, an electric generator for light and power, the air compressor and a rotary blower for circulating the freezing water.

About two years after the plant had been turned over to the owners we were requested to send a man to the plant to report upon some changes that their engineer had proposed. Upon reaching the plant, I found that there had been a change of engineers, the new man being a young fellow who had been an oiler in a large central station employing turbine units. He had previously taken a correspondence course in refrigeration and then sought a job of greater responsibility, finally landing his present position.

He began his argument for the proposed changes by stating that, although the steam consumption per horsepower-hour of this plant was as good as the turbine plant, the vacuum on the machine did not average more than 24 inches, while the turbine plant averaged 28½ inches. He had looked up the theory of the loss due to incomplete expansion and had found that if the steam in the ice plant could be expanded down to 28½ inches, the consumption would be decreased at least two pounds per horsepower-hour. According to his figures this saving in steam would be equivalent to 18 per cent. of the coal used. The owner of the plant was interested when he saw these figures and signified his willingness to take a chance, providing the machine builders would say that it was feasible. The engineer was not sure as to the cheapest way of increasing the vacuum but had thought of getting a larger air pump, a larger circulating pump and a cooling tower so that the barometric condenser could be forced to its limit. There were a number of other suggestions, such as moving the condenser nearer the low-pressure cylinder, etc. After he had said all he could think of, I started in to have my say, which was somewhat as follows:

"There are many who do not understand why a high vacuum is not as good for reciprocating engines as it is for turbines, but most of us have read or been told that with the former it does not pay to run the vacuum any higher than 26 inches, with the barometer at 30 inches.

"The expansion and compression of gases follow the same laws whether the range of pressures be high or low. For example, consider the compression in an ammonia cylinder when carrying 15 pounds back pressure and it is desired to find what the pressure in the cylinder will be at half of the compression stroke. Add the atmospheric pressure to the gage pressure and multiply the 30 by two, because the volume is halved at half stroke. This gives 60 pounds as the absolute pressure in the cylinder at half stroke. When the 15 pounds atmospheric pressure is subtracted from the 60, it will give 45 as the gage pressure at half stroke, that is, when the volume is halved.

"The same law holds true for the expansion of gases. In a compound engine with 15 pounds receiver pressure and cutting off at half stroke in the low-pressure cylinder, when this 30 pounds absolute steam pressure has expanded down to a full cylinder volume, the pressure will be halved. This is because the volume has been doubled and there will be just atmospheric pressure in the cylinder when the exhaust valve opens at the end of the stroke.

"A pound of steam at atmospheric pressure occupies about 26 cubic feet of space and that is about the capacity of the 36x48-inch low-pressure cylinder. This same pound of steam at 15 inches of vacuum occupies 53 cubic feet of space. To hold this steam the low-pressure cylinder would have to be 4 feet in diameter. At 26 inches of vacuum the volume of a pound of steam is approximately 175 cubic feet and the required cylinder diameter would be 7½ feet, and at 28 inches of vacuum the volume would be 340 cubic feet, necessitating a cylinder diameter of 10½ feet. Or, further, a 29-inch vacuum would require a 14½-foot cylinder. To attain the benefit of the extra inch of vacuum between 28 and 29 inches, the area of the cylinder must be doubled."

The engineer replied that he would be satisfied with the 28 inches; but I told him that his low-pressure cylinder was about right for 21 inches of vacuum and to expand to 28 inches would necessitate a low-pressure cylinder of 60 inches in diameter. To compensate for the attending cylinder condensation, the steam would have to be superheated 500 degrees above that corresponding to the throttle pressure. This would mean a temperature of 865 degrees Fahrenheit and it would be hard to find oil and packing to withstand this.

He accused me of not knowing what I was talking about and said that the engines of the new cotton mill in town often ran 28 inches of vacuum. I admitted that anyone could get 28 or more inches of vacuum if he had water enough and offered to wager that if they took diagrams from the mill engine when it was carrying 28 inches of vacuum that the diagrams would show the exhaust valves opening early in the stroke with the pressure in the cylinder corresponding to 28 inches of vacuum when the piston reached the end of the stroke. There would probably be more than 6 pounds absolute pressure in the low-pressure cylinder when the exhaust valve opened and all this heat would be rejected into the condenser.

He admitted that I might be right, but could not see what difference that made as the 28 inches of vacuum in the exhaust pipe would represent a removal of most of the atmospheric pressure, and he claimed that a pound of pressure removed from the front of a piston was just as good as an extra pound behind the piston. I replied that there was a big difference between the actual and theoretical mean effective pressure when an engine is run condensing. As a rule there is 5 pounds less mean effective pressure with 28 inches of vacuum than calculations would indicate.

His next question was, "What did I think of lowering the exhaust pressure by means of a larger air pump?" This is another way of wasting power. To lower the vacuum from 26 to 28 inches would require a condenser temperature 23 degrees lower and the pump would have to take out about 60 cubic feet more vapor for every pound of steam the engine used.

Our friend then got out his notebook and made these few entries: "Turbines show a gain, due to complete expansion to a high vacuum because the temperatures remain the same at each point in the turbine. They have no condensation loss. Reciprocating engines running with complete expansion to a high vacuum do not show as good results, because the loss from the cylinder condensation is high. Look up the question of B.t.u. per horsepower and see how much of the available heat in the steam I am getting. Charge the heat required to run the auxiliaries, to gain by condensing."

An Efficient Boiler Installation

By H. R. Mason

The description of a recent boiler and economizer installation embodying some novel features. The results of economic tests are given, showing that, by the adoption of these improvements, a rating 28 per cent in excess of the guarantee was attained under actual running conditions.

An efficient steam-generating equipment is the first essential to a satisfactory power plant, and this feature depends as much upon the design and arrangement of the boiler-room apparatus as upon the skill of the attendants after the plant is completed. The present article deals with the arrangement of boilers, economizers and stacks of a certain large plant which was recently completed.

The original plant consisted of three Heine boilers of 420 horsepower each, in connection with a single economizer, the boilers arranged so that each could be connected directly to one of three 500-kilowatt units. The load increased rapidly and plans were adopted for an extension of the plant by the addition of 2000-kilowatt Parsons turbines, each served by four 480-horsepower Heine boilers with individual economizers, constituting distinct units which could be operated independently from the boiler-feed pump to the condenser discharge.

The boilers were of the standard Heine type and special attention was given to the baffling, exhaustive tests being made to determine the most advantageous arrangement of baffles. It was found that in boilers of this size with only the customary top and bottom baffles, the gases followed nearly a diagonal path from the edge of the lower baffle to the edge of the top baffle, leaving a very large portion of the heating surface ineffective and resulting in excessive stack temperatures at heavy loads. This, of course, brought about a serious reduction in both efficiency and capacity, and was overcome by putting in an intermediate baffle in the following manner: The lower baffle was extended from the front tube header to a point approximately 4 feet 10 inches from the rear tube header, securing an area of about 25 square feet for the gases to leave the combustion chamber and enter the tubes. Under favorable conditions it was found that the combustion-chamber temperature approached 2000 to 2200 degrees Fahrenheit, and that there was an exceedingly rapid transfer of heat to the first tubes which the gases came in contact with. As the gases, in cooling, contract in volume in proportion to their absolute temperatures, the necessary areas and surfaces for the most effective results were easily calculated and an intermediate baffle of cast-iron plates was inserted on top of the ninth row of tubes, extending from the rear header to a point 3 feet from the front header, as shown in Fig. 1. This left an area of 18 square feet at this point for the passage of the gases, and this area was preserved from that point to the top of the stack, as it was feared that the draft would suffer through friction losses if the area were reduced sufficiently to maintain the same velocity. The top baffle was then extended from the front header to a point 3 feet from the rear header, thus reversing the ordinary arrangement. The spaces between the two drums and between the drums and the side walls was such that the breeching was carried back about 6 feet and the remaining areas of the boiler drums, having no strong circulation of gases about them probably did but little work. This amounted to less than 200 square feet and being in the coolest portion of the path of the gases, it was considered best to sacrifice this small percentage of the heating surface in order to gain the 30 or more per cent. which was lost through the usual form of baffle.

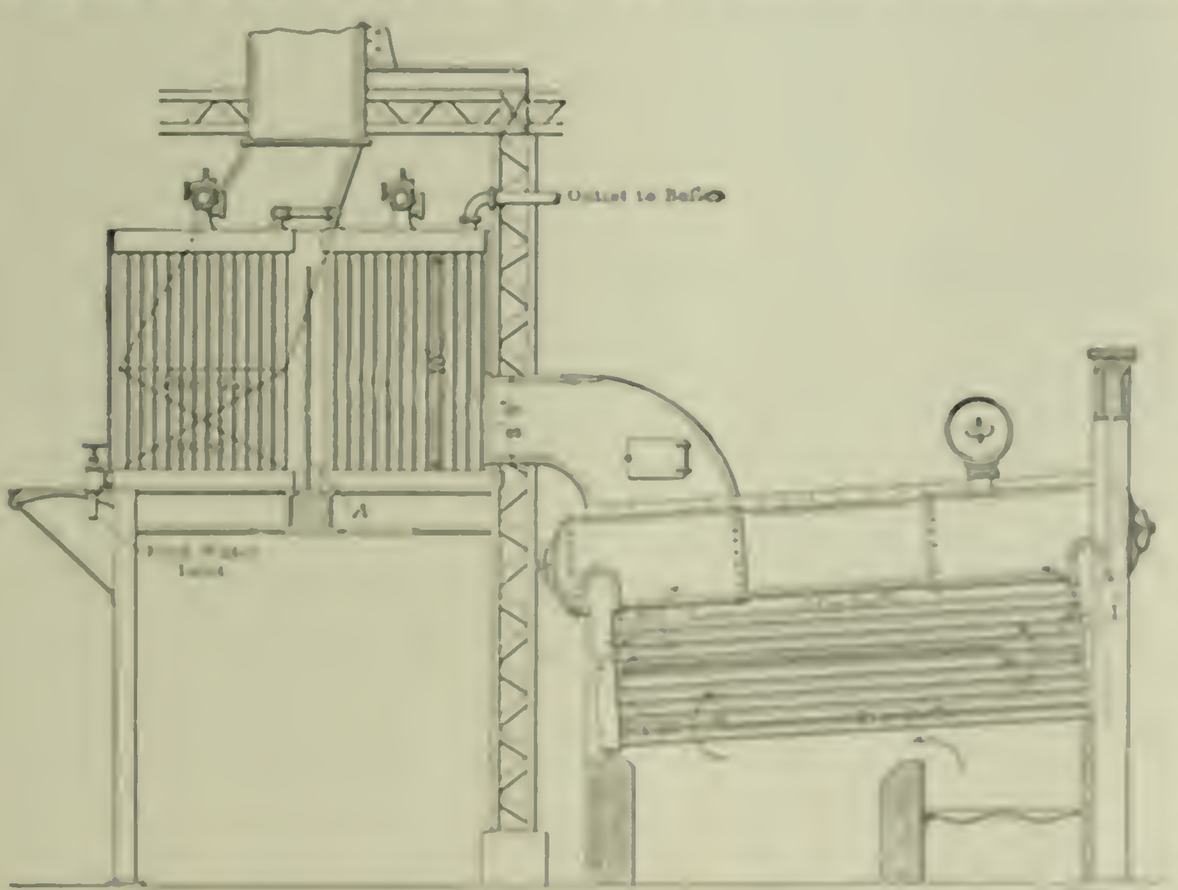

Fig. 1. Section through Boiler and Economizer

The columns supporting the front portion of the boilers extend about 22 feet above the boiler-room floor, and carry 24-inch box girders, from which the boilers are hung by yokes passing under the front end of each drum, as shown in Fig. 2. This was done to get the boiler supports away from the heat of the furnace, and also to accommodate any type of mechanical stoker which might be decided upon. The rear ends of the boilers rest upon rollers. The walls are of reinforced concrete lined with fire brick, instead of brick throughout, as is the usual custom. The rear wall is built solid, but the side walls are in sections about six feet square, separated by barriers of ½-inch sheet asbestos, as it was anticipated that undesirable cracks would form in a solid wall of such size when exposed to the varying temperatures. In two years these walls have shown very little tendency to crack, and having a hard finish, much less air passes through them than through the ordinary form of brick wall.

In the design of the breeching, economizer baffles and the uptake to the stack, special care was observed to avoid, as far as possible, all abrupt turns which would be liable to cause eddies or back drafts. The gases from each boiler are discharged into an economizer of the standard Green type, provided with mechanically operated scrapers. These economizers are supported by cast-iron columns and inclosed with a series of double sheet-iron plates, 1½ inches apart, with asbestos tamped between, as shown in Fig. 3. The gases enter near the bottom of the discharge section of the economizer and are prevented from going straight through to the stack by a cast-iron baffle plate, shown at A, Fig. 1. The boiler-feed water is delivered to the section nearest the stack and passed from the first group of sixteen sections to the second group, through return bends at the top of the economizer, and is finally discharged from the section nearest to the boiler, where the gases have the maximum temperature.

The steel stacks are 78 inches in diameter and extend 150 feet above the economizer; for the first 75 feet the metal is ¼ inch thick and 3/16 inch for the remaining distance.

Before the erection of the first set of boilers it was argued that the draft might prove insufficient, as the path of the gases seemed unduly long and tortuous, and much of it was in a horizontal plane. In practice, however, it was found that there was little more to be desired. The draft gage and pyrometer showed readings averaging substantially as follows:

	Temperature Flue Gases, Degrees Fahrenheit.	Draft, Inches.
Base of stack	300	1.25
Breeching between boiler and economizer	485	0.75
End of intermediate baffle	770	0.50
Combustion chamber (estimated)	1600	0.37
Furnace (estimated)	2100	0.25

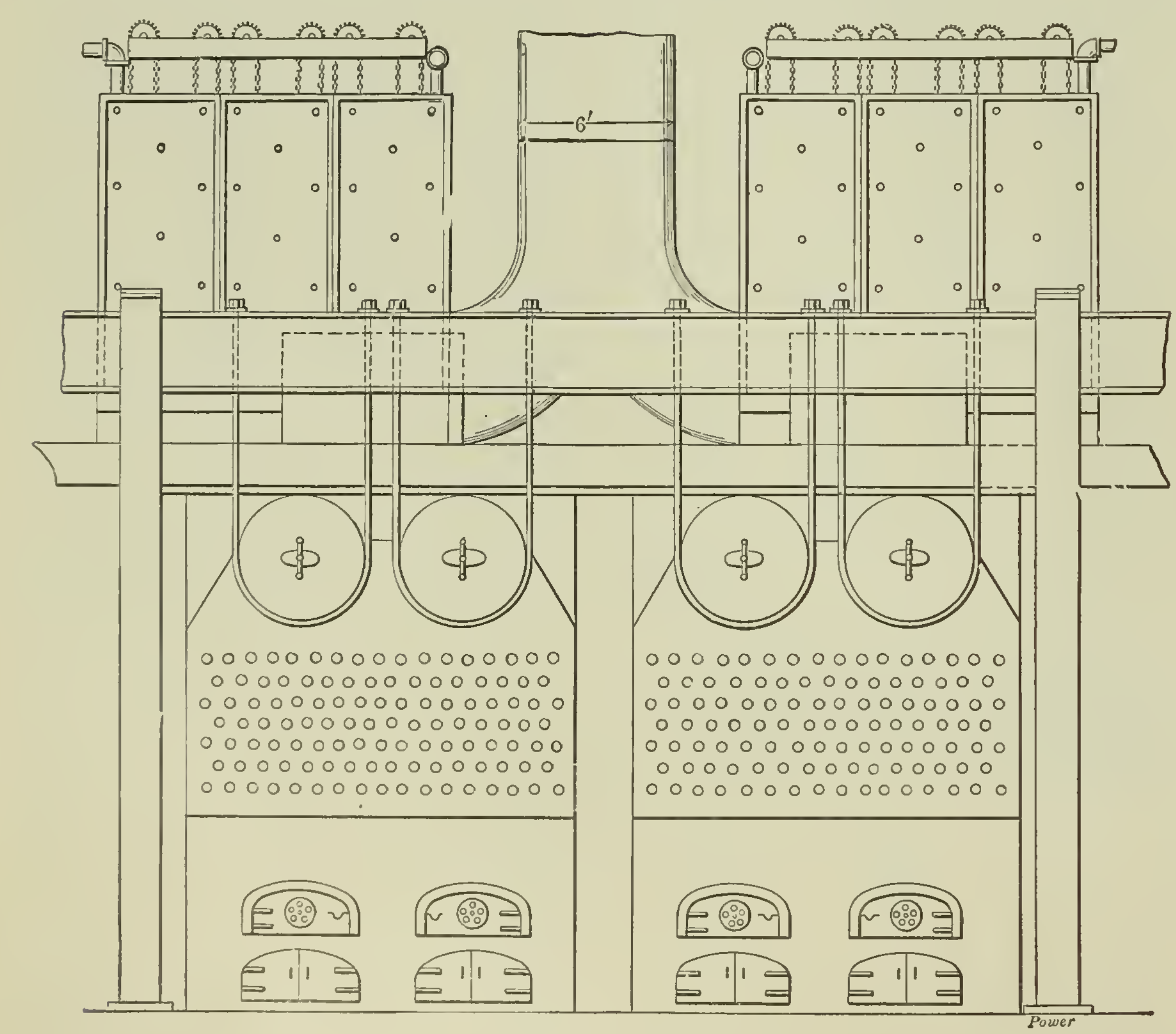

Fig. 2. Front View of Boilers

This draft proved sufficient to consume over 30 pounds of screenings per square foot of grate surface, and as the grate of each boiler is 10x7 feet, this produced ample heat with the low grade of bituminous coal to run the boilers far above their rating. The coal had a heating value of about 10,000 B.t.u., and monthly averages showed an evaporation of approximately 6 pounds of water per pound of screenings burned, or an efficiency of nearly 60 per cent. As 70 per cent. is considered very fair on test performances, this result was quite exceptional. The feed water entering the economizer averaged about 150 degrees Fahrenheit and the economizer delivered it to the boilers at temperatures varying from 240 to 300 degrees.

Following is the report of a test on one of these boilers:

RESULTS OF BOILER TEST.

Breese, Trenton Coal, Fresh Screenings, 1-inch Size.

Grate surface, 71.75 square feet.
Water heating surface, 4,820 square feet.

Total Quantities.

Duration of test, hours	9
Weight of coal as fired, pounds	21,988
Percentage of moisture in coal	6.58
Total weight of dry coal burned, pounds	20,541
Total weight of ash and refuse, pounds	3,546
Pecentage of ash and refuse to coal as fired	16.16
Percentage of combustible in ash. Not determined.	
Total weight of water fed to boiler, pounds	161,360
Quality of steam, per cent	98.8878
Water actually evaporated, pounds	159,569.7
Factor of evaporation:	
Boiler	1.071
Boiler and economizer	1.1928
Equivalent water evaporated from and at 212 degrees Fahrenheit, pounds:	
Boiler	173,930
Boiler and economizer	192,470

Hourly Quantities.

Coal consumed per hour as fired, pounds	2,443.1
Dry coal consumed per hour, pounds	2,282.4
Coal per hour per square foot grate surface, pounds	34.1
Dry coal per hour per square foot grate surface, pounds	31.8
Apparent water evaporated per hour, pounds	17,928.9
Water per hour corrected for quality of steam, pounds	17,729.0
Equivalent evaporation dry steam per hour from and at 212 degrees, pounds:	
Boiler	19,110.0
Boiler and economizer	21,147.2
Equivalent evaporation per hour per square foot heating surface, pounds:	
Boiler	3.961
Boiler and economizer	4.38

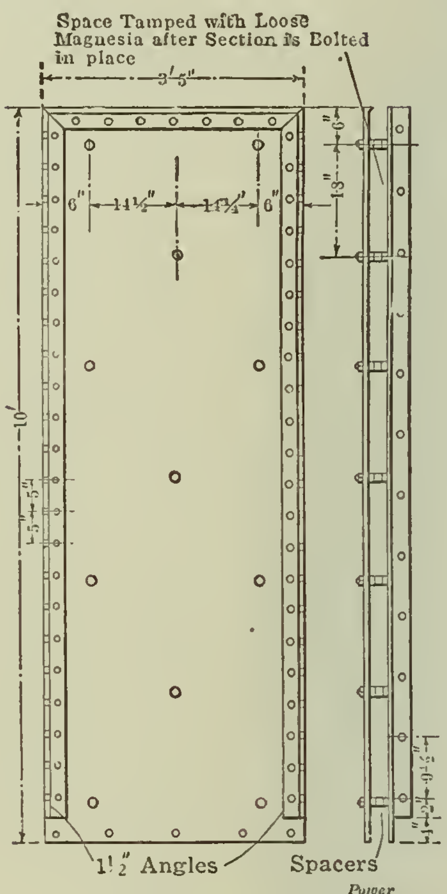

Fig. 3. Economizer Jackets

Average Pressures, Temperatures, Etc.

Steam pressure, gage	160
Temperature of feed water, degrees Fahrenheit:	
Boiler	194
Boiler and economizer	74.2
Temperature of escaping gases:	
Boiler	480
Boiler and economizer	326
Draft over fire, inches of water	0.189
Draft in breeching, inches of water	0.484
Moisture in steam, per cent	1.1122
CO_2 in flue gas, average per cent	11.35
Calorific value of coal in B.t.u	10.168.0

Horsepower.

	Boiler.	Boiler and Economizer.
Horsepower developed	560.2	619.8
Builder's rated horsepower (boiler only)	482.0	
Per cent. of rated horsepower developed	116.2	128.5

Economic Results.

	Boiler.	Boiler and Economizer.
Apparent evaporation per pound of coal as fired		7.34
Equivalent evaporation per pound coa as fired	7.82	8.65
Equivalent evaporation per pound dry coal	8.41	9.22
Efficiency of boiler, per cent	74.2	
Efficiency of boiler and economizer, per cent		80.9

This is one of a large number of tests on these boilers, most of which showed about the same general results. In these tests cold water was used, with the result that the economizer tubes sweated and gathered a coating of soot, which detracted somewhat from the efficiency of the economizer. Tests with a much better grade of coal gave results as high as 950 horsepower per boiler unit for occasional periods, with nearly the same efficiency. The test shown above was taken under conditions which were substantially the same as those under which the boilers were normally operated, and the object was to determine the most satisfactory operating conditions.

The first cost of the plant averaged very close to $10,000 per complete boiler unit, including one boiler, setting, supports, economizer and one-half the cost of one stack and its supports. The addition of the intermediate baffle increased the capacity of the boiler to a great extent, and the further addition of the economizer brought the working capacity of the unit up to nearly 650 horsepower. This brings the total cost per boiler horsepower to something over $15, which cannot be termed excessive in view of the high efficiency secured, as a very small percentage of saving in the annual coal bill of a moderately large plant will justify a large outlay of capital in improved methods of construction, provided the plant is subsequently managed in such manner as to realize this saving.

Expansions in Compound Engine

By F. R. Low

In reply to an inquiry the author tells what is meant by the number of expansions in a compound engine and in a simple way shows how the ratio is calculated.

A volume of steam is taken into the high-pressure cylinder. This volume equals the capacity of the high-pressure cylinder up to the point of cutoff and including clearance. It is eventually expanded to the full volume of the low-pressure cylinder, including its clearance. The final volume divided by the initial volume equals the "ratio of expansion," or the number of times the steam is expanded.

It is not necessary to work with actual volumes. Suppose in the accompanying diagram the stroke or displacement of the high-pressure cylinder represents 1; then the clearance volume will be directly represented by the clearance expressed in hundredths of the displacement, the volume displaced up to cutoff by the fraction of the stroke completed at that point, and the total volume up to cutoff by the sum of the two. If, for instance, the engine cuts off at quarter stroke and the clearance is 5 per cent., the volume inclosed behind the high-pressure piston will be

$$0.25 + 0.05 = 0.3$$

of the displacement of the high-pressure piston, or since that displacement is taken as unity, will be represented simply by 0.3.

The areas of the cylinders are to each other as the squares of their diameters. Suppose the low-pressure cylinder has a diameter twice that of the high; its area will be four times as great and with the same stroke (which is usually the case) its displacement will be four times as great, and the same percentage of clearance would give four times as much volume, so that, supposing the clearance of the low-pressure cylinder to be 5 per cent. also, the final volume would be

$$4 + (4 \times 0.05) = 4.2$$

Then the number of expansions or the "ratio of expansion" would be

$$4.2 \div 0.3 = 14$$

This can be boiled down to the simple rule:

Divide 1 plus the clearance of the low-pressure cylinder by the fraction of the stroke completed at cutoff plus the clearance of the high pressure cylinder, and multiply the quotient by the ratio of the cylinders, i.e., by the square of the quotient of the diameter of the low divided by the diameter of the high.

$$R = \left(\frac{D}{d}\right)^2 \times \frac{1 + C}{f + c}$$

where

R = Ratio of expansion;
d = Diameter of the high-pressure cylinder;
D = Diameter of low-pressure cylinder;
c = Clearance of the high-pressure cylinder;
C = Clearance of the low-pressure cylinder;
f = Fraction of stroke completed at cutoff.

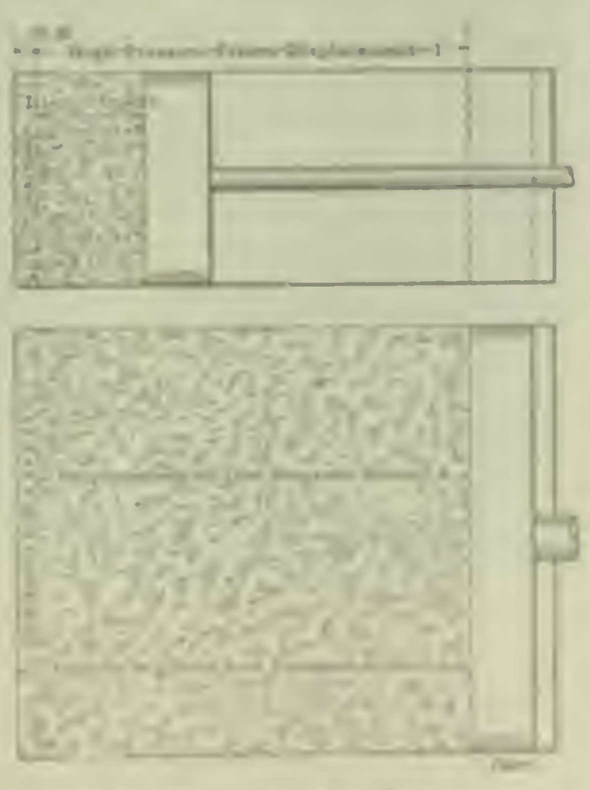

DIAGRAM OF HIGH- AND LOW-PRESSURE CYLINDERS

Substituting the figures of the previous example where each clearance was 0.05, $\frac{D}{d} = 2$ and $f = 0.25$,

$$R = (2)^2 \times \frac{1 + 0.05}{0.25 + 0.05} = 14$$

To be accurate, all of the steam included in the initial volume does not appear in the final volume, for a part of it is retained in the high-pressure cylinder when the exhaust valve closes. The real case is that a certain quantity of steam is expanded in the high-pressure cylinder and then a portion of this steam expanded in the low. Where extreme accuracy is desired or where a high degree of compression is used it is well to consider the cylinders separately, deducting from initial volume in the low-pressure exhaust, which will depend upon the receiver pressure as well as the point of closure of the exhaust valve. When there is no free expansion or cylinder drop, i.e., when the high-pressure diameter ends in a point, there is no escape of steam into the receiver except as the piston pushes it out. The proportion of the steam passed on to the low-pressure cylinder in this case would be the proportion of the stroke completed at exhaust closure. If, for instance, the exhaust valve closes when the stroke is four-fifths completed, then the volume displaced will be four-fifths of the displacement of the high-pressure piston, and since the entire displacement is taken as unity, will be correctly represented by four-fifths or 0.8. Since the volume of the low-pressure cylinder is proportional to $\left(\frac{D}{d}\right)^2 \times (1 + C)$, the number of expansions in the low-pressure cylinder is, calling the portion of the return high-pressure stroke completed at exhaust closure e,

$$\frac{\left(\frac{D}{d}\right)^2 \times (1 + C)}{e}$$

The number of expansions in the high-pressure cylinder is

$$\frac{e + c}{f + c}$$

and the total number of expansions is the product of the two, or

$$\frac{(e + c) \times \left(\frac{D}{d}\right)^2 \times (1 + C)}{e\,(f + c)}$$

Substituting the figures of the above assumed case, and calling e = 0.8, this would give

$$\frac{(0.8 + 0.05) \times 4 \times 1.05}{0.8 \times (0.25 + 0.05)} = 14.9$$

a considerable difference, for a very ordinary ratio of compression.

Confessions of an Engineer

By R. O. Warren

The chief gives the firemen their own way and fails to realize how much coal is being wasted. The manager makes some suggestions which result in a large saving.

Over a week passed before Manager Wood again came into the engine room, although I had seen him several times out in the boiler room, not that he interfered with the firemen, but he seemed to be noting how the men did their work.

If I had had enough sense, I would have known that Wood was getting interested in the combustion conditions of the plant, but for eight months I had seen that the firemen kept up steam and that seemed, to me, to signify that my fireroom force was well organized.

I had read about and discussed boiler-room conditions, time and time again, and had pointed out the mismanagement of other steam plants, but somehow or other it never seemed necessary for me to look into the working condition of my own.

The local association members had been discussing the combustion of coal for years, and had taken up the subject of CO_2, showing how the economy of a steam plant could be increased if a high CO_2 could be maintained. I had been greatly interested in the subject, but as soon as I found out that an instrument cost up in the hundreds of dollars, I came to the conclusion that the matter was not of enough importance for me to bother with, as the chances were, I assumed, that the firm would turn it down if I should ask them to purchase a CO_2 recorder costing so much money.

Now, I knew that air leaking into a furnace through a boiler setting reduced the furnace efficiency to a considerable extent, and I had, therefore, sealed all cracks, so that the boiler setting was in good shape.

For this reason I did not bother much about Wood looking around, but I did make up my mind that if he interfered with the men there would be an understanding as to who was chief engineer.

Wood, however, was a sensible man, and gave me no opportunity of demonstrating which of us was "boss." If I had known him better, and cut out some of my own self-importance, I would have been better off in many ways.

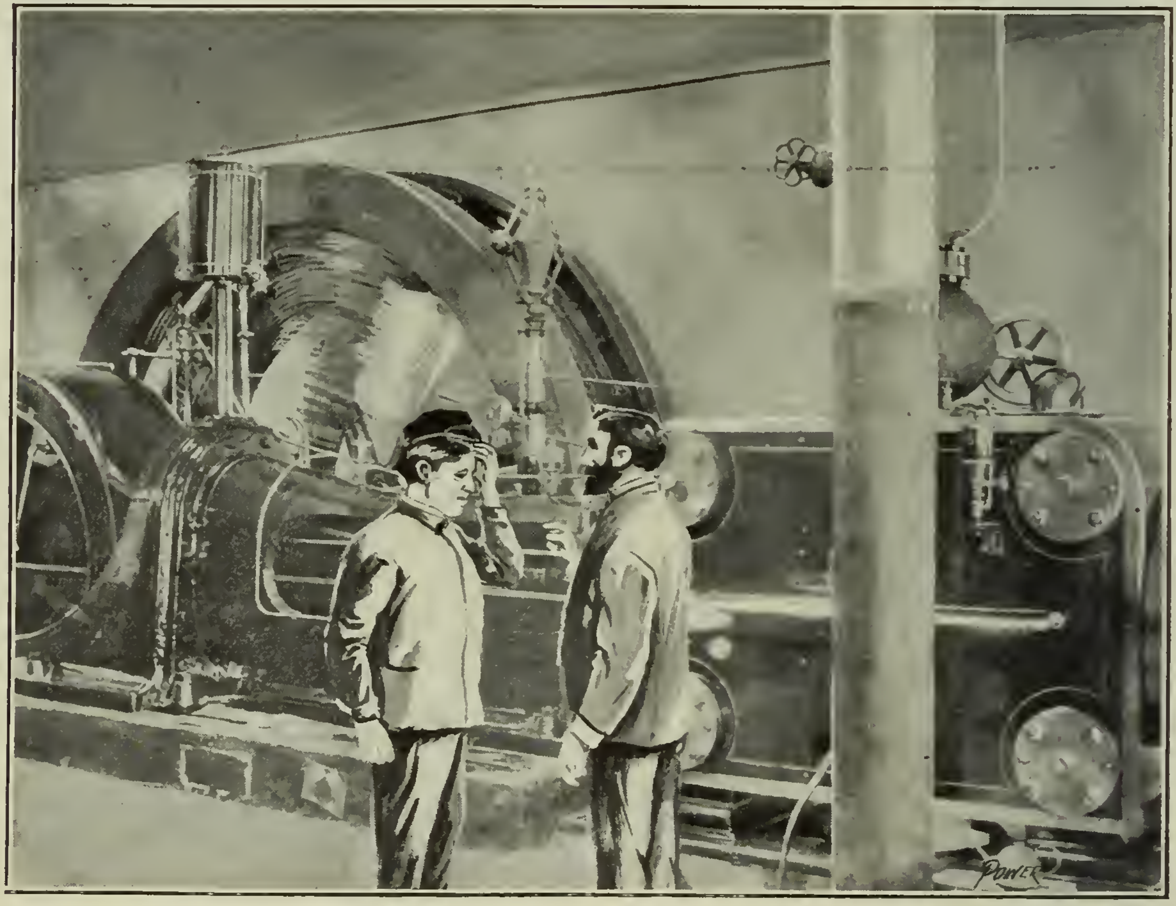
The second visit of Wood was made one forenoon while everything was working to perfection. The firemen had the boiler pressure at the blowing-off point and were sitting down, contented that there was sufficient steam and a little more.

"Good morning, Warren," said he. "How are things going?"

"Fine as a fiddle," I answered, noting with satisfaction that the boiler pressure was up above the normal working point, and that the engine was cutting off shorter than usual.

"Got some pretty good firemen?" was his next question.

"Can't be beat," I answered. "They are the best boys in the town, willing to work and will do just what they are told. The only trouble is that they will take advantage of me if I am not strict. They are like most people for that matter. If you give them an inch, they will take a foot. I don't have much to do with them, because they are apt to get familiar, which won't do." I said this with considerable pride, as I felt that such a stand added to the dignity of my position.



The Manager Had Me Guessing

Wood said nothing, but coughed slightly. After a pause he said, "Good firemen are scarce, and men who would make good firemen are not properly trained. The losses a fireman causes in a steam plant are next to the furnace losses, which are the largest. In my opinion a good fireman has greater responsibility, as far as fuel is concerned, than the engineer. The engineer's business is to see that instructions are carried out, and if he fails to do so and the fireman shirks his duties, the plant is in a bad way, from an economical standpoint at least."

I acknowledged that he was right, supposing that Wood was speaking on generalities.

"You said a little while ago that the firemen would take a foot if you gave them an inch. I should judge they had taken something like a yard this morning."

"How so?" said I, and I was never more surprised in my life.

"Well," said Wood, "they have allowed the safety valves on the boilers to blow for over ten minutes since I've been in here, and I have heard them blowing off several times before this morning. They surely have different instructions than that."

"Of course," I replied. But to tell the truth I had never told the firemen anything about blowing safety valves. I assumed that they would look after the matter without instructions from me.

I made up my mind I would give them a "jacking up" as soon as Wood went away. I never did, however, for, after our little séance was over, I came to the conclusion that no one was to blame but myself.

Continuing, Wood said: "The blowing of a safety valve means that coal has been burned in heating water and changing it into steam that will never do any work in the engine cylinder. So far as the company is concerned, the coal might just as well be thrown into the streets. You can see the point, can't you?"

Yes, I could see the point, and I felt like kicking myself when I thought that it was necessary for the new manager to call my attention to the fact that I was allowing my firemen to waste coal by letting the safety valves blow off for long periods. I tried to justify myself by saying, "The firemen should know better than to get up such a head of steam."

"You can't blame the firemen for getting through the day as easily as they can. If they were getting three or four dollars a day it would be a different proposition. It is up to the chief engineer to see that only such methods are practised as produce economy."

"A man don't like to keep jawing his men all the time," I grumbled, trying to justify my shortcomings.

"It isn't necessary," replied Wood. "A chief engineer should be obliged to issue an order but once and the men should be made to know that when an order is issued, there is but one way out of it, and that is to obey it."

"I guess you would have a good time getting the men in most boiler rooms obeying every order," I answered, for I was becoming nettled by the way Wood was getting at me.

"There would be no trouble at all. The first disobedience of orders might be overlooked, but the man should be warned. The second occurrence would probably end in the discharge of the man unless a good excuse was forthcoming. If an engineer cannot enforce his orders—if he does not know how to handle men, then he is most likely to be a failure. There must be someone about the steam plant who is in charge."

As Wood said this he looked through me, so it seemed, and somehow I felt that he meant me, and that I was getting just what I deserved.

"I don't have that kind of trouble with my men," I protested. "We get along all right."

"No, I've noticed that there is very little friction, but perhaps you do not exert your authority. Most men will get on with their chief so long as they have their own way—so long as he is an 'easy mark.'"

"I'm no easy mark," I remonstrated.

"I hope not," replied Wood, and after a pause said, "The point is just this. You are chief engineer of this plant. I am manager. It is up to me to get economy out of the mill, and it is up to you to get the steam plant running on as economical a basis as possible, but the firemen won't do it. They won't save coal unless they are shown how, and that is where you come in."

"The men don't throw away coal. I have watched the coal pile for that very thing," I rejoined, and my spirits began to rise.

"There is more than one way of throwing away coal," replied Wood. "I have seen it done more than once since I came here."

"I'd like to know where," I challenged, although I was beginning to see that Wood had me cornered, but just at what point I did not know.

"Well, for instance," replied the manager, "just as I was coming in through the boiler room, one of the men had a fire door open, but before throwing in a charge of fresh fuel, he stopped to fill a pipe, light it and crack a joke with one of the other men. All of this time cold air was being drawn into the furnace over the fire, and coal was thrown away in heating that cold air. There can be no doubt about that, can there?"

"N-o-o," I said, rather faintly, for he had me "going," as the saying is. There was nothing else to say. I knew he was right. I knew that a loss was occasioned every time a furnace door was opened, but here again I had failed to put my knowledge into practical use. I had just the thing that was lacking, but did not use it. Why? Because I did not think that such a small matter made much difference one way or another. I had not taken the trouble to figure out that a little loss here and a little loss somewhere else, added together, made a big item in the total loss account. Here again it was a case of dozing in the engine room while the firemen allowed wastes to occur that I should have prevented. And the worst of it was, the new manager had noticed the loose way in which the boiler room was being managed.

"That was only one instance," I managed to say. "You could probably come into the boiler room a hundred times and never see a man do such a thing again."

I went a little further as my courage returned and was willing to bet that he could stay in the boiler room all day unnoticed and would not see a second like occurrence. But I knew he would, for if a fireman would do any particular thing once, he would do the same again.

"Let it go at that," said Wood. "I noticed another practice that seems to be followed regularly. I refer to the men firing heavy and then allowing the damper regulator to take care of the steam pressure."

"What's wrong with that?" I asked, although I knew well enough. Here was another case of knowing and not seeing that the proper thing was done.

"You wouldn't think of building a furnace of the latest design and then stopping up the tubes of the boiler in order to prevent heat going up the stack, would you?"

"Of course not," I answered.

"Then, why should you build a furnace under a boiler and then allow the fireman to stop up the smoke uptake?"

"I don't allow any such thing. The men don't do it either," I replied, rather nettled.

"It amounts to practically the same thing. You allow the firemen to fire heavy, and in any manner they choose, and then when the pressure rises the damper closes, shutting off the draft in the uptake and deadening the fires in the furnace. The result is that the fires, the furnace and the boiler are not allowed to work efficiently and good coal is thrown away, because the furnace is not worked to its greatest capacity."

"That's splitting hair," I retorted, although I knew he was right.

"Nothing of the sort," replied Wood. "Let's get down to coal dust and see if the thing isn't about as I say it is. Now the rate of combustion in a boiler furnace depends upon the ratio of heating surface to grate surface, the draft and the condition of the furnace and the character of the coal."

"Of course, everybody knows that," I replied.

"Well, now," said he, "what is the lowest rate of fuel consumption per square foot of grate surface that you know of, and what kind of coal would you use?"

"About 8 pounds, I guess, and poor coal and boiler setting," I added, as vague recollections of such figures came before my mental vision.

"And what is the best?"

"Between 35 and 45 pounds," I answered, "but it would have to be good coal and the best of furnace conditions," I added.

"I guess that would be about right," replied Wood. "That would mean about 3.5 pounds to 10 pounds of coal per horsepower per hour. Quite a difference. Now, boilers such as we have here should burn between 12 and 15 pounds of coal per square foot of grate surface per hour. If the amount of coal is less, the furnace is not doing the proper amount of work. If the rate of fuel consumption is increased, the efficiency of the furnace is increased."

There was no getting around that and I admitted that he was correct.

"If that is so, then better conditions can be obtained if a high rate of combustion is maintained, but it can't be done with the damper closed a portion of the time. And if the damper is frequently closed, it shows that more boilers are being used than is necessary."

"I don't believe that condition exists here," I protested, but having had my attention directed to the matter I was aware that the dampers were closed a whole lot more than I had thought.

"I am not so sure about that," was the rejoinder. "My observations of the way the men work and the condition of the fires and working of the damper lead me to think that a boiler could be cut out just as well as not. Of course, I am not running the steam end—only have an interest in it as a general—but if I were you, I would try getting along with one less boiler."

The tone was not threatening at all, but it had a ring that caused me to act upon the suggestion.

The result was a surprise to me. When the firemen were told to get out one boiler, as they were at the end of the day's run, considerable grumbling was indulged in, which showed me that the manager was correct when he said that men could get on with their chief so long as they had their own way.

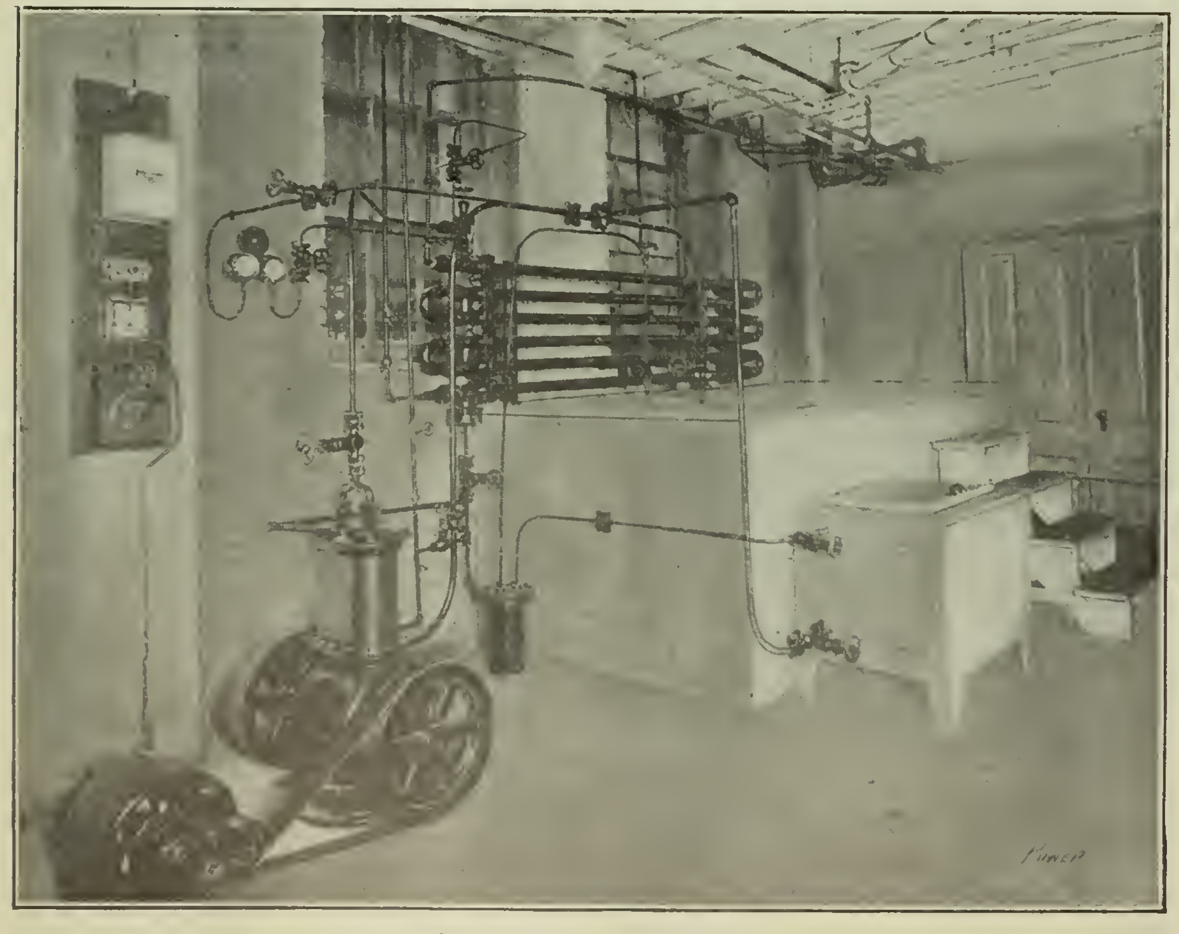
But the boiler was cut out, and the plant was run with one less boiler than it had been for the remainder of my stay. The difference was that the men had to fire oftener; the damper seldom closed and the coal consumption was greatly reduced; just how much, I do not recollect at this late day.

Low Pressure Refrigerating System

By R. C. Turner

The illustration shows an interesting little refrigerating system which is installed at the Commerce Hall building in Atlanta. The machine is of the single-acting type, of 1 ton capacity, and is driven by a 2-horsepower motor. The refrigerant used is Picteau fluid, and only a very small charge (22 pounds) is required for the system.

It will produce a ton of ice upon the cost of 12 kilowatt-hours and 60 minutes labor charge, the machine being in charge of the elevator operator. The cost of power being 36 cents and that of labor 25 cents, shows that a ton of ice is produced for 56 cents, not including any depreciation charges, which at the most would be only a cent or two.



Refrigerating Outfit

The method of operation is as follows: First, the expansion valves are closed tightly, then the motor is started and the freezing coils are pumped down to 2 inches of vacuum; next, the expansion valves are cracked slightly and the system is ready. The best results are obtained with a condenser pressure of 60 pounds, a suction equal to 2 inches of vacuum, and the machine running at about 65 revolutions per minute.

The machine, having an inclosed crank case, requires no attention; one gallon of oil put into the crank case being enough for a six months' run. The best oil for the purpose is a fine grade of transformer oil, on account of its freedom from moisture.

Exhaust Steam in Low Pressure Turbines

By George F. Fenno

There are enough good things that can be said about exhaust-steam turbines, without giving false impressions; and engineers should realize just how much power an exhaust-steam turbine can get out of the exhaust from reciprocating engines. The statement is usually made that, theoretically, there is very nearly as much power to be gained from the expansion of steam from atmospheric pressure to a 28-inch vacuum, referred to a 30-inch barometer, as is possible from steam at 150 pounds gage expanding down to atmosphere. This is very nearly true; but in a recently issued catalog of a turbine builder the statement is made that if a pound of dry saturated steam is expanded from 150 pounds gage to atmospheric pressure, 176 B.t.u. are available for conversion into work, when the expansion is adiabatic; that is, without receiving heat from or imparting heat to any outside body. It is then stated that a pound of dry saturated steam expanding from atmospheric pressure to a 28-inch vacuum renders 169 B.t.u. available for turning into work. A comparison of these figures shows that the expansion of steam in the lower range renders available for useful work only 7 B.t.u. less than that given up by the expansion of steam in the upper range. While these statements are true, the comparison is not fair, for if starting with a pound of dry saturated steam at 150 pounds, this same pound of steam is not saturated after expanding down to atmosphere. Therefore, the statement of the turbine builder assumes that the steam at atmospheric pressure has a much higher heat content than is usually the case. For instance, using the Marks and Davis entropy diagram, it will be found that when the original pound of dry and saturated steam expands from 150 pounds gage to atmospheric pressure it does give up about 176 B.t.u. which a perfect engine could convert into work, but that at the end of this expansion which, it must be remembered, is done at the expense of the internal energy of the steam, the steam has a quality of approximately 85.7 per cent. This is on theoretical grounds alone. In actual practice the quality of the steam will not be as high as this, due to cylinder condensation and radiation. However, to give the turbine the benefit of all doubt, assume that the quality is as high as 85.7 per cent. Now, in order to make a fair comparison, it must be remembered that the exhaust turbine must take the steam at this point and expand it down to the vacuum. Of course, in practice the turbine does not receive wet steam, as separators are inserted in the line; but this does not alter the argument, for this means that for every 100 pounds of dry steam used by the reciprocating engine, the exhaust-steam turbine receives only 85.7 pounds of dry steam at atmospheric pressure.

Starting at this point, with the steam at atmospheric pressure and with a quality of 85.7 per cent., and expanding it down to a 28-inch vacuum, referred to a 30-inch barometer, the heat content will drop from 1018 B.t.u. to about 869.7 B.t.u. That is, in the lower range of expansion there are really only 148.3 B.t.u. available for converting into useful work during adiabatic expansion, instead of 169 B.t.u. as claimed in the pamphlet referred to. So that, whereas this pamphlet claims that 96 per cent. as much energy is available in the lower range of expansion as in the upper; in fact, when correctly figured out, this proportion is only 84.3 per cent.

However, this 84 per cent. is well worth conserving, and turbine builders should be satisfied with it. Nevertheless, manufacturers should be careful about the statements they make in their literature, especially as engineers nowadays freely consult the catalogs of manufacturing concerns, realizing that they often contain the latest information in regard to the advance of engineering science.

The Straight Flow Steam Engine

By Rulof Klein

This engine, designed by Professor Stumpf, discharges its steam through large slots at the center of the cylinder. It compares favorably in economy with compound or triple-expansion engines and is much simpler and cheaper to build. The engine has met with great favor in Germany.

In a paper read before the Berlin District meeting of the Verein Deutscher Ingenieure, Prof. J. Stumpf, of the Charlottenburg Engineering College, Germany, inventor of the straight-flow steam engine, of which the principle of operation has been described in a previous issue of this paper, has described its thermal principles and published the vital details of construction and some operating performances, which should be of great interest to all readers familiar with steam-engine operation.

General Principles

In treating the thermal principles, he compares his one-cylinder creation throughout with the triple- and even the quadruple-expansion engine, because its ratio of steam expansion is about equal to that in these types, running from 1 to 15 to 1 to 30 or even higher, according to the load and initial steam pressure. See Fig. 1.

That these high expansions can be obtained economically in a single cylinder is due to the straight flow of the steam through the cylinder similar to the expansion and exhaust flow of the double-acting two-stroke-cycle gas engine of which the elongated piston acts as an exhaust valve, opening slots in the middle of the cylinder shell toward the end of the expansion stroke and closing them at the beginning of the compression stroke. As Fig. 2 shows, the live steam, which preferably is highly superheated, enters the engine through the cylinder head, which it heats and is admitted into the cylinder through the double-seated poppet valve and after expansion is exhausted through the large slots in the middle of the cylinder shell which, as described before, are opened by the piston acting as a large valve. The advantages of this arrangement above that of the ordinary steam engine can be classified as thermal, constructive and operative.

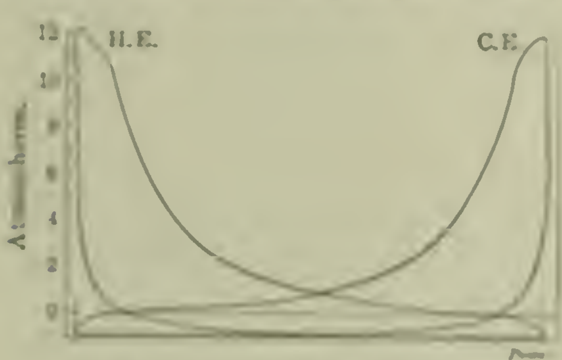


Fig. 1. Sample Diagram

Thermal Features

The main thermal advantage is the fact that the reëvaporation of the steam during the latter part of the expansion stroke in the ordinary steam engine does not occur here. The loss of heat necessary for this process is prevented in this engine as follows:

The steam entering the cylinder is heated by the compression charge, which is of extremely high temperature. During the expansion, condensation occurs to such an extent that at the end of the stroke the steam contains a great deal of moisture, with the exception, however, of the portion nearest to the steam-heated cylinder head which is kept in superheated condition by radiation from that source. The steam following nearest the piston is in contact with the coolest surfaces and therefore contains the highest percentage of moisture, the more so as here the cylinder wall is of still lower temperature and absorbs some of its heat, to return it later during the compression.

During the period of exhaust the straight-flow engine expels the coldest steam, which contains the largest amount of moisture, retaining the driest portion for compression, in contrast with the ordinary engine in which the hottest exhaust passes out carrying along the heat of the hot surfaces it strikes when leaving the cylinder.

Compound-, triple- and even quadruple-expansion engines have been built to reduce the disadvantage of great temperature differences of this nature, and equipped with all modern refinements, steam jacketed and superheated, these engines have not been able to establish any record of economy of steam consumption which cannot now be approached by the simple single-cylinder straight-flow steam engine.

A comparison of the combined diagram of the triple-expansion engine, Fig. 3, with the diagram of the straight-flow engine indicated by dotted lines in the same figure brings out the advantage at once.

Although the ratio of expansion is almost the same, the combined diagram is at a disadvantage at points A and B, the points of release of the high- and intermediate-pressure cylinders. At those points not only a portion of the indicator-card area is lost, but also the corresponding amount of heat on account of the sudden partial expansion. It has been tried to reheat the steam by jacketing but only with its application to the low-pressure cylinder, material advantage has been gained, as the steam entering that cylinder has gradually become so moist and cool that on account of the great temperature differences between itself and the jacket, it is able to absorb heat effectively and regain some lost energy. However, it is all too evident that most of this extra heat is exhausted directly to the condenser. Imagine that during almost the entire revolution of the engine the jacket of the low-pressure cylinder transmits heat to the coolest steam of condenser pressure to have it driven out through the wide-open exhaust valves. In the straight-flow steam engine the extra heat is only absorbed by the steam near the cylinder head, and, as pointed out before, is trapped, as it were, by the returning piston.

Besides the above features, Fig. 3 is also a comparison between the indicator diagrams of the two types of engines for the same brake horsepower. On account of its high mechanical efficiency of 92½ per cent., the straight-flow engine does not need as great a cylinder diameter for the same amount of power as the triple-expansion engine in its low-pressure cylinder. The diameters shown here are respectively 33 inches and 35.4 inches. Professor Stumpf claims that under equal conditions, the engine cost, leaving the

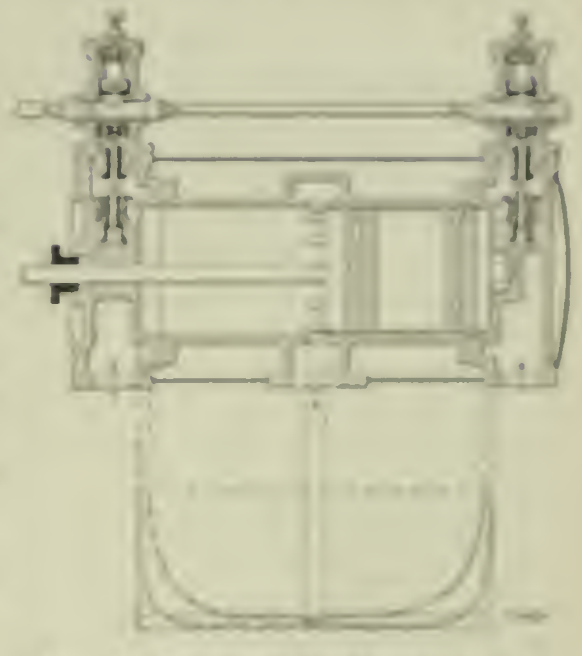

Fig. 2. Cylinder Arrangement of Straight-flow Engine

same power as a compound engine, although its efficient area is only four-fifths of the area of the low-pressure piston of the latter.

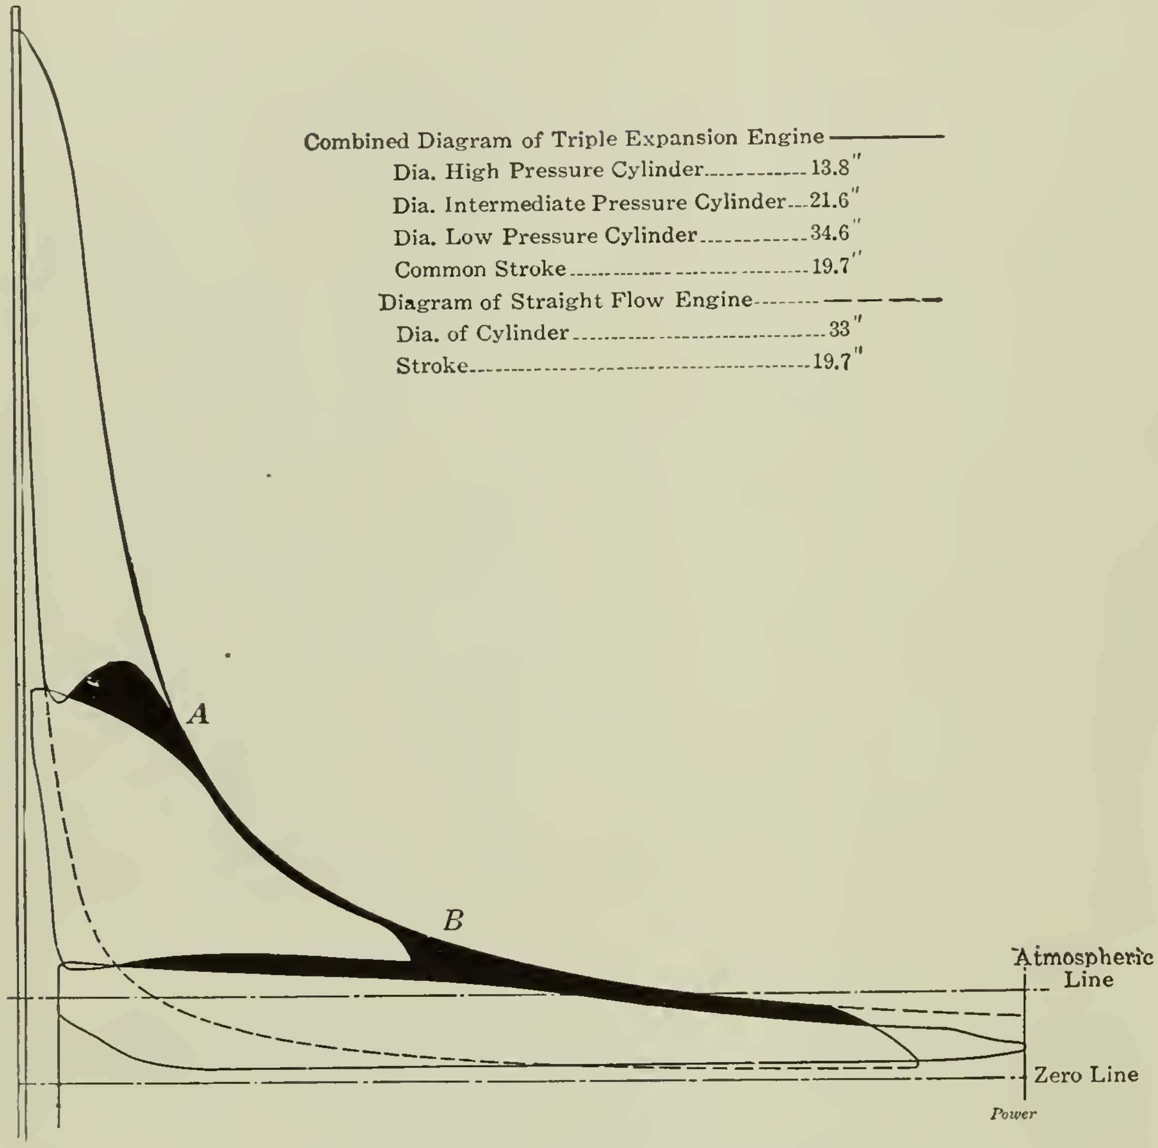

Fig. 3. A Comparison of Diagrams

The compression stroke for the straight-flow engine has also its advantages above that of an ordinary triple-expansion engine as the steam comes in contact with hotter surfaces the more it is compressed, while in the ordinary engine the surfaces of the compression chamber are immediately before swept by the cool exhaust steam. The compression in the new engine, which is carried higher than that in an ordinary engine, equals about the combined compression of the triple-expansion engine with which this engine should be compared. That the temperature of the steam at the end of the compression stroke is well above that of the inlet steam and greatly superheated, is shown by the following figures. Dry saturated steam at 28½ inches vacuum, compressed adiabatically to 177 pounds absolute, or 162 pounds gage pressure, will have a temperature of 1730 degrees Fahrenheit. The temperature of steam at 177 pounds gage pressure and 250 degrees superheat is only 628 degrees Fahrenheit.

High compression from high vacua to steam-inlet pressures seems more or less a necessary evil of this type of engine as the time of closing of the exhaust port is fixed at such a fraction of the stroke as the length of the exhaust slots is to the entire stroke. At lower vacua or atmospheric exhaust, modifications have been made in the described simple construction, in order to prevent the compression from running above the admission line.

To meet these requirements three distinct modifications have been made. For the stationary engine with atmospheric exhaust the clearance has been artificially enlarged by means of an extra compression chamber in each of the cylinder heads outside of the actual steam chest. With a valve in the head, this addition of the clearance can be closed off. For noncondensing operations a clearance of 16 per cent. has been found necessary, quite a good deal larger than the 1½ per cent. of clearance necessary with a vacuum of 28½ inches, or the 3 per cent. of our Corliss engines.

For locomotive engines running likewise noncondensing, the clearance is enlarged artificially to 17½ per cent. by concave construction of the piston ends. See Fig. 4. This design, in principle the same as the previous, has proved very efficient in tests made by the Prussian State Railway. Three locomotives were built especially to compare the merits of the straight-flow, the piston-valve and the Lentz valve engines. The comparison of coal consumption for these different types was respectively in the ratios 1, 1.19 and 1.285, giving the straight-flow engine an advantage of 19 per cent. over the piston-valve engine and of 28½ per cent. above the engine equipped with Lentz valves.

The poor showing of the Lentz valves was partly due to the design of the cylinder, of which both inlet and exhaust valves were located in one long steam port. This feature is in direct opposition to the straight-flow principle, as the steam passage is effectively cooled by the exhaust just before the admission of the live steam.

The latest design of noncondensing straight-flow steam engine, which bears witness of the resourcefulness of the inventor, is shown in Fig. 5. A piston valve is placed inside the piston directly below the rod. It is operated by a little rocker arm, which is attached to the crosshead end of the connecting rod, and rocks about the crosshead pin as center. The valve alternately opens one side of the piston or the other to the respective cylinder ends, procuring passage for the ex-

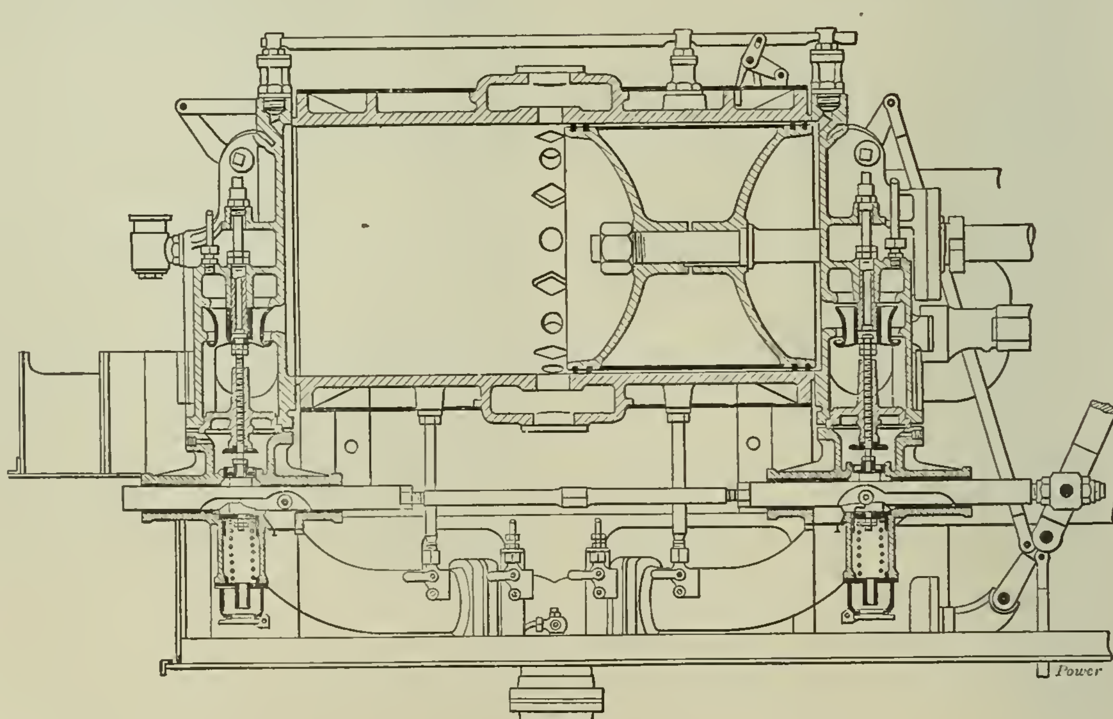

Fig. 4. Locomotive Cylinder, Showing Piston of Concave Construction

haust steam from these ends through its seat and the holes in the side of the piston to the exhaust slots. These valves close a trifle after the exhaust slots are closed by the second set of piston rings passing them. It is clear that the pressure inside the piston is kept atmospheric throughout the stroke.

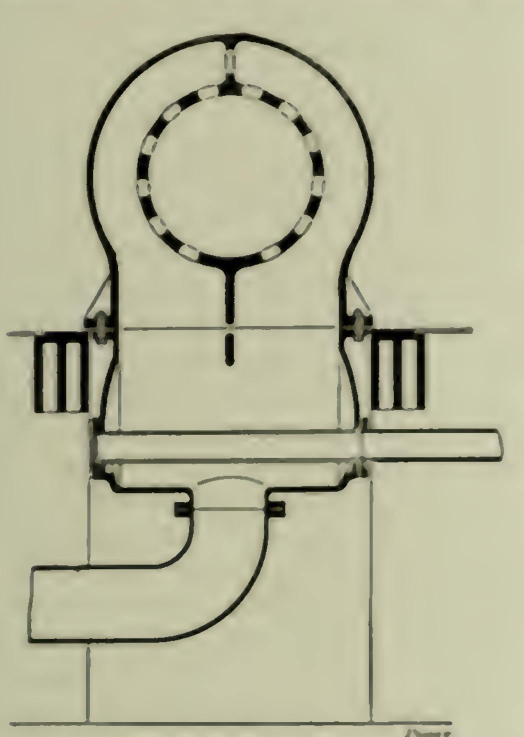

Fig. 5. Latest Design of Noncondensing Straight-flow Engine

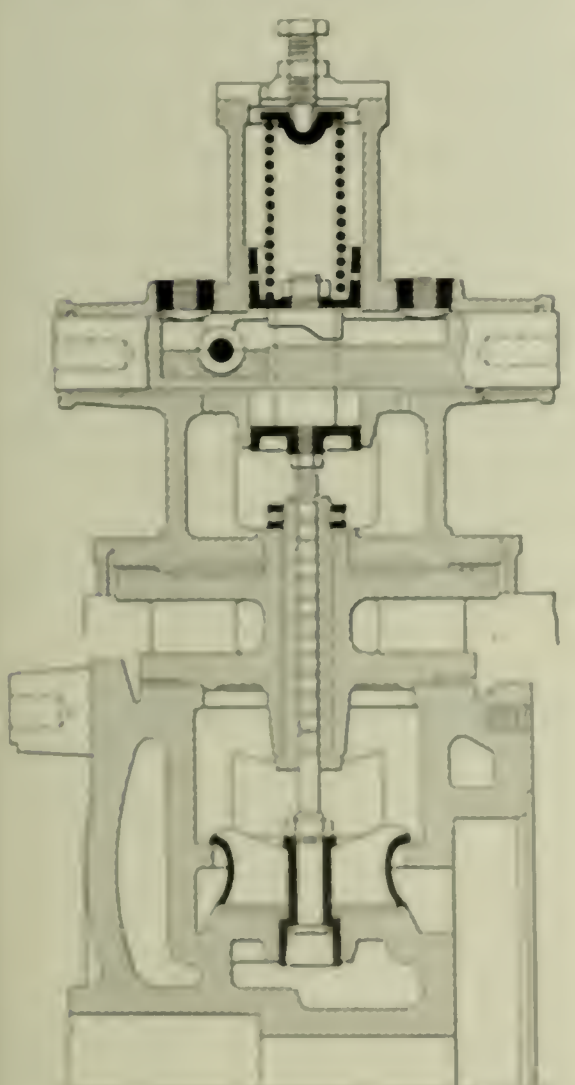

Fig. 6. Inlet Valve and Gear

We have seen that during the thermal cycle of ordinary engines hot steam strikes cooled surfaces and cold steam strikes hot surfaces to the detriment of their efficiency, while this is almost entirely omitted in the new engine and even that portion of the steam which absorbs heat from the cylinder heads during the latter part of the expansion stroke is trapped for use during the compression.

As Professor Stumpf says, in the ordinary engine a thermal washing takes place. Surfaces are heated and cooled constantly, while in his engine both inlet ends are hot and stay hot, while the common exhaust end in the middle of the cylinder is cool and stays cool.

Yet, with all the thermal advantages of his engine, the inventor calls for still higher superheat than is already used in European power houses. He claims that his engine is in better condition to utilize it than any other, on account of its large ratio of expansion. This leaves the steam very moist at the end of the stroke, even if the highest degree of present superheating is applied.

Constructive Features

As to the constructive advantages of this engine, we detect immediately the absence of exhaust gear and valve; the only visible moving valve part is the rod, shown on top of the cylinder, operating the valves by means of roller and cam similar to the valve gear of the blowing tubs of the Southwark Foundry and Machine Company, of Philadelphia.

As is shown in Fig. 6, the slot containing the rollers is at the same time an oil reservoir which never passes the end of its guide so that oil cannot be spilled nor dust enter. The valve stem is packed by means of a labyrinth packing. The piston, elongated to the length of the stroke minus that of the exhaust port, offers a large bearing surface to the cylinder wall, which is coolest at the point where the piston speed is highest. Therefore, favorable friction conditions exist.

On account of the high compression, a great piston speed is possible in spite of the heavy reciprocating parts, preferably 800 to 900 feet per minute. The diagram, Fig. 7, which corresponds to this speed condition shows that the resultant pressure on the crank pin is approximately constant over the entire stroke, most of the high initial steam pressure being absorbed by the inertia of the reciprocating parts to be imparted later to the crank pin, when the steam pressure has decreased. No knock does occur, however, for the compression line passes the inertia line before the end of the stroke, as shown in the lower part of the diagram. As a matter of fact, this engine has attracted attention in operation on account of its smooth running.

No wonder that with this high speed and heavy reciprocating parts a heavy counterweight opposite the crank pin is

Fig. 7. Diagram of Resultant Piston Pressure for Engine Running Condensing

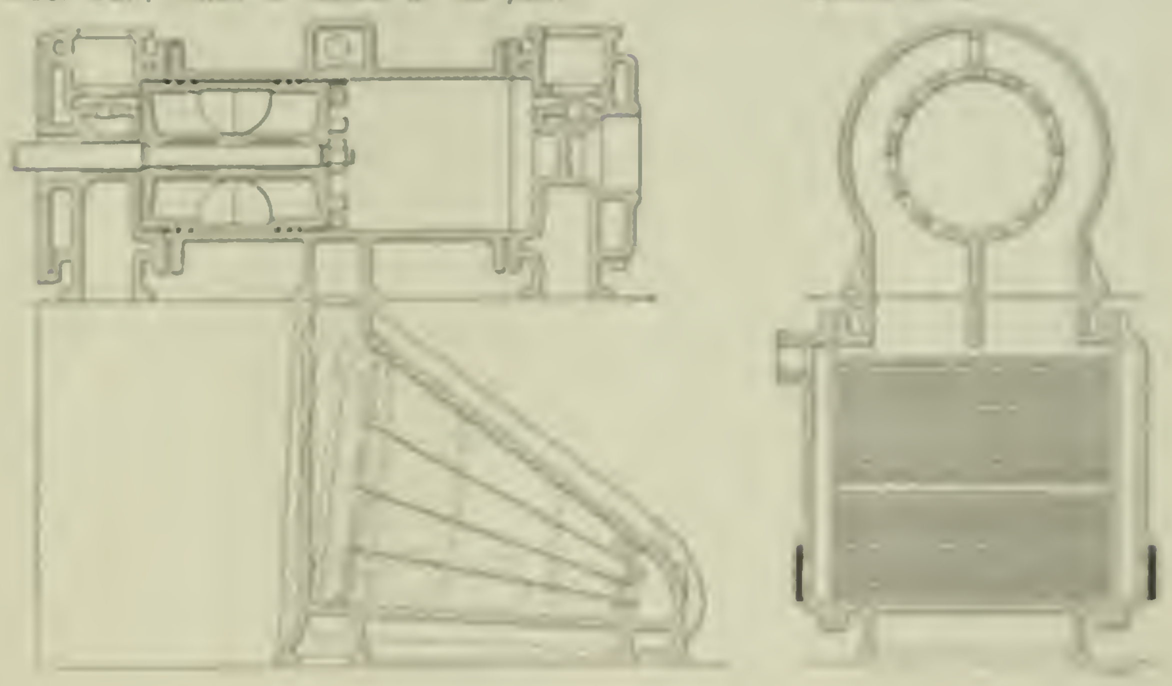

Fig. 8. Straight-flow Engine with Surface Condenser

necessary, and also a very solid foundation, for the inertia, which tends to cause vibration, is many times greater with this engine than with an ordinary steam engine of the same power, especially with cross-compound or triple-expansion engines where the different sets of reciprocating parts balance each other more or less.

FIG. 9. DIAGRAM FROM QUADRUPLE-EXPANSION ENGINE

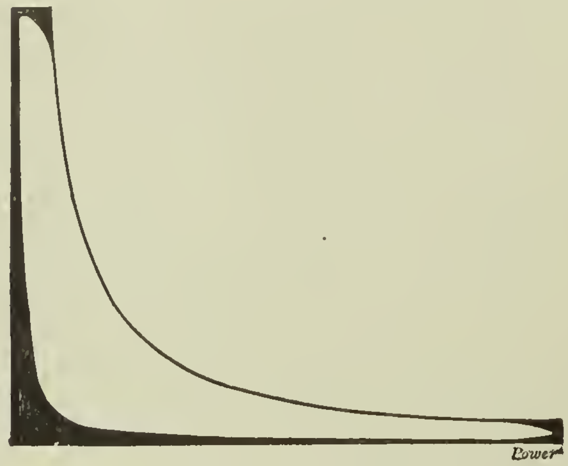

FIG. 10. DIAGRAM FROM STRAIGHT-FLOW ENGINE

On account of the absence of valves below the cylinder of this engine, room is left for immediate connection to the condenser. A surface condenser attached is shown in Fig. 8. The design of the condenser proper is interesting. It offers a large tube area to the inrushing exhaust steam, and is provided with simple trays, which convey the condensate to the outlet, preventing the detrimental flooding of the tubes.

Where an invention has so many advantages as just described, it is hardly possible that not a few drawbacks are attached to it. To the great inertia forces of the reciprocating parts and the large clearance necessary for the noncondensing engines of this type, may be added its enormous maximum piston pressure per horsepower, which necessitates the design of extremely heavy parts.

It is to be compared with the low-pressure part of a triple-expansion engine able to stand the live-steam pressure, necessitating a heavy construction throughout and to develop the energy of all three cylinders combined requiring enormous bearings. To add to this feature the piston and correspondingly the cylinder are abnormally long, which is a feature of all center-exhaust engines.

The cost per unit of power of this engine, calling for a lean diagram for the most economical operation, will therefore be somewhat higher than that of the ordinary single-cylinder engine, although the absence of exhaust-valve gears rectifies this feature to a certain degree. Compared with a compound- or triple-expansion engine, however, with which it so successfully competes in economy, this engine is a good deal cheaper, the reason why it has met with great success in Europe, where its manufacture is taken up by almost all leading engine builders. To date, over half a million horsepower are built or in course of manufacture.

OPERATIVE FEATURES

After the completion of a couple of small experimental engines in 1908, the first 500-horsepower engine was tested in February, 1909. A log of this test is given in Table 1. It shows that with a gage pressure of 179 pounds, 628 degrees steam temperature and a vacuum of 26.4 inches at an oil separator, which unfortunately throttled the connection to the high vacuum in the condenser, the engine consumed 10.1 pounds of steam per indicated horsepower-hour and 16.5 pounds per net kilowatt-hour, including power for the operation of the condenser. That these records have been lowered to 8.5 and 14.4 respectively by a 300-horsepower engine, is shown in Table 2, where the performance of such a small single-cylinder engine is compared with the hitherto most economical triple-expansion engines. In this table are also shown performances of still smaller engines.

Besides the merit of high economy, the straight-flow engine has also a flat efficiency curve, which means that at fractional load or overload it consumes only little more steam per unit of power than at normal load.

The 33 moving parts compared with the 228 on the other engines show its simple construction, which is reason of its low oil consumption and of its being called the "engine with nothing to it." This feature is especially important with marine engines, where vibrations have to be reduced to a minimum..

Professor Stumpf admits that for smaller capacities, when three or more cylinders are not necessary, his engine stands behind the ordinary type, but claims its superiority with capacities where the application of a great many cylinders is justified, giving for comparison the diagrams of a quadruple-expansion and the new engine, Figs. 9 and 10.

In these diagrams the shaded parts represent losses which are 45 to 40 per cent. in Fig. 9 and only 20 per cent. in Fig. 10. This proves also that the cylinder diameter of the four-unit straight-flow engine can be made smaller than that of the low-pressure cylinder of a quadruple-expansion engine of the same power.

Catechism of Electricity

The Self-starting Single-phase Induction Motor

1134. *Why are single-phase motors built with commutators and brushes as described in the last lesson?*

In order to make them start automatically and with a strong torque when the connections with the supply circuit are closed. An ordinary single-phase induction motor will not start when current is passed through the stator winding.

1135. *Why is the ordinary induction motor unable to start itself?*

Because the magnetic field set up by the winding is stationary and merely induces currents in the rotor conductors exactly as the primary winding of a transformer induces current in the secondary winding. The currents in the rotor conductors do not react on the field in such a way as to cause the rotor to turn, and it must, therefore, be started up by some external means. The commutator motors start automatically, and with a fairly good power factor.

1136. *Is it necessary to use a commutator to make a single-phase motor start automatically?*

No. A single-phase motor can be made to start without using a commutator, and many self-starting motors are built without the commutator arrangement.

1137. *What means is used to make the motor start itself?*

An auxiliary stator winding which produces a magnetic field that is out of phase with the field produced by the main winding. The result is a sort of two-phase rotating field somewhat like that produced in a two-phase motor, but not so uniform or regular in its variations. This rotating field serves well enough to start the rotor, however, if there is no load or a very small load on it while starting. Fig. 371 shows a motor of this kind.

1138. *Describe the construction of this motor.*

The stator is of the same general con-

Fig. 371. Self-starting Single-phase Induction Motor

struction as that of the ordinary single-phase induction motor, but the stator winding is divided into two parts, a main winding and a starting winding, and these are arranged in the slots exactly like the windings of a two-phase motor. The two windings are not alike, however. The main winding is of much larger wire than the starting winding. The rotor is of the simple squirrel-cage type. The construction of the stator and rotor cores is mechanically the same that is used in all induction motors.

1139. *Why are the two stator windings made different as to the size of wire?*

In order to obtain the "split-phase" effect. The starting winding, being of smaller wire, has a much higher resistance than the main winding, but, as the number of turns in the two is the same their reactances are equal. Consequently, the ratio of reactance to resistance is different in the two windings and this causes the currents in them to be out of phase with each other. The magnetic fields produced by the two windings are therefore out of phase and combine to form a resultant rotating magnetic field somewhat like that of a two-phase motor. This rotating field pulls the rotor around with it.

1141. *Is not the starting winding liable to overheat?*

It would if left in circuit continuously, but the rotor contains a centrifugal governor which operates a switch to cut out the starting winding when the speed is almost up to the regular running speed. Then the machine operates as a simple single-phase induction motor.

1142. *What are the advantages of single-phase motors?*

A single-phase motor requires only a single transformer and two lead wires; it can be supplied from any alternating current—single-phase, two-phase or three-phase—and the starting apparatus is of maximum simplicity. The self-starting type has the additional advantage that it can be thrown on and off the circuit from a distance by means of a simple knife switch and if the supply of current should be accidentally cut off, the motor automatically returns to its starting condition and therefore will not be damaged if the current is cut off and restored when no one is around.

Fig. 372. Single-phase Motors on Two-phase Line

Fig. 373. Single-phase Motors on Three-phase Line

1143. *How are single-phase motors connected to two-phase circuits?*

If the circuit is of the proper voltage for the motor, it is connected directly to either of the two "legs" or phases of the circuit, but if the circuit is a high-voltage primary line, a transformer must be used between the line and the motor; in that case the transformer may be connected to either leg of the supply circuit. Fig. 372 is a diagram showing these methods. The motor *A* is connected directly to a 110-volt lighting circuit which is supplied through a transformer from one leg of a two-phase primary circuit. The motor *B* is supplied through a transformer from the other leg of the same primary line, and the motor *C* is connected to one leg of a secondary 220-volt circuit which delivers current also to a two-phase motor *D*.

1144. *How are single-phase motors connected to a three-phase circuit?*

Each motor is connected to two wires of the circuit, either directly or through a single transformer. Fig. 373 shows connections in which each motor is connected in the same way, relatively, as the motor bearing the same letter in Fig. 372.

1145. *Are there any disadvantages in the operation of single-phase motors on two-phase and three-phase circuits?*

Yes. Both two-phase and three-phase circuits should be balanced as to the division of load between the different phases, and a single-phase motor operated on one phase or leg will unbalance the system. It is important, therefore, to have the same total motor load connected to both legs of a two-phase or all three legs of a three-phase system, and it is almost impossible to get such a division of load with a large number of single-phase motors on either of the systems, especially a three-phase system.

A New Method of Setting Brushes Accurately

By C. A. Boddie

A great deal of the sparking and commutator trouble in direct-current machinery is due to incorrect brush setting. In most industrial plants the voltmeter method of finding the neutral is either unknown or inconvenient.

Those in charge of direct-current machinery usually determine the best brush position by shifting the yoke back and forth until a position of minimum sparking is found. If the brushes are in good condition, they may be shifted through a considerable range before sparking develops. The usual intention is to fix the brushes in a mean position between the forward and backward limits set by sparking. This method is too rough. As long as the brushes are in good condition the machine may run sparklessly even though they are not on the neutral lines; but invisible sparking due to local currents at the brush faces will in time injure the contact surface and visible sparking will result. An examination of the motors of numerous industrial plants shows that the majority of motors are running with their bruhes not set at the neutral lines.

The writer has devised and used successfully a method of setting brushes which does not require expensive instruments or special apparatus. All that is required is a short piece of No. 12 insulated copper wire from which the insulation has been removed for a couple of inches from one end; this end is

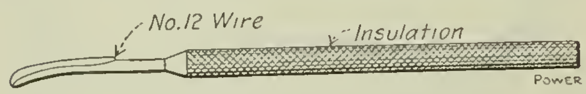

Fig. 1. Testing Wire

flattened and tapered to a point, as shown in Fig. 1. It will be found convenient to bend the end backward as indicated. When the machine is running and carrying its regular load, the wire should be brought into contact with the commutator and carefully moved toward the brush until it touches it. Usually the toe of the brush is the edge which sparks, and this edge should be tested first. If the brush spits and glows when touched with the wire, the brushes are not on the neutral line corresponding to the load on the machine.

Both the toe and the heel of the brush should be tested and the yoke shifted until the glowing stops. The brushes on each arm of the machine should be tested. If some spark while others do not, this is an indication that the spacing is not right. If a position cannot be found where the glowing stops, it shows there is something

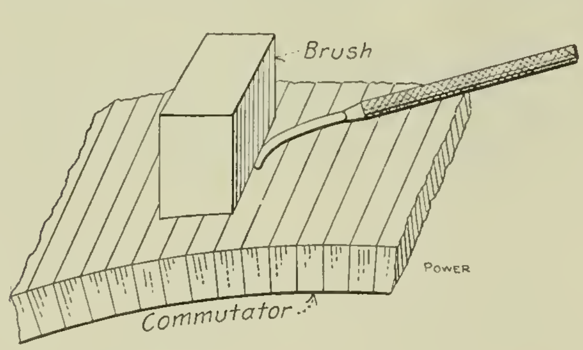

Fig. 2. Method of Testing

wrong in the adjustment or in the design of the machine. Small 500-volt machines and machines having high commutator speed will always spark more or less under this test, but the sparking is very slight if the machine is in good condition, even when carrying full load.

This test is based on the fact that a copper wire simultaneously in contact with the commutator and brush provides a low-resistance path between the two. The carrying capacity at the point of contact on the brush is low, so that if the potential is greater than it should be, enough current flows to heat this point to incandescence.

LETTERS

Mr. Greer's Rotary Converter Trouble

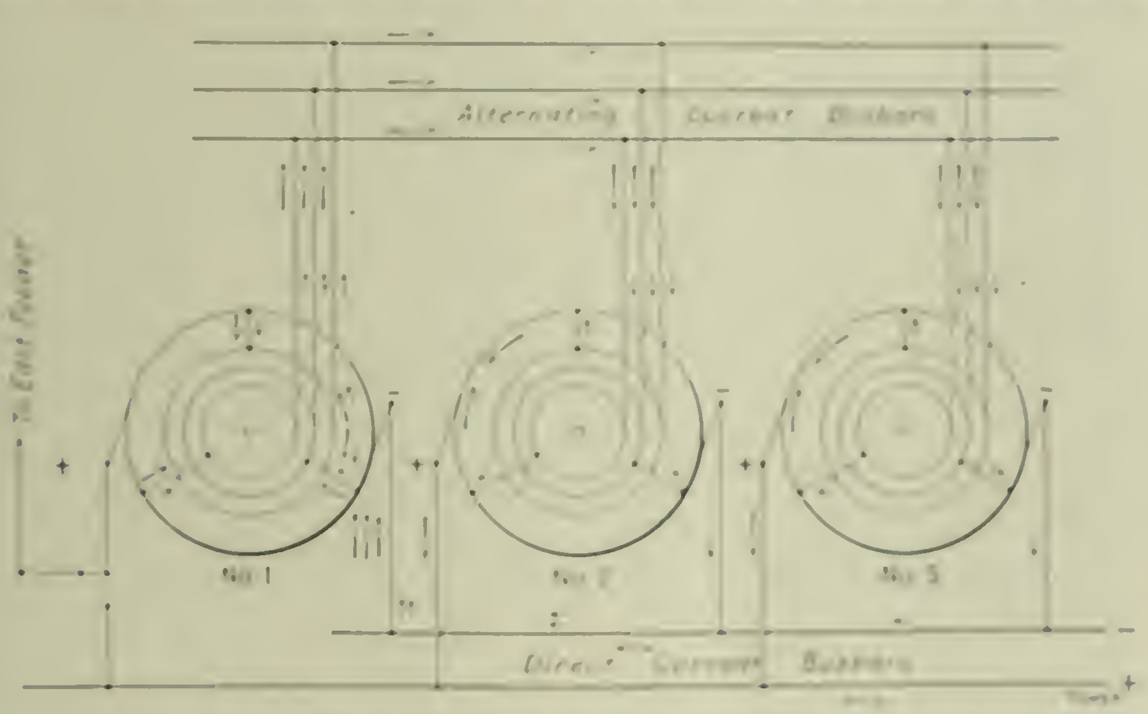
Mr. Greer's description, in the November 15 issue, of the peculiar behavior of his rotary converters interested me very much. For several years I have been operating rotary converters in parallel on both the alternating-current and direct-current sides without intervening transformers on the alternating-current side, and have had abundant opportunity to observe the conditions which arise from this method of operation.

When rotary converters are connected together on both the alternating-current and direct-current sides, a complete local circuit is formed by two converters and the alternating-current and direct-current busbars and a difference in the conditions of operation in the two machines—a slight difference in the relative positions of the direct-current brushes of the two machines, for example—will cause large cross currents to flow in this local circuit and produce many other peculiar conditions, one of which Mr. Greer described.

When two converters are running in parallel under the conditions stated, if one direct-current terminal of one machine is disconnected from the busbar, current will flow in the other lead, provided the direct-current voltages of the two machines are not exactly equal. The direction the current will take through this lead depends on whether the direct-current voltage of that machine is higher or lower than that of the other machine. With the machines I am operating, if the positive and equalizer switches are opened on machine No. 1 (the equalizer is on the positive side), and the field strengthened until a leading current of 94 per cent. power factor is obtained, equal currents will flow in the negative leads of both Nos. 1 and 2. Weakening the field of No. 1 will decrease the current in its negative lead until at 100 per cent. power factor the current is zero and further weakening of the field causes current to flow in the opposite direction—that is, in a positive direction in the negative lead—and at 94 per cent. leading power factor the current reaches the same value as before, but the machine is running inverted.

Mr. Greer's diagram of circuits does not show the direct-current ammeter connections, but the proper connections for them would be in the negative leads and I have assumed that they are so connected. He says that when an attempt was made to run the large machine, No. 1, in parallel with the smaller machines, No. 1 took all the load, indicating that at the busbar connections No. 1's voltage was slightly higher than that of the smaller machines, and this condition would cause all the current from the rail to pass through No. 1's negative lead and armature, and that coming from the west end passing through the alternating-current leads and busbars to the smaller machines. If Mr. Greer had inserted ammeters in the positive leads of Nos. 2 and 3, he would have found that current was flowing in them to the west feeder and when the direct-current sides of 2 and 3 were disconnected from the busbars that current was interrupted, which accounts for No. 1 dropping the west load and the potential falling to that of the distant west-end substation. The reason the ammeter needles on Nos. 2 and 3 went against the stops was because an equalizing cross current was flowing in the local circuit mentioned above, between the two smaller machines and No. 1.

In the accompanying diagram the paths and directions of the currents from the smaller machine to the feeder and rail through the armature of No. 1 and the alternating-current busbars are shown by the long arrows. The triple arrows on the negative lead of No. 1 converter mean that not only its own negative current but the negative currents of Nos. 2 and 3 are passing through it. The short arrows indicate the path of the cross current in the local circuit.



Mr. Harvey's Diagram of Circuits

The resultant current due to the combined direct and alternating currents flowing through the alternating-current busbars was probably alternating in character, though the wave form was doubtless very much distorted. The manner in which the current distributed itself among the collector rings and alternating-current leads varied with each position of the armature. For example, when one wire was carrying the greater part of the direct current the other two wires would probably be supplying the greater part of the alternating current. A study of conditions similar to the above, by means of an oscillograph, would be very interesting and instructive.

S. H. Harvey.

Hamilton, O.

In the issue of December 20 are three answers to my inquiry concerning the peculiar trouble with rotary converters which was described November 15. Of the three, that of Mr. Farwell is without doubt the correct solution. A more clear and concise explanation would be difficult to find. Mr. McKenney was correct in his statement that the trouble was due to operating the converters from a common set of alternating-current busbars, but the remainder of his explanation is wrong. By reading the description of the behavior of the machines one will see that it was not simply an exchange of current between No. 1 and the others, but that No. 1 actually was carrying the load on both feeders, although the feeders were actually separated at the switchboard because, as Mr. Farwell points out, the machines were tied together through the armatures and the alternating-current leads until separated by Nos. 2 and 3 being taken off the direct-current busbars.

Mr. Filkins is wrong in his explanation; the east and west end trolley wires were separated by a section insulator. I stated in the article that there was no link between the east and west end, and this was proved by the fact that the voltage of the direct-current busbars was that of the distant west-end substation (less the line drop) when Nos. 2 and 3 were taken off the direct-current busbars. If it had been as explained by Mr. Filkins the voltage of the direct-current busbars would have been practically that of converter No. 1, since the drop in the feeders to the first trolley tap and that of the trolley wires between the first taps would have been slight.

Handley, Tex.

The Light That Failed

In a certain power plant, which was so small as to require only one attendant, a disagreement arose between the employer and the operator, which so angered the latter that he quit on one day's notice. It was impossible to get an experienced man to take the position in time to keep up the service, so an unskilled laborer was put on the job. The retiring operator refused to give this man any instructions, and it was more by luck than anything else that he kept the plant going for three days. At the end of that time an operator was secured who found no difficulty in understanding the plant, for it was a simple water-power installation of two units.

It was winter and the load was so light that it was unnecessary to run both generators together until one evening in early January, when some slight trouble with the machine in operation caused the attendant to decide to parallel the generators and take the first one off the line. His tracing of the connections had shown him that the synchronizing lamps should be dark when the two machines were in synchronism, and so, after getting No. 2 up to speed, he switched on the lamp ready to throw the main switch when the lamp darkened. He was surprised to find that the lamp did not glow at all and after rejecting the supposition that the machines had happened to come into step and stay there, he investigated the lamp and found that it was in good order.

Evidently there was some trouble in the connections of the lamp circuit and as it was therefore impossible to synchronize the generators, he kept the load on the first one until time for shutting down. A very careful search of the lamp connections was made, with the result that nothing could be found the matter with them. As a last resort the synchronizing lamp switch was taken apart and the source of the difficulty was revealed. A brass strip, intended to carry the current to the lamp, had been filed very thin in one place, and when the metal had contracted in the intense cold of the winter, had pulled apart there.

The fresh appearance of the filed place made it evident that it was the work of the preceding operator. He doubtless expected that the strip would be fused by the current to the lamp when at its maximum, that is, when the two generators were as far as possible out of step. If, when the light went out, the new operator threw the main switch, it would bring the two machines into dead short-circuit with each other, resulting possibly in the destruction of both generators. But for the unforeseen cold snap, this ingenious bit of spite work would probably have succeeded.

Everything worth while in the gas engine and producer industry will be treated here in a way that can be of use to practical men

Some Simple Handy Tools

By James E. Noble

A friend has several tools which cost only a few cents for material; the work of shaping them he did himself.

Fig. 1 is a tapered wedge made of steel, which is useful for separating flanges, prying off cylinder heads, scraping off old packing from flanges, etc.

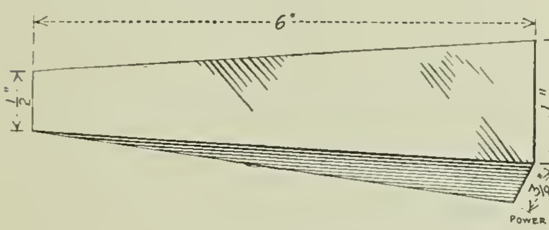

Fig. 1. Steel Wedge

Fig. 2 is a cleaner for gasolene and oil pipes. A piece of steel rope 8 feet long and ¼ inch in diameter is bound tightly near one end with fine wire, leaving about 2 inches of the wire ends to be spread out and act as a brush. A wooden or other handle with a thumb set screw is slipped over the rope and can be set at any point along the length of rope. In using this device, the spread end of the rope is inserted in the gasolene or other pipe and

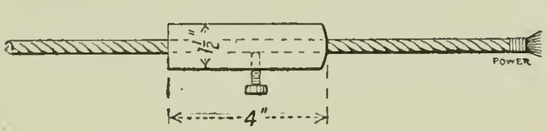

Fig. 2. Oil-pipe Cleaner

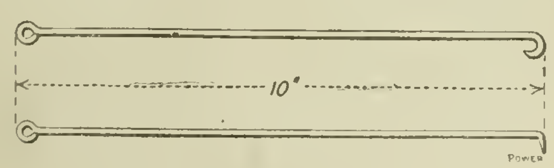
the handle is set an inch or so from the end of the pipe and the rope end forced into it; then the handle is moved another inch or two away and the rope forced farther in, and so on. A small pipe is easily cleared of any ordinary obstruction.

Fig. 3 shows a piece of stout wire with a hook formed at one end. It is handy for lifting out springs, picking up anything which may fall in a place difficult to reach with the hand, and so on.

Fig. 4 shows a steel wire with a straight bend at one end, and that end sharpened



Figs. 3 and 4. Packing Hooks

to a point; it can be used to pull out fine packing from packing boxes, etc.

Fig. 5 is a special bit, squared at one end so that it can be used in an ordinary brace or breast drill. The other end is widened out and sharpened as shown; it is especially useful for grinding in small valves and valve seats on gas engines, and for other kinds of work requiring a wide screwdriver blade and extra power.

Fig. 6 is a bolt-hole marker. It consists of a piece of round lead rod with an ordinary iron-pipe cap on one end. In cutting out paper washers as gaskets for gas-engine cylinder heads, some engineers use a hammer to mark the bolt holes, and this sometimes breaks away

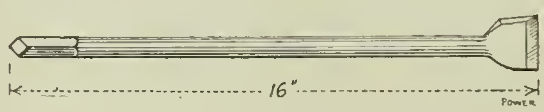


Fig. 5. Screwdriver Bit

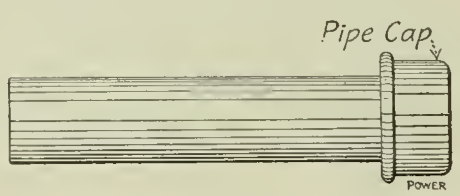

Fig. 6. Bolt-hole Cutter

the sharp edge of the iron around the holes. With this tool you simply lay the paper on the flange, place the lead end over the hole and strike the iron cap with a hammer; the bolt hole will be cut in the paper washer neat and clean. With bolt holes larger than the lead end, it can be used at the opposite side of the flange to mark the holes on the paper far better than an ordinary lead pencil, as the edges are square or sharp at *A* and reach right against the bolt hole.

According to reports received by the United States Geological Survey, the production of coal in the United States during 1910 was between 475,000,000 and 485,000,000 short tons, a considerable increase from the output of 459,715,704 short tons in 1909 and approximately equal to the maximum previous record of 480,363,424 tons, produced in 1907.

Of the total production in 1910 the anthracite mines of Pennsylvania contributed nearly 83,000,000 short tons and the bituminous mines between 390,000,000 and 400,000,000 tons.

Pertinent Features Relating to Gas Power*

By Edwin D. Dreyfus

During the fifteen years of commercial use of the gas engine in this country, abundant experience has been furnished from which may be deduced two features of importance:

1. The distinct fields of usefulness of gas engines may be determined definitely under any conditions, and, in general, are very well defined. Contrary to the frequent implication that gas is a direct competitor of steam power or other source of energy supply, there are unmistakable regions where a gas plant is unqualifiedly superior; and, on the other hand, there are places where it would be a positive economic disadvantage. Evidently there exists a line of division or equality but occasionally encountered, where the decision rests upon probable changes in industrial or operating conditions.

2. Gas-power machinery is less responsive to the ingenious fancy of the designer than the other well known types of station equipment, because the requisite characteristics of satisfactory operation and continuity of service may be satisfied only by a simple and effective design, from which but small deviation is feasible.

The disregard of these factors more than any other cause has been harmful to the gas-engine art. Notwithstanding this, the industry has materially prospered, and, owing to the inherent high efficiency in the conversion of latent thermal energy into useful mechanical power, it will increasingly continue to hold the attention of the engineering profession and commercial world as well.

The available fuels for engine operation are enumerated below and their approximate composition and calorific values are given in Fig. 1.

1. *Natural Gas,* existing principally in western Pennsylvania, western New York, West Virginia, Ohio, Kentucky, Kansas and Louisiana districts. It is a gas of ideal quality, possessing high heat value, being free from suspended impurities and containing only a small percentage of highly inflammable constituents (hydrogen chiefly).

2. *By-product Gas,* obtained mainly from blast furnaces and coke ovens; also from oil refineries as distillate. These gases are, in their crude form, accom-

*Extracts from a paper read before the Pittsburg Railway Club.

panied by objectionable impurities—entrained ore dust in the first two and oily vapors, lampblack and sulphurous compounds in the distillate gas—which must be removed to a reasonable degree by cleaning and scrubbing apparatus before delivery to the engine.

3. *Artificial Gas.* As several different fuels and processes are employed in the manufacture of combustible gases, there are several kinds available, such as:

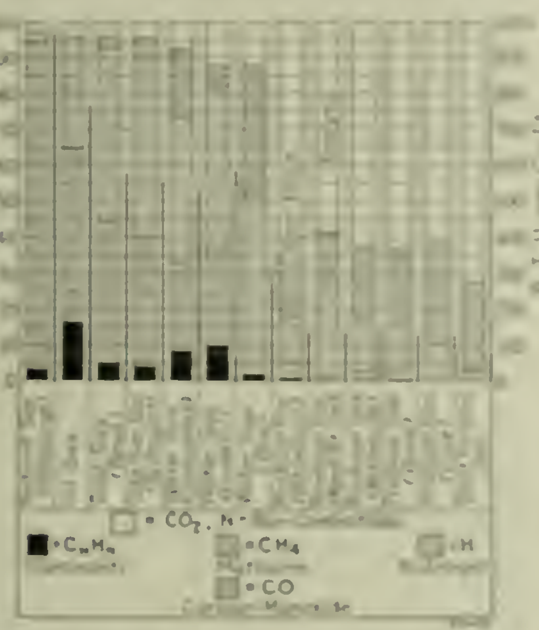

FIG. 1. COMPOSITION AND HEAT VALUE OF FUEL GASES

a. Illuminating Gas, produced from coal in benches or retorts by destructive distillation. This is available in practically all large cities; it is of high heat value and is a fairly clean gas. It contains a high percentage of hydrogen which compels the use of comparatively low compression pressures to prevent preignition. The enrichment essential for illuminating purposes and the added expense of distribution make the cost of this gas to the consumer ordinarily so high that its use for power purposes is restricted to very special cases.

b. City Gas, either made from the partial oxidation of coal and carburetted, or from crude oil, possesses the same limitations as illuminating gas so far as the gas engine is concerned. Blue-water gas of somewhat lower heat value and cost, is also less satisfactory and economical than the familiar producer gas.

4. *Producer Gas. A.* The gases made from anthracite and bituminous coals present the logical solution for the use of the gas engine in the absence of by-product or natural gas at low prices.

B. Oil gas producers for power purposes have not yet attained a sufficient degree of development to warrant extended use, but where crude oil is the predominating fuel supply, some installations have been made with fair success.

THERMAL EFFICIENCIES

The foremost characteristic of the gas engine lies in its uniformly high thermal efficiency in all sizes. This virtue is not found in either reciprocating steam engines or steam turbines; therefore, the greatest utility of the gas engine, barring by-product or natural gas supply, will occur in the smaller operations.

As an illustration, Fig. 2 shows conservative heat requirements in B.t.u. per kilowatt-hour of output for turbines ranging from 500 to 10,000 kilowatts inclusive, and a typical gas-engine curve which applies to all sizes. The latter is based on the total heat of the gas and a gas quality containing a high hydrogen content (lowering the effective value, say 8 per cent.), preferably to place the two types of units on the same plane. It is evident that as the larger capacities are approached, the disparity between gas and steam units steadily vanishes, either plant at best consuming approximately two pounds of coal per kilowatt-hour. Conversely, with a decrease in size of the plant, there is a wider gap between the two types of equipment. Thus the gas plant will continue to develop a kilowatt-hour on two pounds of coal, while the steam station may use eight to twelve pounds.

OPERATING ECONOMY

The impression that gas power invariably implies a lower cost of operation is being dispelled through the critical analysis of the elements of power cost. Fuel is manifestly only a fraction of the entire expense. Customarily a division is made between fixed charges, embodying interest, depreciation, taxes and insurance, and the purely operative expense, which includes fuel, labor, oil, waste, water, supplies and repairs. Fig. 3 illustrates the importance of the cost constituents. It is based on plants consisting of two units and burning coal which costs $3 delivered.

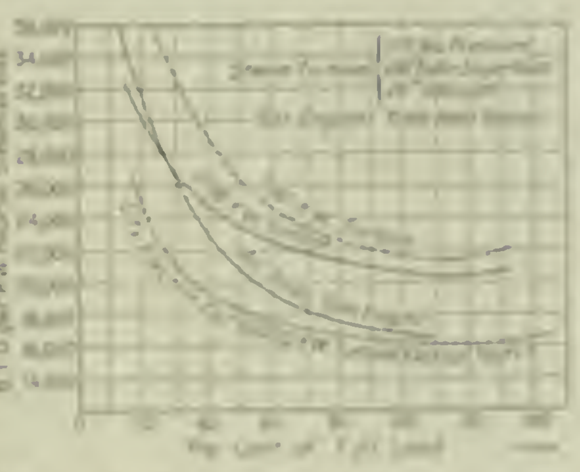

FIG. 2. HEAT ECONOMY OF TURBINES AND GAS ENGINES

The composite cost of a gas-power plant exceeds that of a high-grade steam plant by approximately 30 per cent. Such difference is quite normal in view of the character of working in the two plants. The gas engines must withstand combustion pressures reaching 450 pounds per square inch and corresponding temperatures up to 3000 degrees Fahrenheit, whereas a turbine deals with pressures of 150 to 200 pounds per square inch and temperatures in the neighborhood of 500 degrees Fahrenheit. Moreover, turbines are operated at relatively high speeds and very efficient use can therefore be made of the material employed.

Labor in small gas and steam plants will not differ greatly, but the simple turbine, with its minimum of parts, places a severe handicap on the gas engine when high powers are contemplated, constituting another reason for the barrier against the use of large gas engines for central stations burning coal as fuel. Having the size and cost of the plant, together with the schedule of operating labor and supplies arranged, the decision hinges upon the probable load factor and also upon the price of fuel, where it may be subject to variation. It is an obvious fact that low load factors work against the use of expensive installations, notwithstanding their superior efficiency.

Fortunately for the gas plant, the embarrassment of low-load factor conditions may be partially overcome by the use of a simple low-pressure turbine in conjunction with a heat storage system supplied by the waste heat of the engine and operated to carry the peak of the load.

Available statistics indicate that the cost of repairs in well designed gas-power plants of moderate size should be about on a parity with those of high-grade steam-turbine stations. That this assertion is reasonable is evident from the fact that the greater cost of cleaning and readjustment of boiler and condenser tubes above the negligible upkeep of the producer largely offsets the increased cost of "conditioning" the gas engine above that of the turbine. Hence fixed charges were arbitrarily assumed equal in plotting Fig. 3.

The real difference in obsolescence between the two types of plant is more or less intangible at present, and, therefore, in order to avoid complications, no distinction has been made.

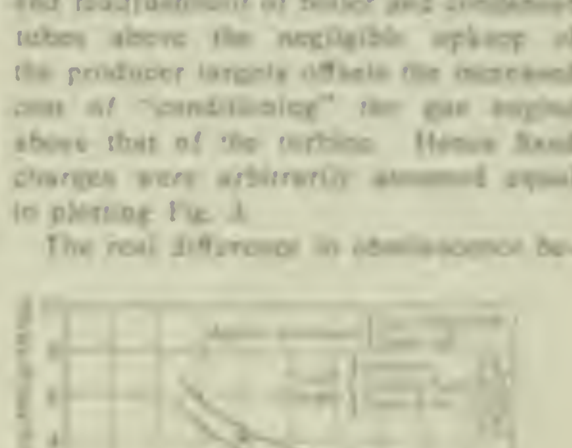

FIG. 3. COMPARATIVE OPERATING ECONOMY

Table 1 is given as an example of the

operating efficiency of a 550-brake horsepower producer-gas plant, including all items of expense:

TABLE 1.

Data on 550 Brake Horsepower Gas Plant. Monthly Record of Operating Costs, December 1909. Unit Load Factor 89.3 per Cent.; Station Load Factor, 67 Per Cent.

Items.	Cents per Kilowatt-hour. Producer Room.	Engine Room.
Fuel	0.202	
Operating labor	0.120	0.036

Auxiliary Heating

Power generation has mainly been reckoned with as applying to central distribution, but in the machine shop, factory and related industries, the power house is subjected to the extra demand of heat supply, especially above latitude 37 degrees. The heating requirement is often improperly allowed to discount the intrinsic value of the gas plant for the reason that the waste-heat energy is not concentrated in the same convenient vehicle for transmission to the point of consumption as is the case with the noncondensing engine or turbine.

More recently gas-engine exhaust heaters have been devised which render available in the form of steam 70 per cent. of the heat of the exhaust. While this quantity represents only two pounds of steam per brake horsepower developed, it will evidently prove sufficient where the ratio of power to steam demand is low. Where the ratio of the pounds of heating steam required per brake horsepower is known, a choice of prime mover may be made as indicated by Table 2.

TABLE 2. POUNDS OF STEAM PER BRAKE HORSE-POWER.

Simple automatic engine	40

Gas engine (waste jacket and exhaust heat used in hot water system)	5
Gas engine only, exhaust applied to steaming	2

A late report from railroad circles is that the engines on the Pennsylvania lines east and west are to be equipped with automatic underfeed stokers. Orders have been issued to the master mechanics of all the shops to install the stokers as soon as possible. The reason given is that the company wants to live up to the law requiring the abatement of the smoke nuisance. No confirmation of this report has been heard. It is said that 6000 engines will be so equipped.—*Exchange.*

Some Ignition Pointers

By Paul C. Percy

The sudden stopping of a gas engine which has been running normally is almost always due to a breakdown somewhere in the ignition system. With a jump-spark system this may be a broken connection in either the primary or the high-tension circuit; "frozen" contact points on the vibrator of the spark coil, or a short-circuit in some part—any part—of the system. It could also be due to a slipping or broken timer or to slipping of the belt or pulley of the generator if one is used, but these are not so likely to happen as the first three defects.

If the make-and-break system is used there is no vibrator to "freeze," of course, but the other troubles mentioned can occur. The failure to "fire" can also be caused by the contact points of the igniter having been burned out; this will either prevent them from closing the circuit at all or make the electrical resistance at the contact points so high that the current will be too weak to produce a good spark when the contacts are separated.

If the igniter is of the electromagnet type, failure to "fire" may be caused by trouble at the timer, such as burned con-

A Good Diagram

tacts, loose connections, or a weak spring. It may also be that the rocking contact of the igniter is jammed so that the magnet cannot move it.

Trouble in the ignition system will also prevent an engine from starting up, of course, but failure to start can also be due to many other causes, whereas a sudden stop is rarely caused by anything else.

Too much current in the primary circuit of a jump-spark system is as bad as too little. It overheats the coil and eats away the contacts of the timer and the vibrator very rapidly and very unevenly. This uneven burning of the points is what causes them to stick together or "freeze." The surfaces are so rough and irregular that they finally touch each other only at a small high spot on each piece of platinum, and the heavy arc produced between the sharp points fuses them together.

To guard against "freezing," as well as other contact troubles, the platinum points of all timer, vibrator and igniter contacts should be cleaned and trued up once a week. This can be done in a very few moments with a sharp, medium-cut file, a very fine file and a piece of emery cloth, using these in the order named. In finishing with the emery cloth it should be backed up by a thin strip of steel, such as a machinist's rule, to avoid rounding the edges. The faces of the platinum points should be left dead flat and true with each other.

If the timing of the igniter be retarded beyond the dead-center position of the crank, the cylinder will almost certainly overheat because the combustion of the mixture is greatly prolonged; also, the power of the engine will be reduced. If the timing be advanced too far, the engine will usually knock, but this cannot be considered a reliable guide because some engines do not begin to knock until the timing has been advanced so far as to be really dangerous.

It is advisable to put stops on the timer mechanism which will prevent retarding the timing beyond the dead-center position and advancing it too far. It is necessary to take diagrams, with the best mixture that will ever be used, to find the point to which the timing should be advanced at full load; the point of maximum advance should be that which gives the nearest approach to a well rounded diagram, such as the one here shown. Sharp corners at the peak and the ignition point on the diagram are not desirable, but with a rich mixture containing much hydrogen it is not easy to avoid them; that can best be done by adding more air to the mixture and advancing the ignition point a little more.

A New Aeroplane Engine

The *Yorkshire Observer,* in an account of a lecture delivered before the Leeds University Engineering Society, by R. J. Isaacson, gives his claims as inventor of an improved aëroplane engine, as follows:

He stated that his new engine was based on the same general principles as the Gnome, but embodied many of his own devices, notably one which enabled the engine to be started slowly and run at almost any speed up to its maximum that the aviator wished. This was a vast improvement, because with all machines in use at present it was only possible to work at one speed, and that the highest. Therefore, when an aviator, having attained a considerable hight, wished to descend, he must shut his engine off altogether. But if the propeller once stopped revolving it was impossible to restart the engine without help, and therein lay the reason for the awe-inspiring volplanes, by which aviators descended from great hights. It was necessary to descend at a great speed, so that the force of the air against the propeller might keep it in motion in order that when the aviator neared the ground he might restart his engine, and thus control his movements. Mr. Isaacson claimed that the use of his engine would obviate all necessity for volplaning.—*Daily Consular and Trade Reports.*

Water Control Valve on Heater

Much worry and trouble are caused by the automatic valve which regulates the flow of feed water into an open heater. I know of no valve of which so much is expected. It must work so freely as to be handled by an ordinary float, it must move from a closed position to wide open during the movement of the float, and it must shut perfectly tight.

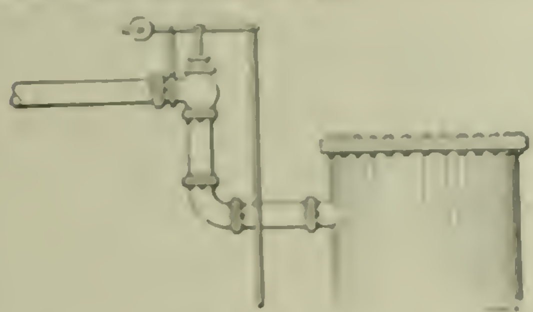

FIG. 1.

I have tried several valves, one of which was made as shown in Fig. 1. The 20-foot head under which it worked would, however, hold it shut until the float was held almost clear of the water. Then, when the valve did operate, it opened wide with a jump and almost deluged the heater with water; in closing it would shut with a vicious bang as soon as the valve got near enough to its seat to be caught in the current of water. Sometimes it would pound on the seat 30 or 40 times before seating.

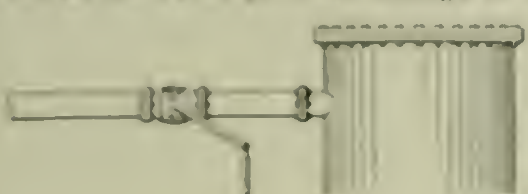

FIG. 2.

The second valve I tried was of the butterfly type, shown in Fig. 2. It had just one fault; it would leak in spite of all that could be done, and if no water was drawn for an hour the heater would be flooded.

Another valve I tried was an ordinary globe valve rigged up as shown in Fig. 3. The fault of this valve was that, although it worked freely, it did not open enough during the travel of the float, and very often small particles in the water would wedge in between the disk and seat and prevent the valve from closing tight.

FIG. 3

Another valve was made from an ordinary brass stop cock with a handle attached, as shown in Fig. 4, but I found that, while it had all the good features of shutting off tight, not clogging, and opening quickly and fully with a small travel, it was too stiff to be operated by the float, and if it was loosened up so that it could be operated by the float it would leak at the washer on the small end. Finally I removed the nut and washer, threw them in the scrap box, and then cut off the small end of the plug so that it lacked 1/4 inch of coming flush with the seat on the body of the valve against which the washer had fitted. Then a small brass disk was soldered over the small opening of the body, making it similar to a marine cock. This put an end to the leakage at the small end of the plug. In order to hold the plug on its seat, I rigged up the pressed spring shown in Fig. 5. The point of the adjusting screw rests in the center plate on the plug and is so arranged that the pressure could be varied. This meets all requirements as it works free, shuts off tight, opens and closes with a small movement and is not affected by the pressure or water head it is controlling.

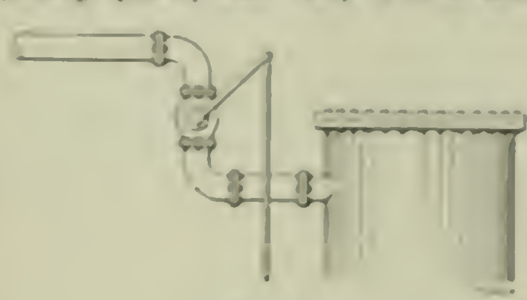

FIG. 4

Estimating Refrigerating Surface

It is often convenient to know the amount of piping required for brewery cellars and the like.

Without knowledge of all of the elements effecting the cold losses from a cold-storage compartment, only general statements can be made, which, while probably fitting the general case, might fall wide of the mark in any isolated special case.

The logical way of computing pipe areas is first to calculate the amount of heat entering through the walls of the cellar and add to this the amount of heat generated by the fermenting wort. For a given back pressure and known number of hours of operation of the refrigerating machine, it is then a simple matter to calculate the amount of pipe required. The estimate of the pipe area is based on the amount of heat that will pass through the metal of the pipe due to the difference between the temperature of the brine or ammonia on the inside and that of the air on the outside.

Obviously, the amount of piping depends on the wall area, insulation efficiencies and differences in temperature. When these factors are not all known, it has been customary to adopt rough rules in the form of "ratios" by which it is assumed that under average conditions a square foot of pipe surface or

RATIOS FOR BREWERY CELLARS

Kind of service	Cubic Feet per Foot of Piping, Running Line, to 1000 Cubic Feet			Temperature
Fermenting room	2" direct-expansion pipe	[illegible]	[illegible]	[illegible]
	1¼" brine pipe	[illegible]	[illegible]	
Storage cellar	2" direct-expansion pipe	[illegible]	[illegible]	[illegible]
	1¼" brine pipe	[illegible]	[illegible]	
Chip cellar	2" direct-expansion pipe	[illegible]	[illegible]	[illegible]
	1¼" brine pipe	[illegible]	[illegible]	
Racking room	2" direct-expansion pipe	[illegible]	[illegible]	[illegible]
	1¼" brine pipe	[illegible]	[illegible]	

running foot of pipe will provide refrigeration for a given number of cubic feet of space. A fermenting room, for example, maintained at a temperature of from 36 to 40 degrees would be piped, according to the practice of one large builder of refrigerating machines, on a ratio of 1 to 14; that is, 1 running foot of 2-inch direct-expansion pipe for every 14 cubic feet of space.

For piping the different cellars in a brewery, the following ratios will offer at least a rough guide, it being understood that they may not fit particular cases and that it is desirable, when it is possible to determine the areas, differences in temperature and nature of the insulation of each wall, floor and ceiling, to compute the cold losses through the walls. Then, after determining the ammonia back pressure and temperature, the required number of square feet and finally the number of lineal feet of heat-absorbing pipes may be ascertained.

The accompanying table will serve as a guide in laying out the piping for brewery cellars of from 10,000 to 40,000 cubic feet in size.

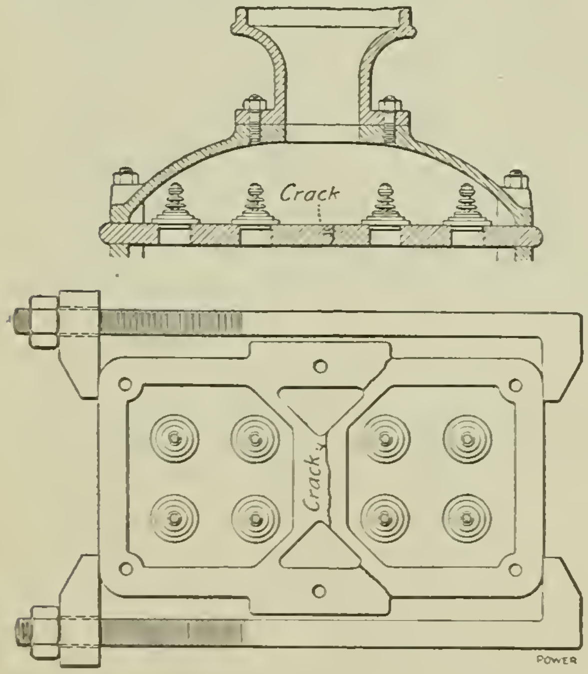
Repairing a Pump Valve Deck

Upon taking charge of a steam plant at one time, I found a broken pump, and nobody knew what ailed it.

Upon removing the cap of the valve chamber it was found that someone, in removing the water-valve plate, had cracked it, as shown in the sketch. This crack was caused by driving a cold chisel under the plate at one end.



CRACK IN VALVE DECK

The plate was repaired by getting two iron clamps from the stop and putting the two broken pieces in place, as shown. A small strand of asbestos wicking was put between the two broken pieces, and the clamps were then tightened.

Next, the top of the valve chamber was put in place and the nuts tightened on the stud. The clamps were then taken off, the pump started, and kept in operation for six months. In the meantime a new plate had been ordered.

In removing a valve plate, use two thin chisels, driving them in slowly, and use a thin knife blade to work the gasket loose before the plate is removed.

Little Rock, Ark.

Topics for Discussion

After reading mechanical papers and books, I have been able to find but little on the design of breechings for boilers. One thing especially was noticed, the lack of discussion of draft losses.

There are a few subjects I would like to see discussed, and I believe they would be of great benefit to many engineers. They are as follows:

The proper area of a breeching for boilers to be operated at the builder's rated capacity; and for boilers to be operated at high overloads, say 175 per cent. or more of their rated capacity.

Draft losses to be expected in a breeching of excellent design.

Draft losses through the sharp angle turns or sudden changes in shape of the breeching.

Losses in draft, due to radiation, in long runs of bare steel breechings.

Losses in draft due to the cooling of gases by the infiltration of cold air in brick breechings.

One case is that of a plant of three boilers and a brick-lined steel stack, 56 inches in diameter and 135 feet high. The stack was of sufficient size and hight to furnish draft for the plant, yet there was insufficient draft. Eventually an induced-draft outfit was installed with the fan arranged to "pull" on the stack. The draft at the base of the stack was then 1.85 inches; on the stack side of the damper, 0.40 inch; and over the fires, 0.17 inch. Later the breeching was altered and some other changes made, all on the stack side of the boiler. Now it is possible to get a natural draft at the base of the stack of 0.83 inch; stack side of the damper, 0.65 inch; over the fires, 0.23 inch. Better conditions can be had by a little more effort.

It will be noted that after the changes there was more draft available over the fire than before. The alterations were made between 9 p.m. Saturday and 4 a.m. Monday, for four consecutive weeks and cost about $800. The motor on the induced fan took 90 amperes at 220 volts, working 24 hours a day, six and a half days a week.

In another case sixteen 400-horsepower boilers delivered their flue gases to a brick breeching. The temperature at the damper was 550 degrees Fahrenheit and at the stack 380 degrees Fahrenheit. Quite a decrease.

Another case was that of three water-tube boilers. The draft in the breeching near the stack was 0.95 inch; on the stack side of the damper, 0.40 inch.

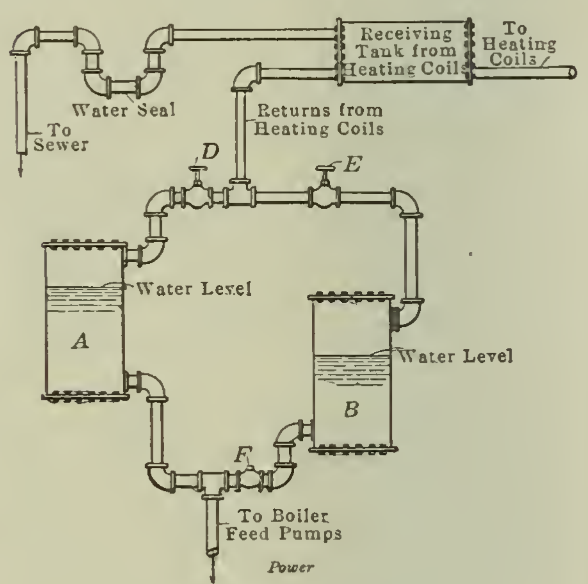
Chicago, Ill.

Heater and Piping Arrangement

A scheme of arranging two feed-water heaters so that the feed pump can automatically draw water from either heater is shown in the illustration. This arrangement also remedied a trouble experienced from air leaking into the drip receiver of a Paul heating system.

Referring to the cut, *A* and *B* are two open feed-water heaters, and *A* is set 17



ARRANGEMENT OF HEATERS

inches higher than *B*, and receives all of the returns from the heating coils, the valve *D* being open and *E* closed. When there is a sufficient supply of return water the greater head of water in the heater *A* keeps the check valve *F* closed, the water level in *B* being kept constant by a float in the heater *B*, but as soon as the returns are not sufficient to supply the boilers and the water level in *A* falls to a point where the head of water in *B* becomes greater, this heater will furnish the boilers with feed water; heater *B* receives its supply of water from the service mains.

As soon as the returns have again brought the water in *A* to such a level that the head will overcome that in *B*, the check valve *F* is closed and the pump again takes its supply from the heater *A*.

This scheme is entirely automatic and has been in service for over five years, and has given excellent satisfaction.

Trouble had been experienced by air leaking into the receiver in which the condensation from the heating coils accumulate. When air leaks into the receiver, through the joint of the cover, a pressure was established and the water in the receiver would back up into the heating coils, rendering part of the coils useless. The cover of the receiver was tapped out to receive a ¼-inch pipe and a pipe and a thermostatic valve were connected to it. A connection was also made from the valve to the regular pipe line leading to the exhauster of the system.

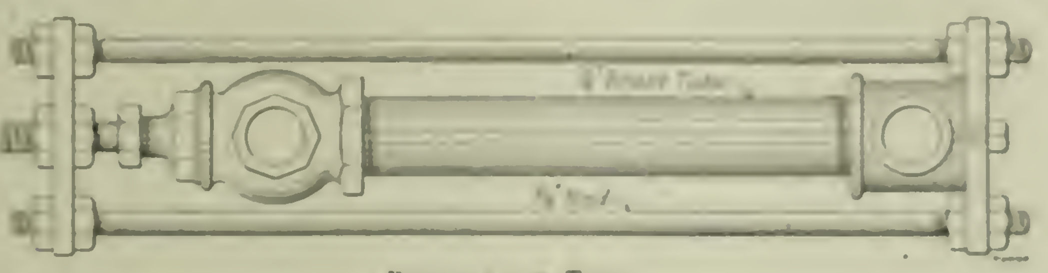
V. T. Kropidlowski.

Winona, Minn.

Homemade Trap

Following is a description of a steam trap that was made with material found lying around the shop. The idea is not new, as I installed such a trap nearly 20 years ago, still I thought, in view of its extreme simplicity, that it might interest someone, as it is perfectly reliable and satisfactory.

The illustration is so clear that a further description is hardly necessary, further than to say that the threads on the valve stem are removed to allow free movement through the stuffing box as the brass tube expands. As the brass tube fills up with water it contracts and draws away from the valve seat, thereby allowing the water to escape. When the water has drained out of the brass pipe it fills with steam, which causes the pipe to expand and close the valve.



Details of Trap

Passaic, N. J.

Valves in Steam Pipes

Notwithstanding the extensive discussion that has been carried on in technical papers concerning placing valves in steam pipes, as good an authority as William Kent, in his eighth edition of "Mechanical Engineers' Pocket Book," just issued, in his article on "Valves in Steam Pipes," page 852, seems to be under the impression that if a globe valve is connected with the pressure on top of the disk it cannot be repacked under pressure.

As a matter of fact, most valves of good manufacture today are equipped with a packing feature on the stem and in the hub, or on the yoke, which enables the engineer to pack the valve when it is wide open and under pressure. This feature consists of two finished surfaces, one on the stem and one in the hub, or on the yoke, which make a joint when the valve is opened wide so that there can be no leakage up through the stuffing box.

I notice further in this same article that Mr. Kent fails to bring out one point against taking the pressure on top of the disk and that is that in opening the valve it is necessary to lift the weight of the entire steam pressure on top of the disk, which is almost as much a strain on the threads as holding the disk down when the pressure is underneath.

E. G. Greenman.

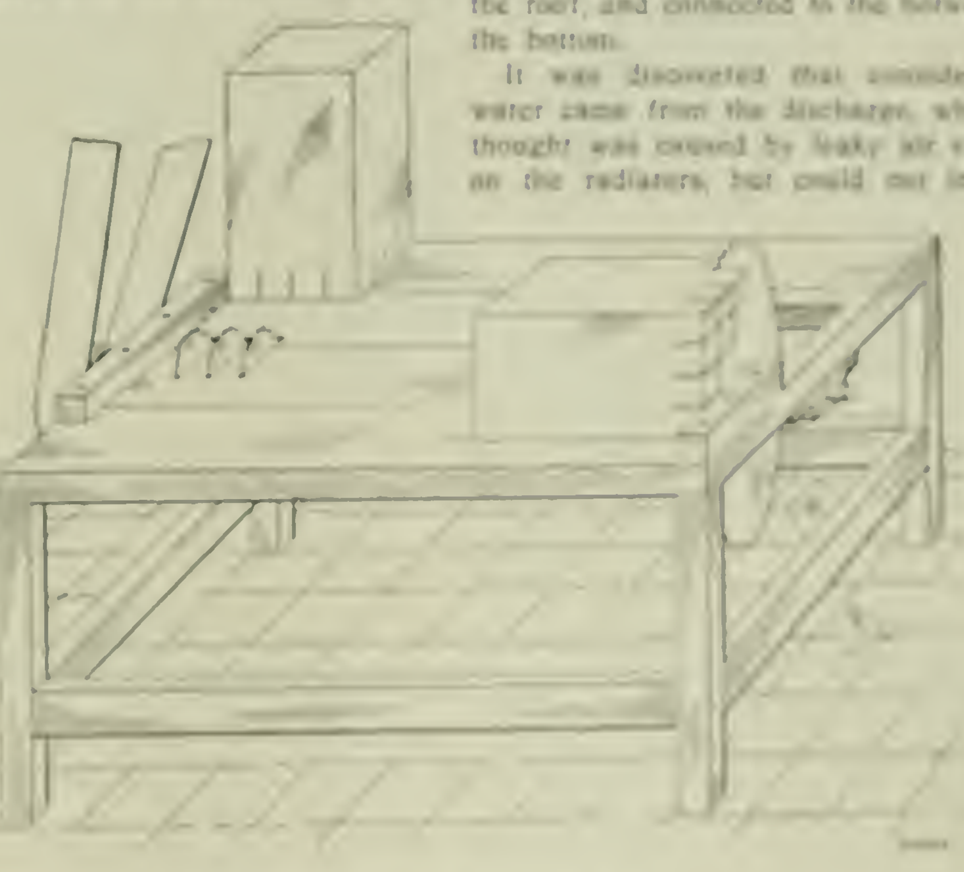
Cincinnati, O.

An Ice Cubing Machine

I was employed for some time at a plant where part of the equipment consisted of a refrigerating outfit. The ice manufactured was in the so called 50-pound blocks, 8 inches square by about 25 inches long.

About this time the manager decided that it was necessary for us to supply the ice to several of the departments in the form of small cubes about 2 inches square. There are machines on the market for doing this work, but the company seemed unwilling to go to the expense of purchasing one, and we were told to make one.

After some planning it was decided to erect a saw bench and use power-driven circular saws to do the work. A carpenter built a stout frame in a convenient position close to a line shaft.



Machine for Cubing Ice

While this work was being done, a 6-inch pulley, three small saws, 8 inches in diameter, and one larger saw, 20 inches in diameter, were procured and secured to a small 1-inch shaft, 4 feet 6 inches long, as shown in the illustration. When the frame was finished the shaft was placed in proper bearings which were secured to the frame. A hard-wood top was made, and slots cut in it for the saws to come up through.

With the top in place the small saws protruded 2 inches at the highest point and the large saw showed a full 9 inches. The slot at the large saw was made large enough to allow the cubes to drop through when sawed off.

A guide was placed 2 inches to the left of the small saws to be used as a gage when cutting.

To operate this saw the block of ice was placed on end and pushed across the small saws, making three cuts in the block 2 inches deep, dividing it into four equal parts. The block was then turned half round and the saws run across the block at right angles to the previous cuts. The ice then appeared something like the sketch.

The 20-inch saw was used to cut these cubes from the block.

Lambton Mills, Can.

Saved Water from Heating System

For more than a year I have had charge of a plant where much of the steam is used for heating through a vacuum system. The vacuum was maintained by a double steam jet and the discharge was led to a tail pipe which went out through the roof, and connected to the hotwell at the bottom.

It was discovered that considerable water came from the discharge, which I thought was caused by leaky air valves on the radiators, but could not induce the management to get new ones, so I connected the vacuum pipe from the heating system to a pump-exhaust pipe leading to a condenser.

It was found that by this method a higher vacuum could be maintained on the heating system than with the jet and [illegible] 1000 pounds of hot water daily.

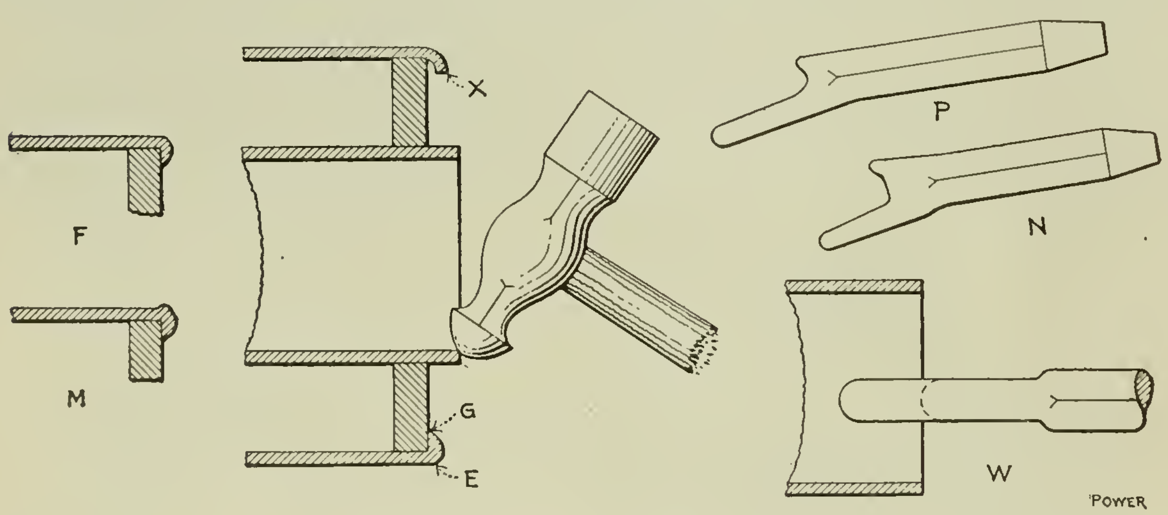
Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

Beading Boiler Flues

In reply to the inquiry in the December 13 number in reference to beading boiler flues, I will say that there is much more skill needed in doing this work properly than is generally considered. As to beading the body of the head down solid, there is no reason why this should not be done. Care must be used, however, not to overbead. When the head is once solid upon the flue sheet any more hammering or beading will stretch the head and tend to loosen it from the plate. The turning of the head should be carefully done from the start. Many workmen start a bead too hurriedly or use too heavy blows. With the ball end of an ordinary hand hammer used as shown in the accompanying figure the bead can be turned nicely. The hammer strokes should not be too heavy, but moderate, until the bead has been started or slightly turned. Flues are too frequently cracked by hammering too much at one point. It is the peening-action of the hammer that stretches the end of the flue; therefore the "licks" must be distributed entirely around the circumference of the flue in order to stretch it evenly. When this has been done (it is fully understood, of course, that the flue has been previously rolled tight in the sheet) the turned edge of the flue will appear as shown at *X* in the illustration.



Beading Tools and Types of Bead

When this has been done the tube is ready for an application of the beading tool. This tool should be properly shaped in order to do the right character of work; for instance, the surface that comes against the end of the flue should be slightly rounded as shown at *W*. With this shape the tool has a stretching effect on the metal. Another view of the tool is given at *P*. It requires a little practice in order to get this little tool just as it should be. Many repairers get the tool shaped as shown at *N;* such a tool makes a poor job, as the surface is too square to do good beading.

Heads are often found that are not properly done; they appear as shown at *M*. A small ridge is thrown up on the inside. In such a case it would be well to use the flue roller.

At *F* is shown a nice form of bead which can be made with a tool like that shown at *P*. Many beads are shaped as shown at *E*, having a rather square corner. With such a bead the edge of the flue does not fit against the edge of the sheet as will a bead shaped as shown at *F*.

To do a beading job properly the sharp edge of the tube hole in the sheet should be taken off with a flue-hole reamer or a half-round file.

I can see no reason for throwing the edge *G* down tight against the head and not beading solid. The beading tool should not reduce the thickness of the metal across the point of turning. One should not attempt to turn a flue that reaches through the sheet too far; usually a distance equal to twice the thickness of the metal is about right, although in some cases three thicknesses is better. If the tube is allowed to stick through too far a bad piece of work will result, as a bead will be formed which will be too full; consequently it is very likely to crack or split in turning down.

Putting in a set of flues and doing the work right is a nice piece of work.

C. R. McGahey.

Baltimore, Md.

Compound Engine Proportions

A. Hoffmann, in an article under the above caption in a recent issue, makes certain statements which are not quite clear to my mind, and with the expectation of receiving more light, I wish to open a discussion on this interesting subject.

In one paragraph he states, "Where both reheater and steam jackets are used, 10 per cent. should be added to the mean effective pressures." Directly below this he writes, "Where an engine operates against a back pressure, the mean effective pressures should be increased about 0.85 pound for each pound of back pressure." The use of reheater and steam jackets is known to be beneficial to the performance of an engine, but is it to be implied from the latter quotation that back pressure is also good?

Further on, he says, "Attention is called to the fact that this terminal pressure is not dependent upon the cylinder ratio nor the cutoff, but is determined solely by the steam pressure and ratio of expansion * *." Is not the latter entirely dependent upon the other? Assuming a compound engine having a cylinder ratio of 4 to 1, with a point of cutoff at 0.25 of the stroke, is it possible to raise or lower the terminal pressure in the low-pressure cylinder under the conditions, assuming normal conditions and neglecting cylinder condensation? In a worked-out example for a highly economical compound engine Mr. Hoffmann states that the cylinder ratio should be 5 to 1, and that the cutoff (presumably in the high-pressure cylinder) should be 27.5 per cent. of the stroke, and that the number of expansions should be 19. Under these conditions, will not most of the expansions take place in the low-pressure cylinder (or in the receiver) and, in consequence, will not the condensation there be abnormal? F. R. Low, in his treatise on the compound engine, teaches us that it is not the total amount of condensation in both cylinders that must be reckoned with, but the greater amount in either, which becomes the factor in the economy of a compound engine.

Suppose a compound engine with cylinders 20 and 40 inches in diameter to be working under conditions that cause a cutoff in the high-pressure cylinder at about 0.2 of the stroke, is it to be understood from Mr. Hoffmann's remarks that if a higher cylinder ratio were used, by making the high-pressure cylinder 18 inches in diameter, that the engine would operate under more economical conditions? It seems to me that his method of proportioning compound engines by arbitrarily fixing the mean effective pressure as referred to the low-pressure cylinder is not commendable, for, as he states, "no definite rule can be laid down giving the proper mean effective pressure upon which to figure." As users of compound engines buy this type with economy of operation in view, and as pounds of steam per horsepower delivered is the true measure of engine economy, why not start designing with this one factor alone given? Suppose a compound engine of a given indicated horsepower were to be designed that should use a predetermined or given amount of steam per horsepower, the total amount of steam could be calculated, and from this the size of the steam pipe, steam chest and valve posts to accommodate that quantity of steam without wire-drawing could be figured. Also, the size of the high-pressure piston and the distance from the heads at which it shall stand at the point of cutoff could easily be determined. Proportioning the rest of the engine would then depend on the price the purchaser wished to pay. The price would determine the length of the stroke and the cylinder ratios.

The designer is in a position to give the buyer what he wants, and by having a high-pressure piston which is more or less of a standard, he will soon be able both in theory and practice to state exactly what the engine is capable of doing when installed, and to quote prices and the degree of economy that he could guarantee with the various cylinder ratios. To design a compound engine based on a given mean effective pressure referred to the low-pressure cylinder or the ratio of expansion, is to forget that the operating engineer is very apt to change the number of effective expansions, and to forget that pistons, valves, etc., are apt to leak.

The reputation of an engine is not made while the engine is brand new, but after some years of service. If the high-pressure cylinder is designed first, then some consideration of future troubles may be employed in the low-pressure cylinder.

N. CASSIDY.

South Framingham, Mass.

Problem in Expansion of Steam

At the present time, when, in technical studies, discoveries are so frequent, and often of so revolutionizing a character, it is necessary for an engineer who wishes to keep abreast of the age to read a large number of technical papers. From the force of circumstances he must read

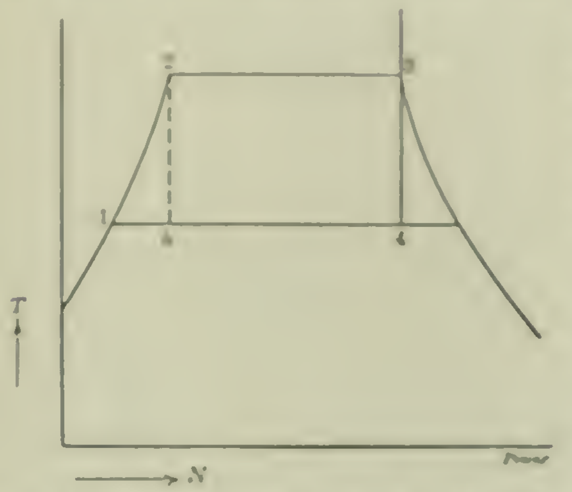


FIG. 1. TEMPERATURE-ENTROPY DIAGRAM

rapidly, and he feels, consequently, that he has a right to demand that these articles be written with especial care; that they be so worded as to leave no shadow of a doubt as to their meaning. It is not fair for the author to expect his reader to puzzle out from indefinite English an important technical fact. Yet not all scientific articles are so written, and in consequence—both of the hasty reading and the poorly stated facts—many wrong conclusions are drawn, and a body of faulty ideas allowed to spring up. Examples of such articles are numerous, but the present writer was impressed with this need for guarded and accurate expression most recently in connection

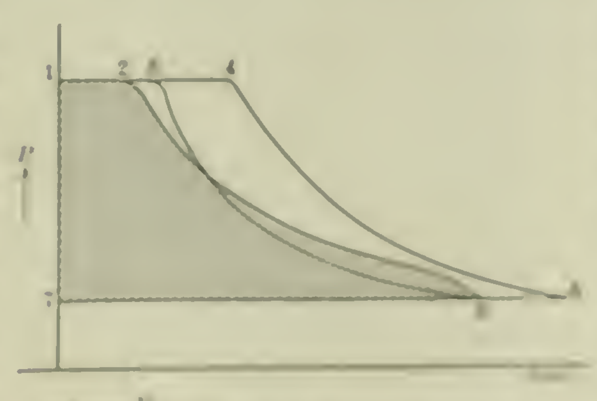

FIG. 2. DIAGRAMS FOR IDEAL ENGINE AND FOR ACTUAL ENGINE

with an article by Mr. French in the December 13 issue of POWER.

Mr. French makes such reference to the Carnot and Rankine cycles as to seem to indicate that they are identical. Now the Rankine, or nonconducting steam-engine cycle may be represented by the area 12541 on the T-N diagram, Fig. 1. The Carnot, or purely theoretical, cycle may likewise be represented by the area 23452. The difference is in the left of the diagram and is due to the necessity of heating up the feed water in the boiler instead of compressing adiabatically from the lower temperature to the upper temperature.

Mr. French goes on to show that an "exact solution" of his problem (i.e., to find the volume of steam at the end of a certain number of expansions in the steam-engine cylinder) can be found by "assuming" adiabatic expansion and figuring for the quality of steam and its corresponding volume. This is perfectly correct, if everyone understands that an ideal Rankine cycle is being considered, but not otherwise, and Mr. French did not make it clear that he meant the former.

The solution of problems similar to those just cited depends, therefore, on what assumptions are to be made. The Carnot cycle is unattainable (although several pumping engines have used cycles having very nearly that efficiency), and while we continue to use metallic cylinders we cannot hope to get a nonconducting engine, but we can reduce radiation and conduction greatly, by using small temperature limits, by polishing

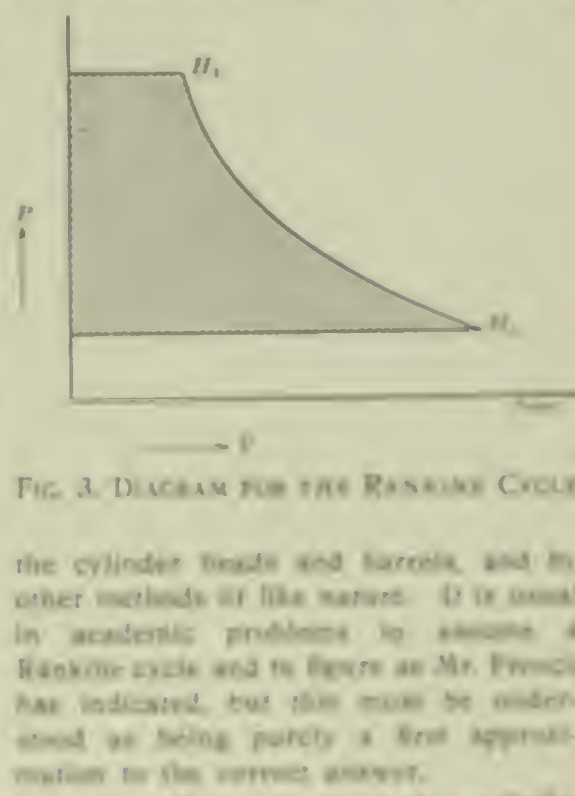

FIG. 3. DIAGRAM FOR THE RANKINE CYCLE

the cylinder heads and barrels, and by other methods of like nature. It is usual in academic problems to assume a Rankine cycle and to figure as Mr. French has indicated, but this must be understood as being purely a first approximation to the correct answer.

In the ordinary steam engine, cylinder condensation and subsequent reëvaporation alter the condition of affairs decidedly. This can be shown by Fig. 2, where 14571 shows the work that could be done in an ideal nonconducting engine by the actual steam admitted to the cylinder. Likewise 13671 represents the ideal amount of work obtainable from the steam, accounted for as dry at cutoff. In distinction from these ideal areas is that of the actual work, shown on the diagram by the [illegible]. The difference between the areas 13671 and 14571 shows the loss in work due to cylinder condensation, radiation, leakages and other losses. The actual volume at the end of expansion is also much less, for the same amount of steam, with the actual cycle than with the ideal cycle.

The actual cycle is affected by a number of factors each varying the work attainable, and the volume at the end of expansion. These are, in part—the temperature range, the per cent. cutoff (the ratio of expansions), the ratio of diameter to stroke, the speed, the clearance and the quality of the steam. The temperature range has the greatest effect on the cylinder condensation, but this is modified by high speed, by small ratio of diameter to stroke or by superheat.

What has just been said shows the impossibility of foretelling how the steam in the cylinder will behave unless some assumptions are permitted as representing typical results, and so we return to the assumption that the real steam-engine cycle is approximated closest by the Rankine cycle. The work done in such a cycle is $H_1 - H_2$, where H_1 is the total heat of the entering steam, and H_2 is the total heat of the exhaust.

Other problems involving total heats are the throttling-calorimeter problems, flow of steam, expansion valves and others involving adiabatic expansion. These problems are greatly simplified by the use of the Mollier total-heat diagram, such as is very admirably given in Marks and Davis' "Steam Tables and Diagrams," a recent publication based on the very latest experimental data. With these diagrams, problems like the above, and also those involving ratios of expansion, are simplified extremely, and made capable of quick solution.

H. J. Mitchell.

Cambridge, Mass.

Power Plant Design and the Operating Engineer

The controversy regarding the operating engineer and the consulting engineer has been waged in the columns of Power for some time. It seems to me that this question as to which is better qualified to design a power plant is entirely uncalled for for the following reasons:

In the small-sized plant where the chief engineer has only one or two helpers, he generally does not get a very large amount of money for his services. As a consequence, a man broad enough to design a new plant, under the best conditions, would not be working at the small salary which that plant warrants. As a consequence, the consulting engineer is called in.

In the large plant, where the chief engineer is something more than the name sometimes implies, there is generally a good mechanical engineer employed steadily by the management, or the head engineer is himself a mechanical engineer. In the latter case, as both are one, there is no cause for argument. In the second case, if the management is good, with no friction between the employees, the chances are that the two would work together and no outside man would be called in.

Any mechanical or consulting engineer would welcome the advice of a capable man who is to have charge of the plant. On the other hand, the chief engineer should certainly welcome the advice of the technical man who, of necessity, makes himself acquainted with the general trend of progress in his line. With two good men working harmoniously together the results should certainly be better than with one alone.

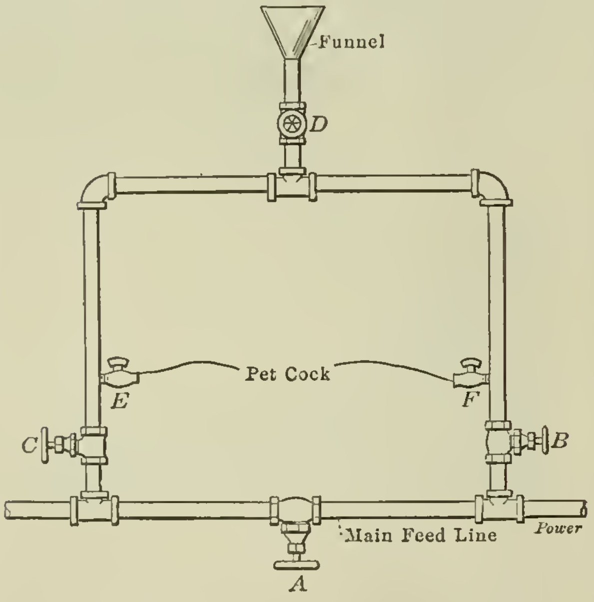
The consulting engineer who knows it all and will not listen to suggestions is not worth having. The running engineer who is afraid to have his ideas criticized by others is certainly not sure that his design is the best under the circumstances. The employer who employs one or both of the above men and brings in an outsider for this work shows a lack of confidence in his own men. If the lack of confidence is unwarranted the best thing the employees can do is to go elsewhere. If it is warranted, the men should realize it and make the best of it.

John Bailey.

Milwaukee, Wis.

Introducing Solvents into Boilers

In the issue of December 6, Charles H. Taylor's letter under the above title is interesting. I agree with Mr. Taylor that solvents should be introduced in small quantities, but it is poor practice to feed them through the suction of the pump. This practice is liable to result



Arrangement for Feeding Solvents

in a scored lining of the water end, scored rods and cut packing.

A much better way is to feed the solvent through the discharge. The accompanying figure shows the manner in which this can be done. Close valves *C* and *B*, open valve *D* and put in a charge of the compound. Close valve *D* and open valves *B* and *C* and close valve *A* for a few strokes of the pump.

M. W. Utz.

Minster, O.

Boiler Efficiency

The efficiency of the Keeler water-tube boiler as reported in the issue of November 29 is exceptionally good; however, it is to be regretted that having so nearly attained maximum efficiency the plant was not arranged to insure getting it.

The temperature of the escaping gases was 473.62 degrees Fahrenheit. This temperature could not be appreciably reduced by enlarging the heating surface of either the boiler or the superheater, the temperature corresponding to the pressure of 188 pounds being 383 degrees; the difference in temperature between the fire-swept and water-swept surfaces of the tubes is 90 degrees. It would be possible, however, to reduce the temperature of the gases by installing an economizer and it should be quite possible with a normal size of chimney to reduce this temperature by 100 to 120 degrees, without impairing the draft. If this were done, then, the gases would impart an amount of heat to the feed water which would depend upon the size of the economizer.

From my calculations it should be quite possible, from the figures given in the test, to so arrange an economizer that an overall efficiency of 80 to 89 per cent. could be obtained from the boiler, superheater and economizer.

It appears that the feed water is at present heated by live steam to 183 degrees Fahrenheit, if this is correct, then the installation of an economizer would save the large amount of steam that must be necessary for this purpose besides effecting the above mentioned saving of 6 to 7 per cent.

It is seen that the makers guaranteed a boiler efficiency of 65 per cent.; from the figures given in the test, it is found that the actual boiler efficiency was nearly 75 per cent., the efficiency of the boiler and superheater together being 82.36 per cent. It is to be hoped, however, that a munificent government paid the bonus upon the latter figure, for the attainment of an efficiency of 75 per cent. with a water-tube boiler is a noteworthy performance.

The attainment of this high efficiency is, no doubt, partly due to the efficient way in which the boiler was incased. The makers' guarantee of a 65 per cent. efficiency, however, is about 5 per cent. lower than is usually obtained.

This test is very instructive and valuable for power-plant engineers as it shows the actual saving in fuel that can be accomplished by a superheater in conjunction with the boiler, and, as is well known, this is not the only saving that is accomplished, for, by superheating, the steam condensation in the steam pipe is prevented, and a great saving in the steam used by the engine is effected if it works with superheated steam.

James Cannell.

Stanford le Hope, Eng.

Does the Crosshead Stop?

Although considerable space has already been devoted to the subject, "Does the Crosshead Stop?" it would be transgressing the requirements of accuracy to let the most unmathematical contribution of Messrs. Stover and Pullen, in the January 3 issue, pass unchallenged. It is merely a problem in the elements of trigonometry to show that the crosshead does actually stop, that is, that its velocity for an infinitesimal moment is zero, but your contributors have gone out of the way to give three different proofs, not one of which is valid.

By reference to Fig. 1, reproduced from the January 3 issue, we are told that the crosshead stops because at the point of dead center the crank-pin center is moving along an arc of a circle described with point H_1 as its center. This, of course, assumes that H_1 will remain

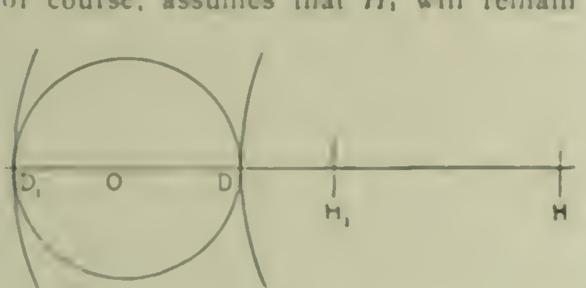


FIG. 1.

fixed while the crank-pin center is moving along this arc. But, if we do not know whether the crosshead stops or not, how can we assume that H_1 is fixed while the crank pin is moving? This is reasoning in a circle.

In proofs 2 and 3 your contributors have attempted to show that the crosshead-pin center has no motion parallel to its axis at the dead center, because the crank-pin center has then no motion parallel to the same axis. That this is not a valid proof may be easily shown by reference to Fig. 2. Here we have a rod AB sliding along, so that its extremities

FIG. 2.

always touch two perpendicular axes. At all times, point A has no motion parallel to OY, yet it is obvious that point B is always moving along the axis OY.

By simple trigonometry, however, it is proved that the velocity of the crosshead center is at any time equal to the angular velocity of the crank pin (which remains constant) multiplied by the perpendicular distance from the crank-shaft center to the connecting rod. At the point of dead center this distance is 0 (see Fig. 1), which makes the velocity of the crosshead center

$$a\ constant \times 0 = 0.$$

This is the only way that I can see of attacking this problem, because this solution deals with the velocity of the crosshead center, which is the only point under consideration, as we know that the crank-pin center is revolving at a constant velocity.

LOUIS GRUSSBAUM.

New York City.

Why Engineers Do Not Write

The question often raised in regard to why engineers, as a class, do not write, may be answered in various ways, each truthfully. I believe that chief among the reasons is the fact that the average practical operating engineer who is not a technical graduate fears that his words may sound uncouth or that his statements may be criticized from an angle from which he is incapable of viewing them before presentation and that if his communication be published a later copy of the paper will contain articles written by some "high brow" who, in terms which are Latin and Greek to him, will inform him that he is a "rough neck" or a "hill billy" and that what he thinks he knows is a delusion and that science and textbook learning can prove that black is a shade of white by another name and he is afraid that some of his friends will read both articles and tease him about it. If he conceives the idea of benefiting his fellow craftsmen by relating his experience he is liable, too, to forsake the idea owing to an attack of "editor shakes." To one who has never screwed up the required nerve to approach an editor the first effort usually causes dreams at night of said party wearing horns and banding back papers with sarcasm. Those of the craft who are in the habit of overflowing should dispel this by splashing and yelling "The water's fine!"

The fact that a practical man lacks the ability to write in technical language or to describe conditions fully in technical terms should not keep him from coming in on any discussion as, after all, it is the "proof of the pudding" which is of most value to us all, and if he does not sometimes differ with the textbooks there must be something wrong with him.

For instance, it may be gathered that water-tube boilers are preferable to flue boilers for any installation. Are they? He might also read that the spring pop-safety valve is always better than the old reliable, easily understood, easily adjusted lever. Is it? He might also get the impression that any expenditure for equipment would be justified if economy in operation were secured, regardless of conditions and size of installation. Would it? He might also, for another instance, find good authorities giving as efficient belt speeds anything between 3900 and 5000 feet per minute, most of them under 5000, and yet all of the big engines he knows of may be running the flywheel rim at a speed of a mile a minute. He may probably have read lately where an eminent authority stated that 11,290 feet per minute belt speed was common in Europe, becoming very popular in America and had exhibited the greatest economy.

In all of the printed matter on power transmission he has at hand he may not find one case where the author states whether his figures are based on a straight, cross or quarter-turn belt; what the size of the belt is, distance between centers, or whether an idler is used or not; whereas he may have an overloaded belt in his plant running under an idler and breaking pulley after pulley without perceptible slippage or any noticeable injury to the belt and a statement of the facts would bring him a satisfactory solution from two dozen readers.

This last is not imaginary. I had a chance once to help a fellow out who had brought about that condition by reducing the belt speed still transmitting the same quantity of power. He thought that the pulleys were defective.

In the little things, at least—those are all that I am competent to speak about—I know that the words of the "old boys" who have had to wiggle out of their own difficulties, are the most valuable that we can read.

W. R. SMITH.

Alton, Ill.

Chimney Problem

In regard to L. G. Watry's "Chimney Problem" in the December 27 issue, I do not think that the stack with the larger opening would draw cold air down the other one, for the reason that the area of both stacks combined is a little on the small side of the right area to give good results for two 50-horsepower boilers. A stack 22 inches square should be at least 50 feet high to give good results for one 50-horsepower boiler. So, with two boilers and two 22-inch stacks the hot gases would naturally fill both and rise in one [illegible].

In Mr. Watry's case I think it would be better to divide the smoke flue, making separate smoke flues for each boiler, and have the flues and openings slightly larger than the area of the stack so as not to retard the draft. Better results would be had if the stacks could have at least 10 feet more added to make their height not less than 50 feet.

GEORGE H. HAMMER.

Newburgh, N. Y.

Burning No. 3 Buckwheat Coal

In the issue of December 27, 1910, Warren O. Rogers, as a result of a visit to the New York Steam Company's plants in New York City, furnishes a description of his visit with some very positive conclusions.

It is with considerable regret that I note Mr. Rogers' visit was entirely confined to the plants above stated, because by no means are his conclusions either accurate or confined to facts.

Wherein does Mr. Rogers err in his conclusions? He errs in the fact that he visits a plant to see something with which he is unacquainted and as a result of his observations in that one plant sets out a set of rules as being the only possible means of burning No. 3 buckwheat coal. If Mr. Rogers had visited the Brooklyn Bridge power house, located in Brooklyn, he would have found that they have been burning at that plant No. 3 buckwheat coal for several years back in place of lump coal which they were previously using, and he would have formed some radically different conclusions from those reached after his inspection.

In addition to the Brooklyn Bridge power house a list of over 100 plants in the city of New York could be furnished, all of which would give him some different ideas in regard to the conclusions which he would put forward as the only means of burning No. 3 buckwheat coal. The rules that he supplies are:

1. "Fire light and often."
2. "Keep a forced draft of from 0.5 to 0.6 inch."
3. "Keep the damper 5/16 open."
4. "Never use a slicing bar."
5. "Level the fires about every two hours or when necessary."
6. "Never throw green fuel on other than incandescent fuel."
7. "When cleaning fires, keep 1 inch of ash on the grates."
8. "Always use a shaking grate."
9. "Never handle the fire as other fuels are handled."

The conclusion is that "A small steam plant with one or two boilers would have trouble in running on this grade of fuel, because it would be difficult to force the fires in case a sudden demand was made for steam."

Commenting upon the foregoing:

No. 1. This rule is imperative.

No. 2. A forced draft must be used but it may be anywhere from 0.5 to 1½ inches, according to the fuel burned per square foot of grate surface, which may be anywhere from 12 pounds (as cited in Mr. Rogers' article as the amount burned at the New York Steam Company's plant) up to 28 or 30 pounds, which is the practice maintained in some of the plants which would be on the list I have previously referred to as being able to furnish. This rule, therefore, should be changed to read: "Use forced draft with such pressure as may be required to burn the amount of fuel necessary."

No. 3. The opening of the damper would be governed entirely by natural-draft conditions of the plant; if natural draft was poor the damper might be entirely open; if the draft was excellent then the damper should be choked down to a point so that no excess of air may be drawn in above the fire.

No. 4. It is good policy not to use a slicing bar on any grade of fuel, but if a clinker formation is prevalent it may be necessary to use a slicing bar to raise the fuel from the grate in order that the air may work through it, but a slicing bar should not be used to break through the fire and elevate the ash on top of the live fuel.

No. 5. The leveling of the fires should be done as often as required and is not governed by any specific time. There are fuels which can be leveled successfully at least twice between each time of firing; this would apply to fuel which is very hard in its character and slow burning.

No. 6. This rule can stand as given.

No. 7. If shaking grates are used, the 1 inch of ash might be of benefit to prevent loss of fuel through the grate bars, but there is no reason to keep ash on the grate for any other purpose than to prevent the coal falling through the grate openings; and if this is the condition, then the grate in use is not a proper one for the burning of No. 3 buckwheat coal as the openings in any grate used for this class of fuel should be small enough to practically prevent the fuel from falling through it. A much hotter fire will be established if the 1 inch of ash is cleaned out and the fresh fuel brought over on the grate.

No. 8. A shaking grate is not necessary; in fact, it is a positive detriment unless arrangements are made for disposal of the ash without opening the ashpit doors, and the larger percentage of power plants have no means of cleaning the ashpits except by hand tools. There is no positive rule as to whether a shaking or stationary grate shall be used to burn No. 3 buckwheat coal. The only feature about the grate is that it should have small openings in it which can retain the coal without the coal working through it in any perceptible percentage.

As to whether a shaking or stationary grate should be used, it depends entirely on the method of disposing of the ash; if a tunnel exists by which the ash can be withdrawn from the ashpit through a hopper bottom, a shaking grate is preferable, but if the ashpits must be cleaned by shoveling out (as the vast majority are cleaned), then a shaking grate is of no advantage as the cleaning can be done more readily from a stationary grate, through the firing doors. Particularly is this true as forced draft must be used in burning No. 3 buckwheat coal and the disturbing of ashpit doors for cleaning simply destroys the use of the forced draft as long as the cleaning is in process.

No. 9. This rule is not at all necessary as it will be found that No. 2 or No. 1 buckwheat or even pea coal will give better results in firing if the fuel is placed uniformly over the grate and not piled in any considerable quantity at any one point. It is furthermore unnecessary to put green fuel on the spots of fire where the fuel has not already become ignited.

Regarding the conclusions, No. 3 buckwheat coal is in successful use in a very large number of plants in New York City as well as other places where they have but one or two boilers. If a proper forced draft is in use, it is an easy matter to overrate the boiler to cover any extra demands for steam, provided the boiler is properly cared for. In a plant with one boiler where they are using No. 3 buckwheat coal if a proper forced draft is in use a fire can be run from six to eight hours, using a fair grade of No. 3 buckwheat coal, prior to cleaning, and with a little head work a time of cleaning can be established where cleaning can be accomplished without detrimental loss of steam, especially so if the furnace and its equipment have been properly designed together with the forced-draft equipment so that cleaning can be accomplished quickly and thoroughly.

Other features of the use of No. 3 buckwheat coal with which the ordinary engineer will come in contact are that there are fuels of this size placed on the market which are so hard that they do not burn freely enough to be a satisfactory steam coal, in which event a small percentage of soft coal added to them will be found beneficial. On the other hand, there are fuels of this size sold which burn out too quickly to be a satisfactory fuel, as their excessive amount of ash will prove a hardship as to disposal.

It will be well, therefore, for anyone contemplating using No. 3 buckwheat coal because of its attractiveness in price, to carefully study the supply of coal offered, and, before jumping at conclusions, investigate the subject broadly so that when he purchases equipment he will be in possession of something of a permanent value and properly studied to give him the best service.

Charles H. Parson.

New York City.

A few small bolts were handed to the writer, with the request that they be charged with electricity to prevent the nuts from coming off. Further questioning proved that my predecessor had simply immersed them in the sal-ammoniac solution of the battery, which caused them to rust fast.

Precautions against Damage from Bursting Tubes

Much is written from time to time about the numerous failures of tubes in water-tube boilers, and recommendations are made that better workmanship and better material be used, and that manufacturers be compelled to stamp each tube with their name, so that responsibility for disaster may be properly fixed. All these recommendations are necessary and good, but in the meantime let us do what we can to protect the personnel in the boiler room and, until a perfect tube is found, let us fit all boiler furnaces with in-swinging doors. With all the doors in a setting of this type there is but one door opening outward—that leading into the smokestack, through which steam and hot water are discharged in the event of the rupture of a tube. In such a furnace, when a tube lets go, all the doors in the setting, if they happen to be open, are closed by the rush of the steam, or if closed they tend to stay closed tighter. This prevents any scalding of the attendants in the boiler room, and the steam and hot water are passed harmlessly up the smokestack, unless it blows down the setting, but this contingency is nothing against the use of the in-swinging doors because all that needs to be done is to make the setting stronger.

Many of the furnaces in continental Europe in many countries by governmental requirement are so equipped. In our own navy in-swinging doors have been fitted to all the battleships and their use is gradually spreading to other naval vessels.

Closely allied with the in-swinging doors to the furnace is the use of check valves in the steam lines. We firmly believe the day is close at hand when a steam line without a check valve close to the boiler will be as rare as a feed line at the present time without its check valve. The use of check valves tends greatly to reduce the damage as a result of the rupture of a tube or of the steam pipe, inasmuch as the valve itself operates either way. If a steam pipe breaks, it shuts off the steam to prevent the boilers from emptying themselves through that break. If a tube in a boiler lets go, it prevents the other boilers connected to the same header from emptying themselves through the rupture of the tube.

It is bad to have to almost roast all day in a hot fire room, it is worse to get only two dollars a day for doing it, but it is worse still to be in constant danger of being scalded when that is not necessary.

Flywheel Explosions

There was a time when the dangers of generating and producing power from steam were confined to the boiler room. Occasionally a flywheel exploded, but steam-plant accidents were, as a rule, in the boiler room.

When engines were made larger, more powerful and designed to run at higher speeds, the engine room took on an added element of danger. Under the old practice the rim speed of the flywheel was so far below the safe speed limit that in case anything did happen to the governor, the engineer had a chance to shut down the engine before an accident occurred.

Nowadays conditions are vastly different, because most flywheels are run with a rim speed very close to the safe limit, and a slight increase in the speed of the engine brings the rim speed up to the bursting point.

Sometimes the cause of a flywheel explosion is easily discovered, but usually it is a difficult matter to determine.

Neglect on the part of the engineer is frequently responsible for such accidents, and usually consists of failure to properly adjust this or that thing on the valve or governor gear. Sometimes this is due to ignorance of the danger incurred by not taking the necessary precautions, but more often it is simple neglect to make a thing right that is known to be wrong.

Some engineers make a practice of examining the governor gear once a day besides making a careful test and inspection of the flywheel as well. To some this may seem "fussy," but it is better to err on the side of safety.

It is true that an engineer might inspect his engine every day for years and never find an adjustment out of its proper position; on the other hand, if the governor were found to be deranged, the valve cams so placed as to be useless, or a cracked flywheel discovered, the time that had been spent in these daily examinations would be a profitable investment.

An investigation would undoubtedly show that thousands of flywheels are seldom examined, the engineer trusting to chance that no crack has developed since the last hasty look, and in all probability would disclose hundreds of engineers who seldom test their engine safety cams in order to determine positively that they will prevent the steam valves from opening in case the governor drops to its lowest position. If governor inspection is a part of the work you have been neglecting, see to it; do not wait until tomorrow, but test it out today and see if the safety cams will work. Then complete the work by giving the flywheel a thorough inspection.

Two Diagrams

Two indicator diagrams alleged to have been taken from the same engine within the space of a few hours show a marked difference in outline and area. One is the conventional Corliss engine type of diagram with a compression line rising to about two-thirds of the initial pressure and there meeting a vertical induction line showing a lead of the steam valve which gives full initial pressure on the piston at the very beginning of the stroke. The cutoff, expansion line and exhaust opening appear to be in accord with good practice. On the other diagram the compression does not rise higher than the terminal pressure. The admission line slants inward so much that it is clear that full pressure is not realized until the piston is well started on its way; the point of cutoff and the expansion are the same as in the other, but the exhaust does not open until the piston has reached the end of the stroke. All of the valve events except cutoff are late, as though the eccentric had been turned backward several degrees.

There is a noticeable difference in the areas of the diagrams, the one with low compression and late admission being appreciably smaller than the other. It is said, however, by the engineer who took the diagrams that the load in both instances was identical and he is asking why, with an apparent maladjustment of the valves, the engine requires less steam and consequently less fuel for a given load than when the valves are properly set.

There is no reason to doubt the sincerity of the man who furnished the diagrams, and there is no attempt on his part to deceive anyone. But has he deceived himself? Can an engine showing a certain indicated horsepower in the cylinder deliver a greater brake horsepower than when showing a greater indicated output? Does it or can it ever happen as this engineer says it does with him? Is compression to any degree economical or otherwise? The clearance space must be filled with steam at or near initial pressure before the piston starts and this steam must give up some of its heat to the cylinder and piston before it can do other work.

What is the source of supply from which this steam can be most cheaply obtained? It is heat and pressure that are wanted. Can these be furnished at a lower cost by the engine or by the boiler? Is it cheaper to fill the clearance directly from the boiler than it is to use the engine part of the time as a compressor taking energy from the flywheel in one stroke and putting it back in the next?

These questions can be answered from the mechanical laboratories of half a hundred colleges and schools in this country. They have been answered by Professor Dwelshauvers-Dery, from the school at Liège, Belgium. But the correctness of the answers has been questioned. Experiments made thus far do not prove conclusively the truth or untruth of the contention. Academic discussion which starts nowhere, applying laws which do not apply, assuming conditions which do not exist and drawing conclusions from false premises ends nowhere and is not conclusive or even enlightening. What is the real answer, and why does not some college laboratory find and announce it?

Engineer or Laborer

In the "Want Columns" of a daily paper there recently appeared the following advertisement:

> "Applications will be received from 9 to 12 o'clock, noon, Tuesday, December 27, 1910, for the position of night engineer for municipal electric-light plant. Duties to commence January 2, 1911. Engineer will be required to do his own firing, salary $60 to $65 per month. Applicants to have necessary qualifications; state age, if married or single, and enclose copies of testimonials."

This advertisement modestly announces an opportunity for a man to act as night engineer and fireman, seven nights a week, for $60 a month; $720 a year, or $1.97 a night of twelve hours' run. It also implies that there will be more than one reply and that the engineer possessing the best qualifications will secure the place—and, worst of all, there *will be* several applications for the vacancy.

Anyone with sufficient intelligence to shovel the coal necessary to keep up the steam pressure would earn all that it is proposed to pay a man for not only firing the boiler, but attending to the engine and generator as well.

The necessary qualifications are, of course, that the night engineer shall have a knowledge of the steam boiler, how to fire and care for it, know something about a boiler-feed pump and injector, steam gage, safety valve, piping and the danger to be avoided in operating a steam boiler.

The successful applicant for this remunerative position must also know about engines and generators, switchboards and a hundred and one other things that are necessary to know before a man can safely operate even a small electric-light plant.

A town treasurer when assuming office is obliged to give bonds, and nobody would think of permitting him to handle the funds of the town without such a safeguard against loss, and yet probably not one word of objection will be raised against placing the machinery in this electric-light plant, costing thousands of dollars, in the care of a man who is capable of demanding a wage of but $1.97 per day.

In all probability those having the authority to hire a night engineer have not given much thought to his competency, and perhaps do not know that the man who obtains the night job can more than save the amount that is offered per month—if he knows how; but a $1.97 a day man will not cut much of a swath in that direction.

Another thing that apparently has not been considered is that in one night the $1.97 man is liable to do more damage to the machinery in the plant than can be repaired with the entire amount paid him for a year's wage.

It does not take much of a mistake to cause several hundred dollars damage; it has been done by merely carrying the water too high in the boiler to allow a longer time to sit down before attending to the feed apparatus, with the result that a cylinder head has been blown out, causing a shutdown and a lot of dissatisfied customers. Doubtless the $60 a month man will be able to make the wheels go around, but that is not economical engineering. A real engineer is needed and cannot be hired at a rate of $1.97 per night.

The same old story, only the number is ever increasing—Three boilers and a steam header exploded during the first half of January. On January 4 the new power house of the Lorain Coal and Dock Company, near Blaine, O., was badly wrecked by the explosion of a steam header. Rushville, Mo., was the scene of another boiler explosion on January 14, which killed two men. Two days later a boiler exploded at the Cleary stone quarry, Marietta, O., and as a variation from the usual a boiler on the towboat "T. N. Davis" blew up on the same date, when the boat was six miles north of Cairo, Ill., on the Ohio river. This disaster resulted in one death.

The master mechanic of a Massachusetts mill is publishing—and evidently believes—the report of a test in which he claims to have gotten an evaporation of *over sixteen pounds* of water from and at 212 per pound of combustible.

Ignorance on the part of the buyer of the good points of high-class machinery compared with the cheap and inefficient, is what keeps the cheap factory running.

Be prepared to make repairs before the breakdown occurs; after it has happened may be too late.

Inquiries of General Interest

Questions are not answered unless accompanied by the name and address of the inquirer. This page is for you when stuck—use it

Dry Sheet

What part of a boiler is the dry sheet?

B. D. S.

It is the extension in front of the tube sheet of a horizontal tubular which forms what is often called the smoke box.

Safe Stress on Stays

What is the safe stress on a boiler stay, and how is the stress calculated?

B. S. S.

The Massachusetts Board of Boiler Rules specifies a maximum working stress of from 6000 to 9000 pounds per square inch of minimum cross-sectional area, depending on material, construction and size. The stress on a stay is the number of square inches supported by the stay multiplied by the pressure per square inch, less the minimum cross-sectional area of the stay itself.

Valve Setting

How shall I set the valves of a 16x30-inch Corliss engine to get a diagram such as the POWER blueprint calls correct?

C. V. S.

With the wristplate in the middle of its travel, give the steam valves 5/16-inch lap and the exhaust valves 1/32-inch lead; that is, instead of having lap the valve will be open 1/32 inch. With the engine on the center, give the steam valves 1/32 lead.

Using Steam Expansively

What is meant by the term using steam expansively in a steam engine?

U. S. E.

When steam is admitted to the cylinder for a portion of the stroke and then cut off. The steam in the cylinder after cut-off stilll has pressure and expands, furnishing the energy to complete the stroke.

Horsepower of Engine

What is the horsepower of an engine 16x20 inches making 120 revolutions per minute with a mean effective pressure of 45 pounds?

H. P. E.

The horsepower of an engine is expressed by the formula

$$\frac{PAS}{33000} = horsepower$$

in which

P = Mean effective pressure;

A = Area of the piston in square inches;

S = Speed of piston travel in feet per minute.

The mean effective pressure is 45 pounds per square inch. The area of the piston, neglecting one-half the area of the rod, is 201 square inches. The piston speed is 400 feet per minute. Substituting these values in the equation, it reads

$$\frac{45 \times 201 \times 400}{33000} = 109.6 \text{ } horsepower$$

Strength of Boiler Seam

How is the strength of a boiler seam found?

S. B. S.

The strength of a boiler seam is the strength of its weakest part. This may be either in the sheet or in the rivets. The strength of the sheet is proportional to the length of the seam less the diameter of the rivet holes in the outer row. The strength of the rivets is the resistance they offer to shearing. The strength of the sheet is found by subtracting the diameter of the rivet hole from the pitch and dividing the remainder by the pitch. The quotient is the efficiency of the plate at the joint. The strength of the rivets is the shearing strength of one rivet multiplied by the number of rivets in a given section. The strength of the weaker of these two is the strength of the seam.

Pumping Hot Water

Why will a pump not lift hot water?

P. H. W.

Because the water which a pump handles is forced to it by the pressure of the atmosphere on the surface of the water outside of the suction pipe as fast as the pump removes the pressure from the water inside the pipe. When the water is hot the reduction of pressure inside the pipe lowers the boiling point of the water and instead of rising to the pump it gives off steam which the pump cannot remove fast enough to reduce the pressure to a point where it will rise in the pump cylinder.

Opening of Throttle Valve

Should the throttle valve of an engine be wholly or only partially open when running?

O. T. V.

The valve should be opened wide but not "jammed." As little obstruction as possible should be offered to the flow of steam from the boiler to the engine and a partially opened throttle is an obstruction.

Sluggish Gage Glass

What would cause the water to rise slowly in a gage glass immediately after it had been blown out?

S. G. G.

A partially stopped pipe or a valve not fully opened.

Pressure on Crank Pin

What would be the pressure on the crank pin of a 16x20-inch engine with 120 pounds steam pressure in the cylinder?

P. C. P.

The area of a 16-inch piston is 201 square inches and the total pressure on the pin with the crank on the center will be

$$201 \times 120 = 24{,}120 \text{ pounds}$$

Counterbore

What is the counterbore in a cylinder, and what is it for?

C. C. C.

It is that portion of the cylinder which is bored slightly larger than the portion through which the piston sweeps. It furnishes an edge over which the edge of the piston ring travels, thus preventing the formation of a shoulder at the end of the piston travel.

Relation of Pump to Heater

What is the difference in the location of open and closed feed-water heaters in regard to the pump?

L. P. H.

The pump is between the boiler and the open heater, but the closed heater is usually between the boiler and the pump.

Two Peculiar Flywheel Explosions

One of these flywheels was wrecked by two waterwheels running away with an engine connected to the same shaft. The other flywheel was crushed in by a driving belt which was cut by the bursting of an 11 foot line-shaft pulley, the belt wedging between the engine flywheel and the cement floor.

Two flywheel accidents occurred recently, the first on Monday morning, January 9, at the B. C. and R. Knight textile mills No. 3, Manchaug, Mass. The flywheel was entirely demolished and the engine badly wrenched. This accident was due indirectly to a fire, as water used in putting it out soaked a belt, which later parted and allowed two waterwheels to run away with the engine.

The power plant consisted of two Corliss engines and two waterwheels. Both waterwheels were set in a basement room under the mill and back of the engine room. One of the engines was run on high-pressure steam and was set at one side of the engine room, with the flywheel next to the mill. The other engine was located on the opposite side of the engine room, with the flywheel set away from the mill; this second engine was run as the low-pressure side of the other engine, but was placed some 25 feet distant. Each engine was controlled by a separate governor and the only connection between them was the 8-inch steam pipe extending from the high- to the low-pressure cylinder. Fig. 1 gives an idea of the general layout of the power plant.

It seems that neither of the waterwheels was equipped with a governor, and the low-pressure engine was not equipped with a speed-limit safety stop. Although the high-pressure engine was protected by such a device, it had no control over the low-pressure engine.

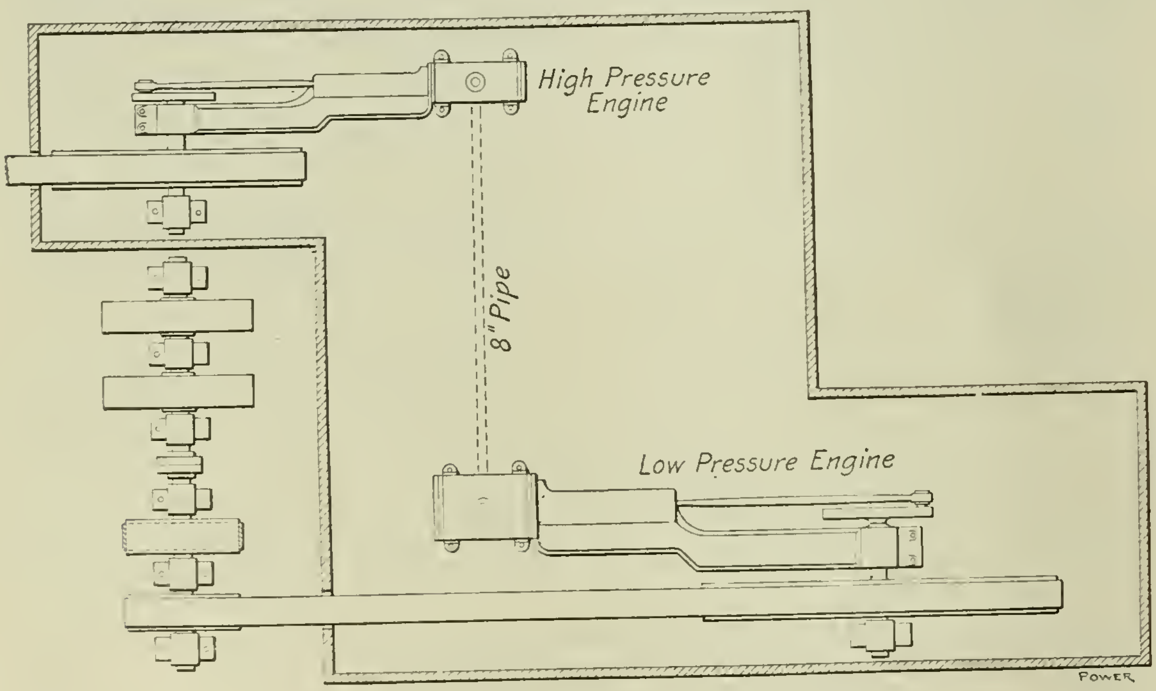

Fig. 1. General Layout of Engine Room

About 8 o'clock on Monday morning, a fire occurred in the mule room of the factory, but was quickly extinguished by water from the company's fire hose. Water, however, saturated a belt that ran from a pulley on a shaft that was connected to the waterwheels. This shaft also supported a driven pulley on which the main driving belt from the engine ran. About half an hour after the fire had been put out, the water-soaked belt parted, relieving the two waterwheels and the low-pressure engine of all load, and, there being no governing apparatus on the waterwheels, they ran away with the engine, the speed becoming so great that the 26-foot flywheel, having a 36-inch face and weighing about 25 tons, burst into dozens of pieces.

Some of the parts passed up through the engine-room roof, some through the rear wall and others into the wheel pit and back into the mill basement through a thick stone wall, wrecking piping, pulleys and shafting which were connected to the waterwheels.

As the engineer noted the increase of speed, an attempt was made to shut down the high-pressure engine and thus cut off the steam supply to the low-pressure engine, but before this could be done, the crash came. Fortunately, no one was killed, or seriously injured. Beside wrecking the flywheel, the main pillow block was broken at the jaws and the outer pillow block wrenched out of place. The engine will require extensive repair before it will be fit to run again.

No photographs were obtainable as the wreckage had been cleared away before a Power representative could get on the field.

The second accident occurred at 1:30 p.m. on Wednesday, January 11, when a flywheel was wrecked at the works of the American Axe and Tool Company, East Douglas, Mass., which is but a few miles distant from Manchaug.

A line shaft on which was mounted an 11-foot pulley was belted to a 310-horsepower compound single-acting Westinghouse engine by a 19-inch belt. The flywheel on the engine was 7 feet in diameter and had a 21-inch face. The belt was given a large arc of contact on both of these pulleys, by means of two idlers which were placed as shown in Fig. 2. The 11-foot pulley was made with a cast-iron hub and spokes and a steel rim made in two sections and riveted to the spokes. The idler next to the line

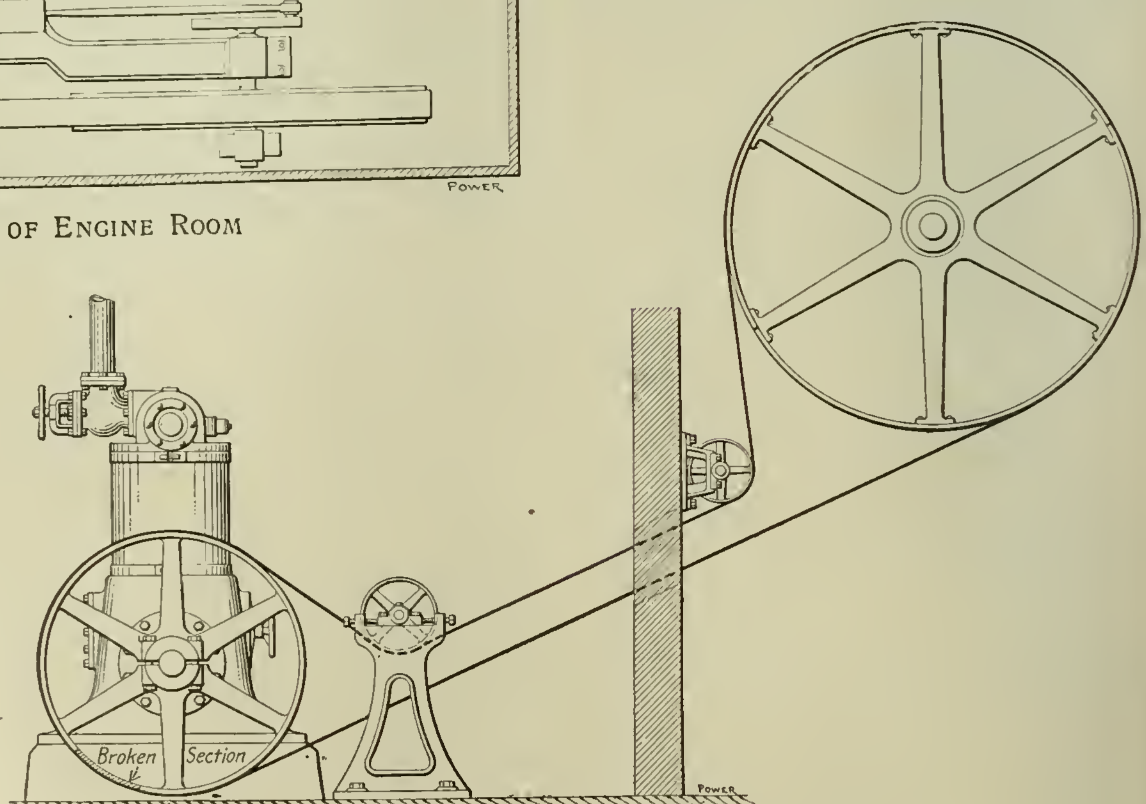

Fig. 2. Arrangement of Belt and Pulleys

shaft was attached to the wall forming a partition between the engine and forge rooms. The other idler was supported by a stand placed back of the engine flywheel, and the top side of the belt was made to travel between the two idlers, a distance of one foot from the bottom, or tight side, of the belt.

FIG. 3. TWO VIEWS OF THE STEEL RIM

This accident was doubtless due to a weakness in the 11-foot driven pulley. The initial rupture started at one of the joints of the rim where it was riveted to the spoke. As the rupture of this wheel was not instantaneous, warning was given to the men employed in the vicinity who got to a safe place before the rim parted from the spokes.

Fig. 3 shows two views of the rim section and portions of the hub and spokes. One-half of the rim was bent double at a point near the center, the face of the rim being on the inside. The other half of the rim was bent into an ogee shape.

When the pulley burst, the 19-inch driving belt was torn in two and, owing to the large contact on the face of the flywheel, instead of coming off the pulley, was wound around the rim, which ran close to the cement floor of the engine room, and so great was the pressure of the belt on the rim of the engine flywheel at the point between the floor and the wheel that a section of the rim between the spokes, 38 inches long, was forced in toward the hub, leaving the break as shown in Fig. 4.

On the inside of the rim is a crack extending part way through the metal that was made as the fractured section of the rim was forced inward. The wheel was made with a solid rim and split hub.

Owing to the prompt action of the engineer, steam was shut off over the boilers before the engine, which was running at a speed of 151 revolutions per minute, did any material damage to itself. In fact, the shaft was not even sprung, although the concrete floor directly under the flywheel was crushed in about 1½ inches, and the anchor bolts were drawn up into the foundation ½ inch.

The damage was small, as it will only be necessary to replace a new pulley on the line shaft, a new flywheel on the engine and a new idler. No one was hurt and a portion of the plant will be operated by water power until repairs are completed. Photographs and data were obtainable through the courtesy of Superintendent W. J. Griffin.

FIG. 4. FRACTURED WHEEL

Award of Perkin Medal to Charles M. Hall

The fifth annual award of the Perkin medal for important discoveries in applied chemistry took place on January 20 at the Chemists' Club in New York, when the Society of Chemical Industry presented this medal to Charles M. Hall for his achievements in the production of aluminum at low cost. The medal was first awarded (1906) to Sir William Henry Perkin for his discovery of mauve. The other medalists have been J. B. F. Herreshoff (1907), Arno Behr (1908), Edward G. Acheson (1909).

Prior to Mr. Hall's invention, aluminum had been almost a precious metal. In 1855 the metal was worth $90 per pound; in 1862 it was worth $12 per pound; in 1889 aluminum was selling at $4 per pound, this reduction having been brought about by Castner's process of producing aluminum by the use of sodium.

Hall's discovery, made in 1886, when he was but 22 years old, consisted in finding in cryolite an anhydrous solvent for alumina and then electrolyzing the alumina out of the cryolite solution. He applied for a patent in 1886, the same being granted in 1889, its validity being later passed upon by Judge William Howard Taft, now President of the United States. After experimenting with two sets of partners for several years, the work was finally taken up by the Pittsburg Reduction Company, now the Aluminum Company of America. At present this company has five establishments in the vicinity of Niagara Falls, and produces annually about 30,000,000 pounds of aluminum at a cost much below the figures given above.

Annual Entertainment and Banquet of the Combined Chicago Associations of the National Association of Stationary Engineers. Held at the Grand Pacific Hotel, Saturday Evening, January 14. A Total of 355 Members and Guests Were Present at the Banquet of which Fred Gielow Was Toastmaster. Among the Speakers Were John Erickson, Former City Engineer, Samuel Forse, of Pittsburg, National Treasurer of the National Association of Stationary Engineers, and John Lane, Editor of the "National Engineer." A Pleasing Feature of the Occasion was the Entertainment by Billy Murray and Jack Armour, of New York. Many Guests Were Present from Milwaukee and Other Surrounding Cities

St. Louis Convention of Marine Engineers

The National Marine Engineers' Beneficial Association made a departure from its usual custom by holding its thirty-sixth annual convention at St. Louis instead of at Washington, where its meetings have been held for eighteen out of thirty-six years. About one hundred delegates were in attendance, representing associations from Seattle, Wash., to Portland, Me., and from the Lakes to the Gulf. The convention was called to order at the Planters hotel, by National President William F. Yates on Monday, January 16, and continued in session throughout the week.

SUPPLYMEN AT ST. LOUIS CONVENTION

The balloting for national officers resulted as follows in the reëlection of the entire board, except the second vice-president: William F. Yates, president; Art Hyde, first vice-president; George H. Bowen, second vice-president; Charles N. Vosburg, third vice-president; George A. Grubb, secretary, and Albert L. Jones, treasurer.

The social features of the convention consisted of theater parties, automobile rides, visits to the local plants, including an inspection of the Anheuser-Busch brewery, and the usual smoker, at which some four hundred of the prominent engineers of St. Louis and vicinity accepted invitations.

The supplymens' association connected with this convention chose the following officers: Frank Martin, president; F. E. Ransley, vice-president; C. A. Willett, secretary.

The next annual meeting will be held at Detroit during January next.

DELEGATES AND VISITORS AT MARINE ENGINEERS' CONVENTION IN ST. LOUIS

SOCIETY NOTES

The third annual entertainment and reception of the Combined Associations of Engineers of the Borough of Brooklyn was held at Kismet Temple, Brooklyn, N. Y., on the evening of January 21. After a very interesting vaudeville entertainment, dancing was indulged in for several hours. The affair was the most successful ever held by the combined associations. The large auditorium with its several galleries was filled to overflowing by a representative gathering of engineers.

The National Electric Light Association has voted to hold the next annual convention in New York City during the week May 29 to June 2, with four days of business sessions. The meetings will be held in the United Engineering building at 29 West Thirty-ninth street, where the offices of the association are located. No hotel has been selected for headquarters but a hotel committee had been formed with Frank W. Smith as chairman, which this year will undertake to make definite reservations. The manufacturing members of the association, in view of the fact that there is another electrical show in New York in October, have voted to dispense this year with the collective exhibit.

BOOKS RECEIVED

THE SCIENTIFIC AMERICAN CYCLOPEDIA OF FORMULAS. By Albert A. Hopkins. Munn & Co., New York. Cloth; 1077 pages, 5¾x8½ inches; 200 illustrations. Price, $5.

HYDRAULIC TURBINES. By V. Gelpke and A. H. Van Cleve. McGraw-Hill Book Company, New York. Cloth; 293 pages, 6¾x9 inches; 200 illustrations; plates; tables; indexed. Price, $4.

ELECTRICIANS' OPERATING AND TESTING MANUAL. By Henry C. Horstmann and Victor H. Toulsey. F. J. Drake & Co., Chicago, Ill. Leather; 359 pages, 4¼x6½ inches; 211 illustrations; indexed. Price, $1.50.

Water Power in New Zealand

It is reported that the New Zealand government has already passed an appropriation of $1,250,000, which is to be followed by more grants later on, to develop several of its water-power possibilities.

The government has absolute control of all the water power. Altogether there is estimated to be 3,000,000 horsepower undeveloped and available in the islands, which are only 1000 miles long and 150 miles wide at the widest part. Owing to the land being so suitable for agriculture and to the European market being so distant, very little attention has been given to manufacturing and so heretofore the water power has not been utilized. New factories are springing up and with cheap electric power a great impetus will be given the growing industries. American manufacturers will surely do well to pay attention to this promising field.

NEW INVENTIONS

Printed copies of patents are furnished by the Patent Office at 5c. each. Address the Commissioner of Patents, Washington, D. C.

PRIME MOVERS

INTERNAL COMBUSTION ENGINE. Thaddeus W. Heermans, Chicago, Ill. 980,946.

WIND MOTOR. Alexander Norman, Dos Palos, Cal. 980,995.

TURBINE. William E. Snow, Dedham, Mass., assignor to B. F. Sturtevant Company, Boston, Mass., a Corporation of Massachusetts. 981,021.

TURBINE. Julian H. Rivers, Niotaze, Kan., assignor to Kaessmann-Rivers Development Company, St. Louis, Mo., a Corporation of Missouri. 981,311.

ENGINE. Joseph Z. Savoie, Providence, R. I. 981,316.

TWO-CYCLE INTERNAL COMBUSTION ENGINE. Donn Irving Twitchell, New York, N. Y., assignor to George H. Benjamin, New York, N. Y. 981,331.

BOILERS, FURNACES AND GAS PRODUCERS

GAS PRODUCER. George P. Davis, Detroit, Mich. 980,923.

STEAM BOILER. John E. Fernstrum, Menominee, Mich. 981,078.

STEAM GENERATING APPARATUS. Wilberforce B. Hammond, Brookline, Mass., assignor to General Fire Extinguisher Company, New York, N. Y., a Corporation of New York. 981,081.

OIL BURNER. Henry J. Hennings, San Gabriel, Cal. 981,083.

APPARATUS FOR GENERATING STEAM OR OTHER VAPORS. Edward C. Newcomb, Boston, Mass., assignor to the Newcomb Motor Company, a Corporation of New York. 981,216.

DOWNDRAFT FURNACE. William H. James, Cincinnati, Ohio. 981,275.

WATER-TUBE BOILER. James L. Butler, Akron, and Norman Slee, Barberton, Ohio, assignors to the Babcock & Wilcox Company, New York, N. Y., a Corporation of New Jersey. 981,377.

GRATE STRUCTURE. John R. Fortune and Harold S. Wells, Detroit, Mich., assignors to Murphy Iron Works, Detroit, Mich., a Corporation of Michigan. 981,408.

LIQUID FUEL BURNER. William A. Wallace and Albert Crume, Brush, Colo. 981,504.

POWER PLANT AUXILIARIES AND APPLIANCES

COUPLING PIPE. Joseph H. Glauber, Cleveland, Ohio. 980,939.

ROTARY VALVE. Brinay Smartt, Nashville, Tenn., assignor to Thomas Maddin Steger, Nashville, Tenn. 981,019.

PUMP. Frank L. Antisell, New York, N. Y., and David W. Blair, Perth Amboy, N. J. 981,518.

AUTOMATIC TIME VALVE. Frederick S. Hutchins, San Francisco, Cal., assignor of one-half to Irvin Silverberg, San Francisco, Cal. 981,271.

AUTOMATIC SAFETY VALVE FOR WATER GAGES. William H. Bray, Manchester, N. H., assignor of one-half to Hattie L. Healey (now by marriage Hattie L. Felch), Manchester, N. H. 981,370.

LUBRICATOR VALVE FOR STEAM CHESTS. Frank W. Edwards, Logansport, Ind., assignor to the Chicago Lubricator Company, Chicago, Ill., a Corporation of Illinois. 981,544.

ELECTRICAL INVENTIONS AND APPLICATIONS

ALTERNATING - CURRENT ELECTRIC MOTOR. Hans Sigismund Meyer, Bremen, Germany, assignor to General Electric Company, a Corporation of New York. 980,986.

RENEWABLE FUSE FOR ELECTRIC CIRCUITS. Joseph A. Volk, Jr., South Norwalk, Conn. 981,038.

ROTARY CONVERTER. Joseph L. Burnham, Schenectady, N. Y., assignor to General Electric Company, a Corporation of New York. 981,059.

AUTOMATIC ARC LAMP. Ernst Sai'er, Rochester, N. Y., assignor by mesne assignments, to Bausch & Lomb Optical Company, Rochester, N. Y., a Corporation of New York. 981,121.

ROTARY CONVERTER. Charles P. Steinmetz, Schenectady, N. Y., assignor to General Electric Company, a Corporation of New York. 981,134.

ELECTRIC SWITCH. Philip Thos. McNally, Mandan, N. D. 981,452.

ELECTRIC HEATER. Milton H. Shoenberg, San Francisco, Cal., assignor to Presto Electrical Manufacturing Company, San Francisco, Cal., a Corporation of California. 981,481.

APPARATUS FOR MEASURING AREAS BY MEANS OF ELECTRIC RESISTANCE COILS. Julius Josef Götz, Offenbach-on-the-Main, Germany. 981,552.

RHEOSTAT. Charles D. Kestner, New York, N. Y., assignor to the Meyrowitz Manufacturing Company, a Corporation of New Jersey. 981,572.

POWER PLANT TOOLS

SCREW DRIVER. Willey B. Lane, Philadelphia, Penn., assignor of one-half to J. C. McCarty & Co., a Corporation of New York. 981,202.

WRENCH. James F. Wright, Canton, Ohio. 981,234.

WRENCH. Rudolph J. Bomblatus and Frank Caviola, Forbes Road, Penn. 981,523.

ENGINEERING SOCIETIES

AMERICAN SOCIETY OF MECHANICAL ENGINEERS

Pres., Col. E. D. Meier; sec., Calvin W. Rice, Engineering Societies building, 29 West 39th St., New York. Monthly meetings in New York City.

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

Pres., Dugald C. Jackson; sec., Ralph W. Pope, 33 W. Thirty-ninth St., New York. Meetings monthly.

NATIONAL ELECTRIC LIGHT ASSOCIATION

Pres., Frank W. Frueauff; sec., T. C. Martin, 31 West Thirty-ninth St., New York. Next meeting in New York City, May 29 to June 3.

AMERICAN SOCIETY OF NAVAL ENGINEERS

Pres., Engineer-in-Chief Hutch I. Cone, U. S. N.; sec. and treas., Lieutenant Henry C. Dinger, U. S. N., Bureau of Steam Engineering, Navy Department, Washington, D. C.

AMERICAN BOILER MANUFACTURERS' ASSOCIATION

Pres., E. D. Meier, 11 Broadway, New York; sec., J. D. Farasey, cor. 37th St. and Erie Railroad, Cleveland, O. Next meeting to be held September, 1911, in Boston Mass.

WESTERN SOCIETY OF ENGINEERS

Pres., J. W. Alvord; sec., J. H. Warder, 1735 Monadnock Block, Chicago, Ill.

ENGINEERS' SOCIETY OF WESTERN PENNSYLVANIA

Pres., E. K. Morse; sec., E. K. Hiles, Oliver building, Pittsburg, Penn. Meetings 1st and 3d Tuesdays.

AMERICAN SOCIETY OF HEATING AND VENTILATING ENGINEERS.

Pres., Prof. J. D. Hoffman; sec., William M. Mackay, P. O. Box 1818, New York City.

NATIONAL ASSOCIATION OF STATIONARY ENGINEERS

Pres., Carl S. Pearse, Denver, Colo.; sec., F. W. Raven, 325 Dearborn street, Chicago, Ill. Next convention, Cincinnati, Ohio.

AMERICAN ORDER OF STEAM ENGINEERS

Supr. Chief Engr., Frederick Markoe, Philadelphia, Pa.; Supr. Cor. Engr., William S. Wetzler, 753 N. Forty-fourth St., Philadelphia, Pa. Next meeting at Philadelphia, June, 1911.

NATIONAL MARINE ENGINEERS BENEFICIAL ASSOCIATIONS

Pres., William F. Yates, New York, N. Y.; sec., George A. Grubb, 1040 Dakin street, Chicago, Ill. Next meeting at Detroit, Mich., January, 1912.

INTERNAL COMBUSTION ENGINEERS' ASSOCIATION.

Pres., Arthur J. Frith; sec., Charles Kratsch, 416 W. Indiana St., Chicago. Meetings the second Friday in each month at Fraternity Halls, Chicago.

UNIVERSAL CRAFTSMEN COUNCIL OF ENGINEERS

Grand Worthy Chief, John Cope; sec., J. U. Bunce, Hotel Statler, Buffalo, N. Y. Next annual meeting in Philadelphia, Penn., week commencing Monday, August 7, 1911.

OHIO SOCIETY OF MECHANICAL ELECTRICAL AND STEAM ENGINEERS

Pres., O. F. Rabbe; acting sec., Charles P. Crowe, Ohio State University, Columbus, Ohio. Next meeting, Youngstown, Ohio, May 18 and 19, 1911.

INTERNATIONAL MASTER BOILER MAKERS' ASSOCIATION

Pres., A. N. Lucas; sec., Harry D. Vaught, 95 Liberty street, New York. Next meeting at Omaha, Neb., May, 1911.

INTERNATIONAL UNION OF STEAM ENGINEERS

Pres., Matt. Comerford; sec., J. G. Hannahan, Chicago, Ill. Next meeting at St. Paul, Minn., September, 1911.

NATIONAL DISTRICT HEATING ASSOCIATION

Pres., G. W. Wright, Baltimore, Md.; sec.

POWER

NEW YORK, FEBRUARY 7, 1911

A WELL KNOWN engineer recently made the statement that he secured his first position as chief because he had formed the habit of doing his work right.

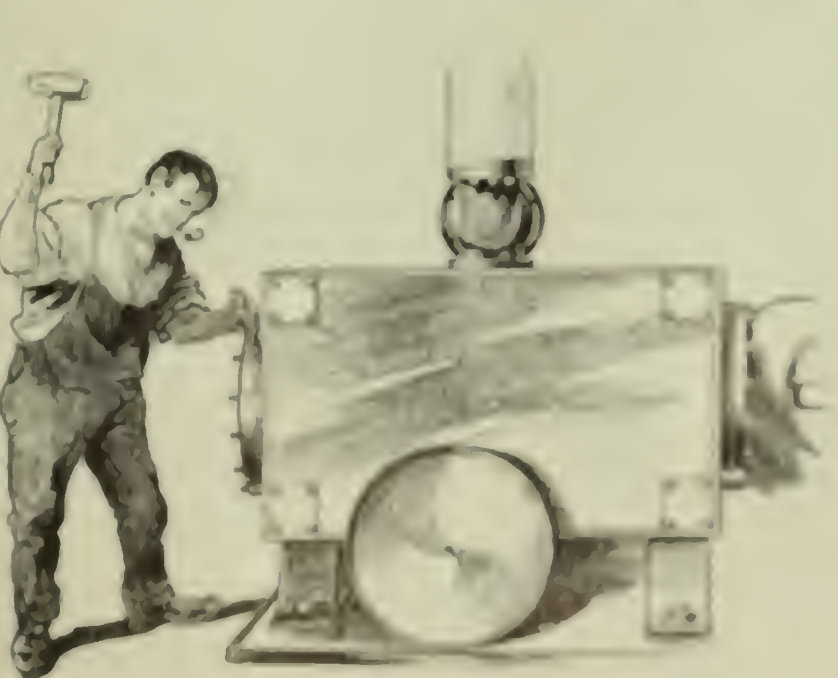
He had been an erecting man for an engine company, and was one of half a dozen men sent to make a new engine run satisfactorily. Five of them simply expressed their opinion as to the cause of the trouble and went away. This engineer used common sense, took off his coat and fixed the engine by making proper adjustments.

He did not know that an impression had been made with the head of the steam plant, but two years later, when he had forgotten the incident, he was offered the position of chief engineer of the very same plant where he had been sent to fix the engine.

The biblical maxim about casting bread upon the water and its return after many days worked out in this case. It usually does, and this man's experience is evidence that when a piece of work is to be done, it pays to do it the very best one knows how.

Some engineers are born, others are made and a whole lot are misfits.

Some engineers pride themselves on the appearance of their steam plant, and take as much care of their engines as if they were living things. Others, from lack of ambition, or because they have never learned to do things right, misuse everything under their care, and do so with apparent relish. Imagine a big, strong, bare-armed engineer taking a delicate steam gage and pounding the pointer in place on the spindle with a heavy hammer. It has been done.



Imagine this same individual, in an attempt to remove a cylinder head, gripping a cold chisel in one hand and a small-sized sledge hammer in the other and mauling with main strength until the heavy head is forced from the cylinder.

Such practice is enough to make a real engineer grind his teeth and protest against such methods of treating power-plant apparatus. Doing work in this way is often the direct reason why certain engineers are never given the opportunity of taking charge of a better plant than the one they have been operating for years.

No sane man expects to obtain something for nothing, and if a return is desired an investment must be made.

On the part of the engineer this means an intelligent understanding of steam engineering and the gumption to do the work around the plant in a workmanlike manner.

A pig will never be invited into the parlor, a common laborer will never be offered work as a skilled toolmaker, and an engineer using sledge-hammer methods cannot expect that an opening in some new, up-to-date power plant is awaiting his coming.

A position of this kind demands a real engineer. Such a man is easily recognized by his methods and the results he obtains in the plant.

Boilers and Piping of Wieboldt Bl'dg

By Osborn Monnett

The main points of interest in this small plant of a Chicago department store are the boiler setting, which was specially designed for restricted head room, and the piping layout.

A new plant which has lately been installed for W. A. Wieboldt & Co., of Chicago, contains some features deserving of attention. The boiler room contains four Kroeschell 72-inch by 18-foot horizontal, return-tubular boilers, arranged in two batteries, as shown in Fig. 1, and fitted with Green chain-grate stokers. Owing to the fact that the sewer level at this point is close to the surface, severe restrictions as to the amount of headroom were imposed. The ordinary setting, which requires considerable excavation, was not desirable, not only because of its first expense, but also because of the continued expense for pumping into the sewer. Therefore the stokers were equipped with ash drags, as shown in Fig. 2, by which the ashes are pushed from the rear of the ashpit to a shallow pit at the front. The drag is composed of angle-iron sections attached to a chain operating over two sprockets which are driven from the stoker lineshaft through a ratchet arrangement keyed to the front drag shaft.

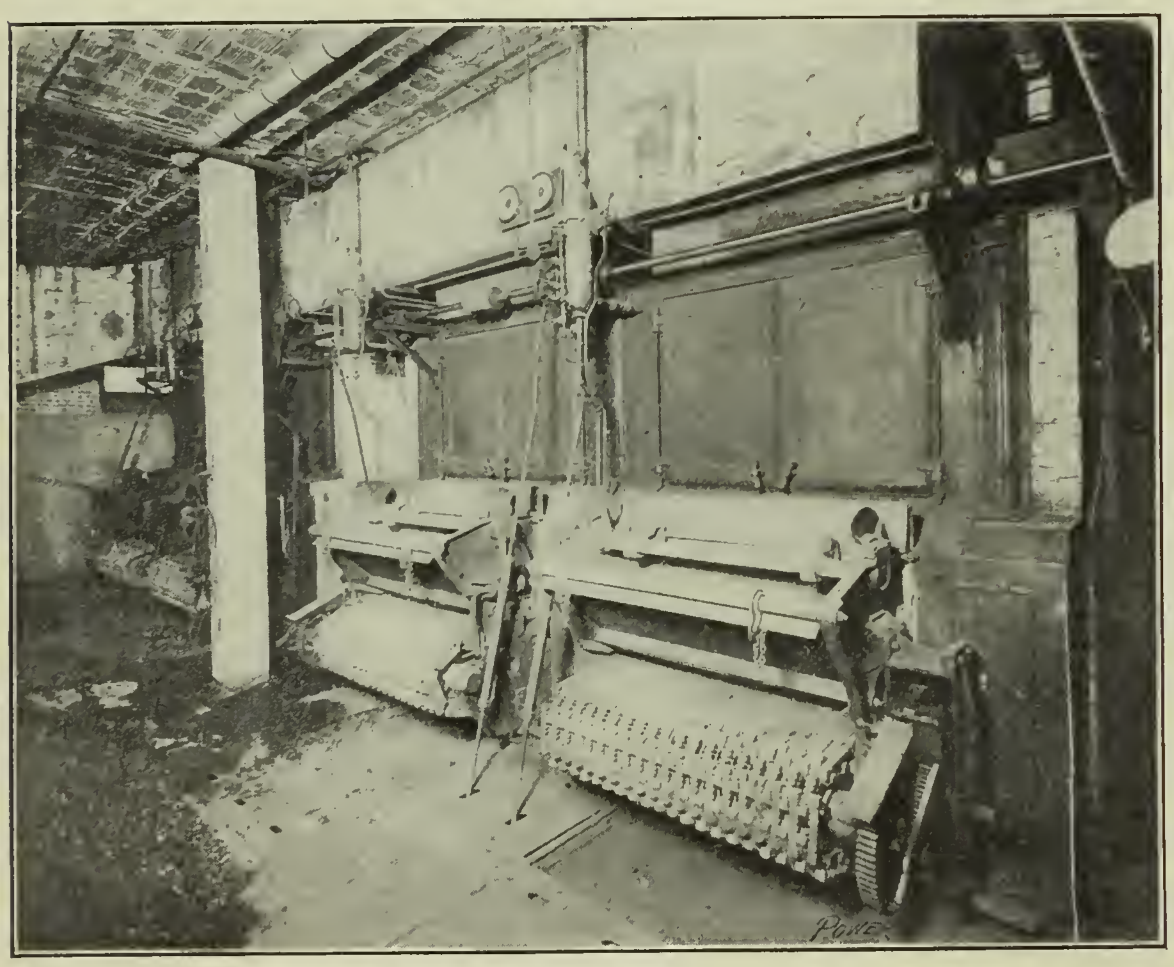


Fig. 1. Fronts of Boilers

The system of piping is unique, and has been found very satisfactory. It conforms to the standard practice of W. L Fergus & Co., the consulting engineers who laid out the new installation, and consists chiefly of a number of small headers and large receiver-separators, the latter located at the engine throttles and designed to furnish a reserve steam capacity to draw upon when the steam valves are open. A portion of the main piping is shown in Fig. 3.

The nonreturn valves connect with long-radius bends which terminate in a manifold located between the two batteries of boilers. At this manifold are located the boiler stop valves, all of which can be manipulated from this point by the operator, standing on a platform provided for the purpose. From the manifold a 6-inch straight header extends directly to the engine room, where branches are provided to distribute the live steam to the engines.

In the engine room there are three direct-connected Ball & Wood units, one of 50, one of 150 and one of 200 kilowatts capacity. Directly over each throttle is located a Cochrane receiver-separator of unusually large capacity for the size of engine. In the case of the 200-kilowatt unit a steam connection 8 inches in diameter is provided at the throttle, although the main steam line to this unit is only 4 inches in diameter. The steam line to the 150-kilowatt unit is 3 inches in diameter, the separator 30 inches in diameter and the throttle-valve connection as provided on the engine is 7 inches. Fig. 4 is a striking illustration of the comparative sizes of piping and separators. Another important feature is the use of an angle throttle valve, which affords a more direct passage for the steam.

The advantages claimed for this system of piping are lower first cost, greater safety, less maintenance cost for bolts and gaskets, reduced radiation, less surface exposed to the steam and consequent minimum condensation, avoidance of dangerous pulsations in the header over the boilers, as is sometimes found in ordinary layouts, and lower maximum velocity of the steam than in standard practice. It is claimed that a steady, constant flow of steam from the boilers to the separators is realized, which takes up any unevenness in the demand for steam

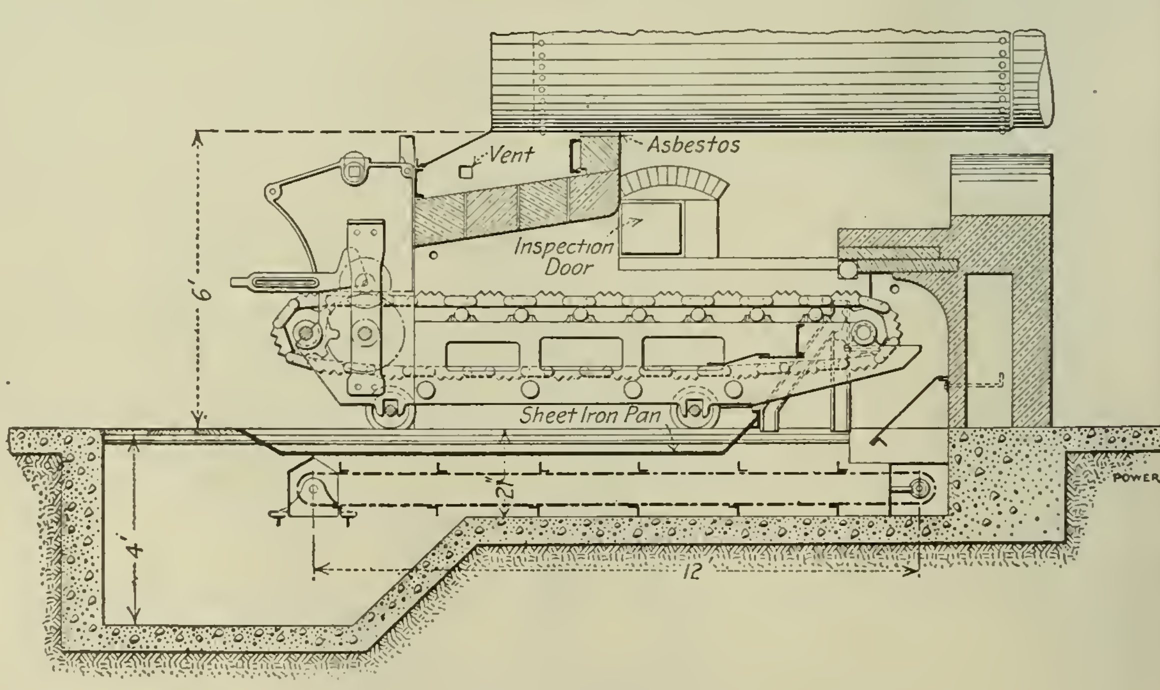

Fig. 2. Section through Furnace

to the engines. No drain is used on the header system, as it is contended that condensation will cause the least trouble at the separator, where the steam is comparatively at rest, and the water will naturally gravitate to the bottom, where it is easily removed.

Fig. 5 shows an indicator diagram taken on one of the engines running under full load, and serves as an indication of how well the system is working out.

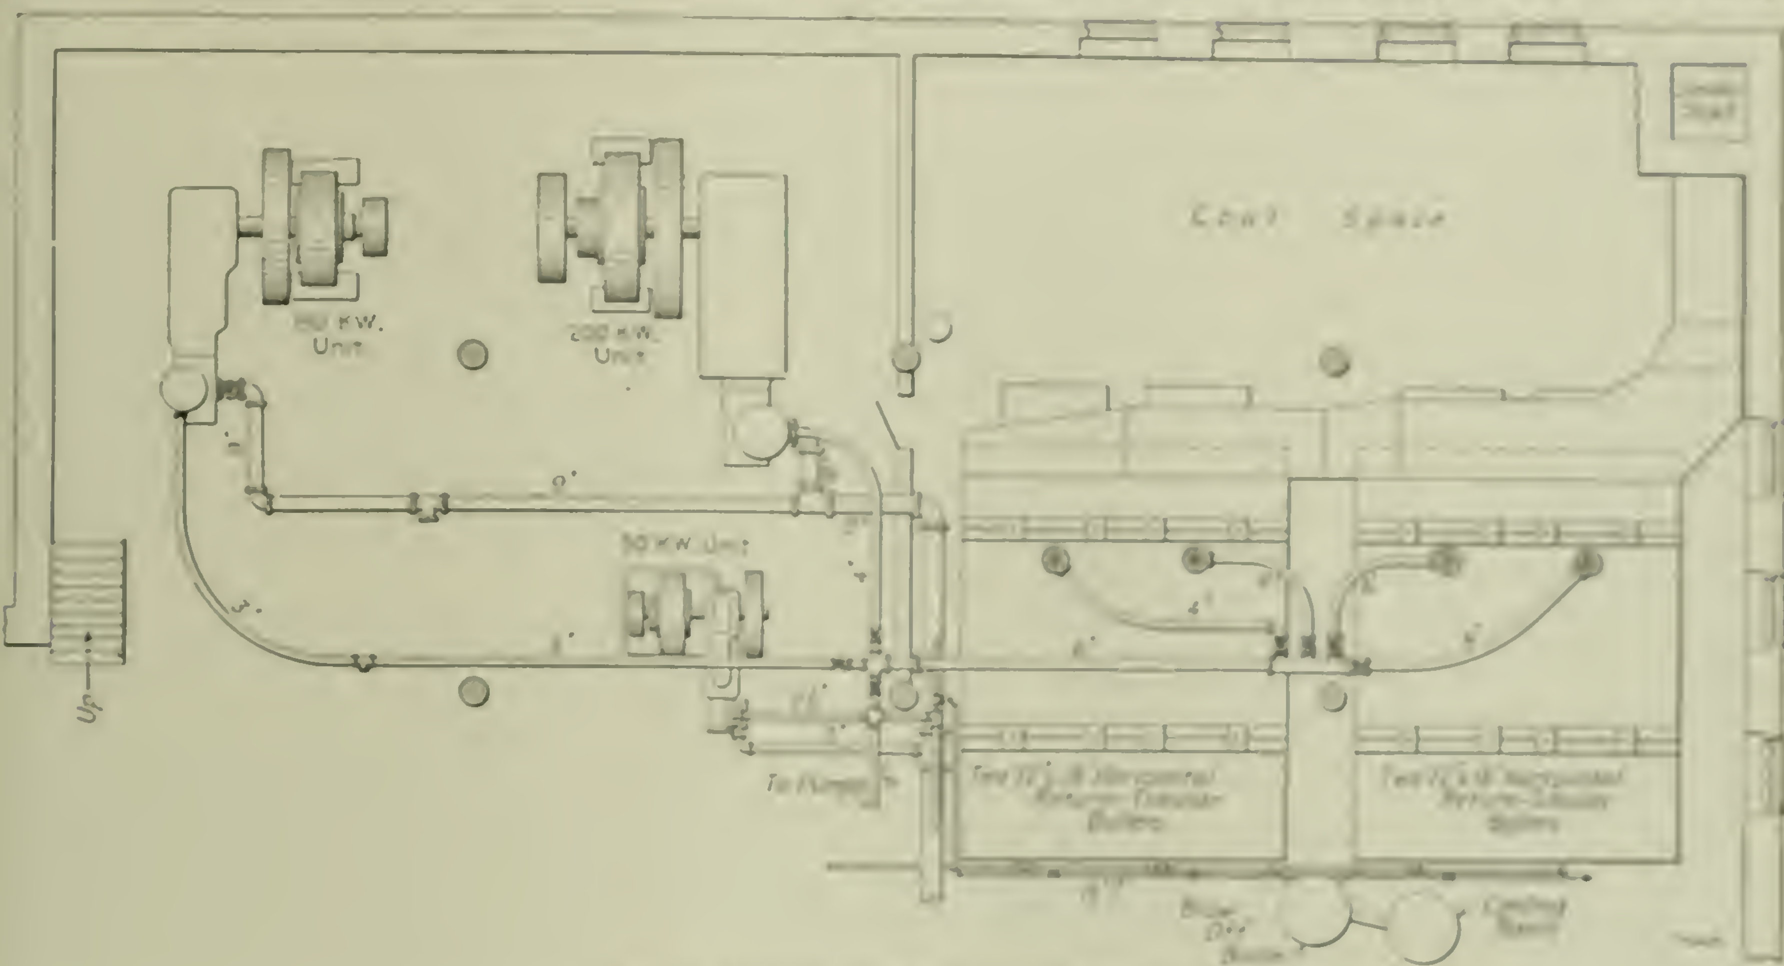

FIG. 3. LAYOUT OF MAIN STEAM PIPING

The Oldest Complete Locomotive in America

At the National Museum in Washington, is exhibited the locomotive "John Bull," No. 1 of the Camden & Amboy Railroad Company, which was built by George Stephenson & Son at Newcastle-on-Tyne in 1830-31 and shipped from Liverpool on July 14, 1831, on the ship "Allegheny," bound for Philadelphia. On November 12, 1831, in the presence of members of the New Jersey legislature, with Isaac Dripps acting as engineer, and a train with two cars, this locomotive made the first movement by steam in the State of New Jersey, at Bordentown, where the railroad monument now stands. The "John Bull" was in continuous service from 1831 to 1865, during which time it was altered and added to. It was exhibited at the centennial exposition in 1876 and at the exhibition of railway appliances in Chicago in 1883. It was placed in the United States National Museum in 1883 and remained there until 1893, when on April 17 to 22 it was run under steam from New York to the World's Columbian Exposition, where, for a time, it made daily trips on the exposition tracks. In December, 1893, it was returned to Washington, having made the last trip under steam on the thirteenth of that month. The original weight was 22,425 pounds. The boiler was 13 feet long, 3 feet 6 inches in diameter; the cylinders, 9x20 inches; the driving wheels, 4 feet 6 inches in diameter, with locust spokes, cast-iron hubs, with tires of wrought iron shrunk on; the flanges, $1\frac{1}{2}$ inches deep; 62 flues, 7 feet 6 inches long, 2 inches in diameter; furnace, 3 feet 7 inches by 3 feet 2 inches high; steam ports, $1\frac{1}{8}x6\frac{1}{2}$ inches; exhaust ports, $1\frac{1}{8}x6\frac{1}{2}$ inches; throw of the eccentric, $3\frac{1}{2}$ inches; grate surface, 10.06 square feet; fire-box surface, 36 square feet; flue surface, 213 square feet. There is also exhibited in the same section one of the original driving wheels of the "De Witt Clinton."

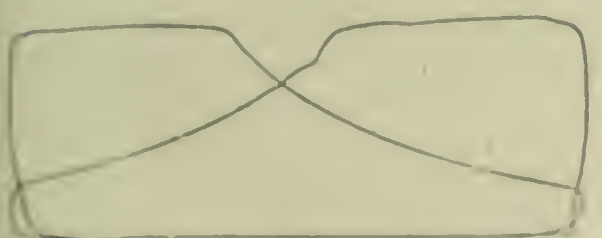

FIG. 5. DIAGRAMS SHOWING EFFECT OF STEAM RECEIVERS

FIG. 4. ENGINE ROOM, SHOWING LARGE RECEIVERS

One of the best preventives of scale in a boiler is good circulation of the water contained within.

Design of Steam Power Plants

By William F. Fischer

In a previous article under the above caption are taken up the location and type of plant, the building and the foundations. The present article deals with the selection of boilers.

In aiming for economy of fuel the whole equipment of boilers, engines, condensers, pumps, heaters, piping, etc., must be considered individually and collectively. An inefficient boiler will counteract the virtues of a good engine, and likewise an engine extravagant in steam may render useless the economy obtained with a good boiler.

Selection of the Boilers

Before the plans for the boiler house are completed, the type of boiler to be used should first be decided upon and its exact dimensions and setting obtained from the manufacturer.

As the efficiency of a steam-power plant, both thermally and commercially, depends primarily upon the boiler installation, it is evident that the selection of proper boilers is of utmost importance. A well selected boiler may give fairly economical results even when poorly installed, but a type of boiler entirely unfitted for the duty imposed upon it may have the best setting and still not give good results. The first cost, though important, should not be the first consideration in selecting any piece of apparatus for a power plant; selecting steam boilers wholly on account of their low first cost frequently means a sacrifice in efficiency and with it the profits on the investment. If, on the other hand, boilers are selected with reference only to their thermal efficiency, the cost of the installation may be prohibitive, and for this reason may forbid a decision wholly upon that basis.

Evaporation

The principal item affecting the cost of operation of a boiler is its evaporative efficiency, which should be a maximum at normal load in a well designed boiler. When forcing to a great extent, although the rate of evaporation is increased, the efficiency is lowered owing to a large proportion of the heat being wasted. Therefore, a boiler plant should be of ample capacity to carry the greatest steady loads without forcing. It is always well to install one or more spare boilers, for use when any of the others are out of service for repairs or for cleaning.

With most boilers the best efficiency under ordinary working conditions is obtained when evaporating about three pounds of water per hour, per square foot of heating surface, from and at 212 degrees. This is equivalent to allowing nearly twelve square feet of heating surface per boiler horsepower.

As the efficiency of the heating surface will be more or less impaired by the accumulation of scale and soot, it is well to provide ample heating surface for the work to be done. This results in a saving of fuel at ordinary rates of evaporation, and also makes it possible to run the boiler considerably above its rating and still maintain a fair efficiency.

Most of the various types and grades of boilers on the market are capable of producing practically the same evaporation per pound of fuel fired, provided they are designed with the same ratio of heating to grate surface and are operated under exactly similar conditions. They differ, however, with respect to space occupied, weight, capacity, first cost and adaptability to particular conditions of operation.

Boiler Horsepower

Strictly speaking, there is no such thing as the horsepower of a steam boiler, for the power from the steam is developed in the engine, the boiler itself doing no work. This phrase was originally intended to mean that a boiler having a certain stated horsepower would furnish all the steam required to develop that amount of power in a given engine. According to the American Society of Mechanical Engineers' standard, a boiler to develop one horsepower must evaporate 30 pounds of water from a temperature of 100 degrees Fahrenheit into steam at 70 pounds gage. This is equivalent to evaporating 34½ pounds of water from a temperature of 212 degrees Fahrenheit into steam at atmospheric pressure, or "from and at 212 degrees," as it is called, which corresponds to 33,305 B.t.u. per hour.

This measure of capacity is merely conventional, as one boiler horsepower will furnish sufficient steam to develop about three actual horsepower in the best compound-condensing engine, but only about one-half horsepower in a small noncondensing engine.

The term "horsepower" should not be used when purchasing a boiler unless the amount of heating surface is also specified, as one bidder might offer a boiler with five square feet of heating surface per horsepower, and another with ten square feet. Both boilers would be capable of the required evaporation, but the boiler having the smaller heating surface, although probably much the cheaper of the two, would do so only at an increased fuel consumption.

Water-tube versus Fire-tube Boilers

Engineers differ as to the design of boiler best suited to certain conditions. As experience has shown that boilers of the water-tube and the fire-tube types give equally good economy if well designed and operated under the same conditions, it is impossible to give any general rule as to which type should be given the preference. The principal considerations with which an engineer has to deal when selecting a type of boiler for a given plant are: The character of the fuel, the character of the feed water; the kind of service and safety, the available floor space, the steam pressure to be carried, the expense of operation and maintenance, and the influence of the locality.

Water-tube boilers are usually employed in medium- and large-sized central stations in high-pressure units of from 300 to 650 horsepower. Where the service is such that large quantities of steam are often wanted with but very little warning, water-tube boilers should always be given the preference. This is because they contain relatively less water than the shell, or fire-tube, type; consequently steam can be raised in them within a shorter time. On account of the larger passage for the gases and the better circulation of water in contact with the heating surfaces, more water can be evaporated per square foot of heating surface in a water-tube boiler than in one having fire tubes, although, as before mentioned, the efficiency of the two types is about the same. On account of their lower first cost, return-tubular boilers are still used to a considerable extent in central-station work in preference to the water-tube type, but as the practice of such initial economy frequently proves to be the most expensive in the end, the consideration of low first cost should not be given too much weight. By this, however, is not meant that the boiler of highest first cost is always the most economical one. Regarding repairs, the water-tube boiler is the more expensive if it is to be kept in first-class condition.

Waters that abound in scale-forming matter warrant a decision in favor of the use of a boiler of the plain cylindrical or horizontal return-tubular types, because of the comparative ease with which they can be cleaned at a minimum cost. Because of their ability to stand almost continual service with a minimum amount of overhauling, horizontal return-tubular boilers should be given the preference where the time allowable for repairing, cleaning and overhauling is limited.

As to safety, water-tube boilers are generally accepted to be superior to those of the fire-tube type. Therefore, in selecting the boilers for a building where a number of people are employed, or are likely to be gathered, the water-tube type should undoubtedly be given the preference, regardless of its additional first cost and cost of operation and maintenance.

Another important consideration in the selection of a steam boiler is the amount of space available. For shallow basements and out of the way corners, probably no boiler is as suitable as the horizontal return-tubular, but where space is plentiful, other considerations may cause a different type of boiler to be selected. As return-tubular boilers are seldom made in sizes over 200 horsepower, they should not be considered for large units.

Vertical Boilers

Where ground space is expensive and overhead room permits, vertical tubular boilers may be considered. As a rule, such boilers are rapid steamers and are comparatively low in first cost. They have the disadvantages, however, of being inaccessible for thorough inspection and cleaning, have a considerably small steam space, resulting in excessive priming at heavy loads, and are poor in economy except at light loads, as the products of combustion escape at a high temperature on account of the shortness of the tubes. Another disadvantage of the vertical tubular boiler is its small water capacity, which usually results in rapidly fluctuating steam pressures with varying demands for steam.

Vertical fire-tube boilers are usually of small size, seldom being over 60 horsepower. An exception, however, is found in the Manning vertical fire-tube boiler, which is constructed in sizes up to 500 horsepower, and suitable for steam pressures of 200 pounds or more. In sizes above 300 horsepower they are usually arranged with a brick furnace and may be equipped with mechanical stokers. As far as safety and efficiency are concerned, the Manning boiler ranks with any of the other first-class types. Vertical boilers are also made in the water-tube type, and in efficiency compare favorably with the horizontal water-tube boiler.

Available Labor

Another important consideration which should not be overlooked in selecting steam boilers is the class and amount of labor available to operate and take care of them. A plant in which there is only one attendant should, as a rule, never be equipped with water-tube boilers, as the attendant will not have sufficient time to care for them properly.

Grate Surface and Draft

The maximum evaporative capacity of a steam boiler is limited mainly by the amount of coal which can be burned upon the grates. With sufficient draft a good boiler can develop a horsepower upon one-half the surface ordinarily recommended. The item of grate surface is one of vital importance, and should conform to the demands imposed upon it by the particular grade of fuel to be used.

Some coals, having less heating power per pound than others, cannot be burned at as high a rate of combustion on account of their peculiar properties. Therefore, the grate surface depends chiefly upon the character of the coal and the rate of draft. With good coal low in ash, approximately equal results may be obtained with a large grate surface and light draft as with a small grate surface and strong draft, the total amount of coal burned per hour being the same in both cases. With good bituminous coal, low in ash, the best results are obtained with a strong draft and a high rate of combustion, provided the grate surfaces are cut down so that the total coal burned per hour is not too great for the capacity of the heating surface to absorb the heat produced. With coals high in ash, especially if the ash is easily fusible, tending to choke the grates, large grate surface and a low rate of combustion are required unless means, such as shaking or rocking grates, are provided to get rid of the ash as fast as it is made. The amount of grate surface required per horsepower under various conditions may be estimated from the accompanying table, which is taken from Kent's "Mechanical Engineers' Pocketbook."

GRATE SURFACE PER HORSEPOWER

	[illegible]	[illegible]	Pounds of Coal Burned per Square Foot of Grate per Hour.								
			[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
			Square Feet of Grate per Horsepower								
Good coal and good boiler	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
Fair coal or fair boiler	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
Poor coal or poor boiler	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
Lignite and poor boiler	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]

This shows that a high-grade coal will permit of a more compact grate than a low-grade coal. When it is intended to burn a low-grade coal the grate should be made as ample as possible and if it is afterward desired to change to a coal of better grade, a portion of the grate may be bricked over, providing the draft, fuel or other conditions render it advisable. As a high rate of combustion is undoubtedly the best for many coals for the reason that the gases are much more thoroughly consumed when the furnace temperature is high, sufficient draft should be provided, either by a fan or chimney high enough to produce not only the proper rate of combustion for ordinary demands, but also to enable the boilers to operate with the desired overload. Not less than one-third square foot of grate surface should be furnished per horsepower.

Boiler Efficiency and Heating Surface

With the best types of boiler having the grate area and heating surfaces carefully proportioned, an efficiency of 75 to 80 per cent. is attainable with a clean boiler in exceptionally good condition and carefully managed.

It is a general practice among manufacturers to furnish about 11 to 12 square feet of heating surface for vertical fire-tube boilers and horizontal return-tubular boilers; ten to twelve square feet per horsepower for water-tube boilers, twelve to fourteen square feet for stationary locomotive boilers, and about eight square feet per horsepower for Scotch marine boilers. As this practice is not uniform, however, bids and contracts for boilers should always specify the amount of heating surface to be furnished.

Boiler Inspector's Fees

J. J. Kelly, State boiler inspector for Allegheny county, Penn., whose office Governor Stuart recommended in his message to the legislature to be made a salaried one instead of being remunerated by fees, gave out recently, according to a newspaper report, some figures in relation to his office and its income, wherein he stated that the fees of his office would approximate about $18,000 annually, out of which he has to pay aldermen's fees incurred in collecting fees of the owners for inspection and the wages of five assistants for inspecting boilers as well as office rent and telephone bills.

According to Mr. Kelly, there are less than 6000 boilers to inspect in the county, due to the fact that the gas and gasolene engines are used to such an extent that the number of boilers is decreasing, also that manufacturers are using fewer boilers but of greater horsepower.

The development of the central power plant is replacing the numerous small boilers in public buildings, which Mr. Kelly asserts has cut down the fees of his office.

Experiences on Construction Work

By S. Kirlin

Attention is called to the fact that on construction work the conditions are often such that when a breakdown occurs repairs must be made immediately. With the limited facilities at hand the repairs often tax the ingenuity of the engineering force. A few of such instances are cited.

Engineers of stationary plants sometimes think they have their share of trouble in keeping their plants in good operating condition, and they undoubtedly do have plenty of it at times; but, when it comes to having all kinds of trouble, and usually that of an unexpected character, the engineers and mechanics of outside contracting plants, such as canal construction, mine development and other plants of this kind, often have difficulties which make the ordinary troubles of the stationary engineer appear comparatively small.

On works of this kind, good buildings or foundations are not attempted, as the work is usually of a temporary character and the machinery must be moved about frequently; consequently, the machinery is operated under conditions which make accidents and breakdown much more liable to occur than in a plant which is installed to be operated permanently. On account of the nature of the work, it is often necessary for the boilers, engines and pumps to be placed in the bed of a stream and protected by a cofferdam, the water being pumped out continuously night and day, to prevent the works from being flooded. This makes quick action on the part of the men in charge necessary in case of a breakdown, especially if it happens to the pumping machinery. They must be resourceful, and quick to find a remedy for any emergency which may arise.

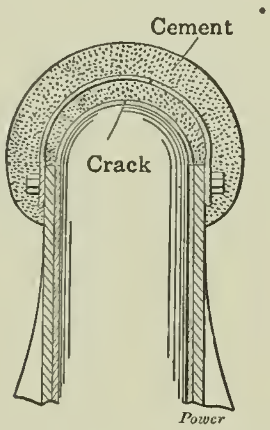

FIG. 1. SECTION THROUGH REPAIRED PORTION

While visiting plants of this kind in various parts of the country, the writer's attention frequently has been called to repairs that had been made to the machinery, many of which would have done credit to the best equipped machine shop. In most cases the work had been done with whatever tools were available, and in the shortest possible time in order to get the machinery in service again. One example of a quick and effective repair was that made on a large centrifugal pump on a hydraulic dredge. It began to leak on one side of the rim, and upon examination it was found that the rim was cracked and almost worn through for a distance of several feet. As there were no facilities at hand for patching it, the master mechanic decided to try repairing it with cement. Fig. 1, showing a cross-section of the pump, and Fig. 2, which shows an elevation of the finished repair, give an idea of how the job was accomplished. A number of pieces of strap iron were cut to the proper length with holes drilled in the ends to fit over the studs which held the sides of the casing. These were bent over the rim and were allowed to stand out about 3 inches to form a reinforcement for the cement. A form was then made, and, after being placed over the rim of the pump, was poured full of cement. As soon as this had set, the form was removed and the pump placed in service.

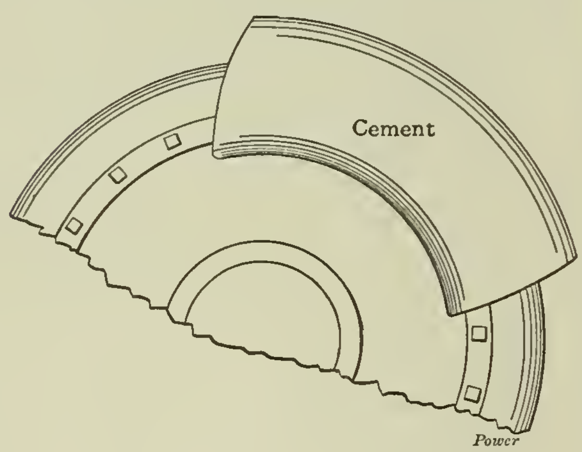

FIG. 2. ELEVATION OF REPAIRED PORTION

Another interesting repair was that made on a broken eccentric rod of a high-speed engine which drove an air compressor. The compressor furnished air for operating a large number of drills, and as all work was stopped while the air pressure was off, it was up to the engineer to make a quick repair and get things running again. He at once put two men to work filing grooves on each side of the break, as shown in Fig. 3. A piece of pipe 10 inches long and about ½ inch larger in diameter than the rod was then slipped over it, the ends of the broken rod being butted together. The rod was then centered in the pipe, the ends of which were stopped with clay, and the pipe was poured full of babbitt. As the rod had not been changed from its original length, it was not necessary to reset the valve or to disturb any of the connections. The engine was running again in less than an hour after the break had occurred.

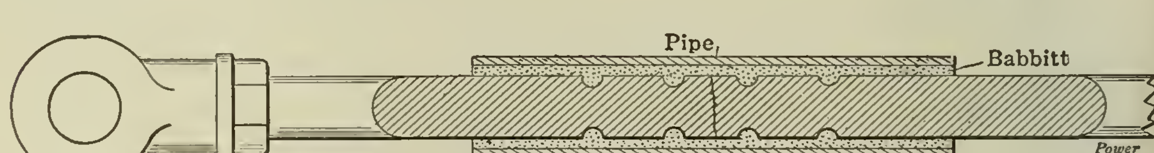

FIG. 3. SECTION THROUGH ROD AND BABBITT

The master mechanic of a large contracting firm who had a reputation for making quick repairs in case of a breakdown, was asked how it was that he was always ready with a remedy for all accidents that occurred. He answered that he made it a point to study the construction of every machine at the works, to ascertain just about what was most likely to break down, and to decide upon the method he would use to repair it in case it did let go. In this way he was prepared with the necessary material for making the repairs on breakdowns which were most likely to occur, and did not lose any time studying out a way to go at it. His system of being prepared for trouble before it occurred might be adopted by a great many others to good advantage.

There is probably no place where it pays better for the companies to furnish their mechanics with plenty of good tools than on work of this kind. It is usually a long distance from any machine shop where repairs can be made, and delay in making repairs is often a serious matter, as a small accident will frequently stop all work and possibly cause heavy damage by flooding work under way.

The chief engineer of a construction company which was notoriously lax when it came to furnishing tools, remarked, that they had a sledge, a monkey-wrench and a screwdriver, and were supposed to repair everything from the Ingersoll air compressor down to the master mechanic's watch of the same make.

Hen Simpkins packed th' piston rod uv his ingin tother day an' sez he'll bet thet he don't hev ter pack it agin fer a year. Sed his darter hed jist graddiated frum th' cookin' school an' he used sum uv her doughnuts, 'stid uv ring packin'.

Boiler Thirty Years Old Explodes

By Albert F. Dedrick

A 40-inch return-tubular boiler which had been in continuous service for twenty-four years in a grist mill, was taken out, left exposed to the weather for four years, and then installed in an electric-light plant where it operated for two years under a working pressure of 100 pounds.

On the evening of January 14, while a committee of engineers in St. Joseph, Mo., were busily engaged in drafting a proposed law relative to the licensing of engineers and firemen and the inspection of steam boilers throughout the State, the boiler of a small electric-light plant in the neighboring town of Rushville exploded. The fireman and his son, who had just dropped in to see his father, were instantly killed, and the entire plant was demolished. Fortunately the engineer, who was also the owner, had left the plant a few minutes before. If the explosion had occurred three-quarters of an hour later, it is probable that a dozen or more lives would have been lost, as it was customary for a number of the men and boys of the town to congregate around the plant every evening.

The boiler was built in 1881 for a Kansas grist mill, and after twenty-four years of service was sold to a mill in Rushville. The purchasers, after making a careful examination of the boiler, decided that it was not worth the expense of installing and therefore let it remain in the yard. After being exposed to the weather for four years it was installed in the electric-light plant where it had been in service for about two years when the explosion occurred.

FIG. 1. HEAD AND TUBES HURLED THROUGH KITCHEN WALL

It was of the horizontal return-tubular type, 40 inches in diameter by 11 feet 6 inches long, and had single-riveted lap joints. The shell, which originally had been 1/4 inch thick, was badly pitted on the inside and rusted away on the outside until in many places it measured less than 1/8 inch. The regular working pressure was 100 pounds per square inch and, with the safety valve, which was of the ball-and-lever type, set at 108 pounds the plate must have failed at a tensile strength of 17,000 pounds per square inch, providing the actual steam pressure did not exceed 108 pounds.

FIG. 2. DOME AND SHEETS

Some idea of the extent of the explosion may be gained from the accompanying views. The two heads with some of the flues intact were blown a distance of fifty feet through the kitchen wall of the owner's house, narrowly missing three small children who were asleep in an adjoining room. The dome and

FIG. 3. 200-POUND PIECE ON HILLSIDE, 300 FEET FROM ORIGINAL LOCATION

several sheets landed in the main street of the town, a distance of about 300 feet from the plant, while another large piece took a direction at right angles to this and landed in a brook.

Upon being questioned after the explosion, the engineer admitted that there was a hole in the sheet just above the fire, through which water oozed, but he had not considered it serious enough to affect the safety of the boiler. From the

Fig. 4. Section of Shell Thrown 350 Feet

Fig. 5. Remains of Dynamo

directions in which the various parts of the boiler were hurled it is evident that the initial rupture occurred at the bottom of the shell, and in the absence of other indications it would seem more than likely that it took place at or near this hole, although the tremendous force exerted by the explosion would suggest a rupture above the water line.

Use of High Gas Speeds in Boilers

> *In this experimental boiler a gas speed of over 200 feet per second was attained, resulting in the transmission of 48,000 B.t.u. per square foot of boiler-heating surface and 2785 B.t.u. per square foot of economizer surface per hour. This resulted in a high rate of evaporation without decreasing the thermal efficiency.*

At a recent meeting of the Institution of Engineers and Shipbuilders of Scotland, Prof. J. T. Nicolson delivered a paper on "Boiler Economics and the Use of High Gas Speeds," based upon the tests of an experimental boiler of the Cornish type, this boiler being arranged as shown in Fig. 2. Within the last 10

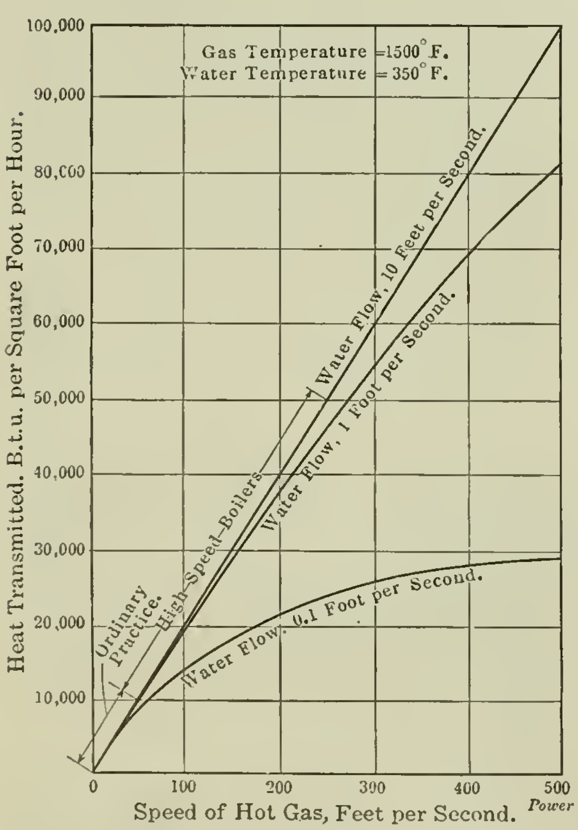

Fig. 1. Effect of Velocity of Gases Upon Heat Transmission

feet of boiler flue was placed a brick plug of such a diameter as to leave an annular space 1½ inches around it for the passage of the hot gases. These, after leaving the boiler, passed over the tubes of an evaporator and then through an economizer. The tubes of both the evaporator and the economizer had square iron rods inserted within them so as to cause the feed water to travel at a rapid rate, yet bring as much water-heating surface into use as possible. It was arranged that the feed upon leaving the economizer should go either directly into the boiler, or go there after mixing with the circulating water drawn by a rotary pump from the boiler and forced through the tubes of the evaporator so as to accelerate the circulation.

The results of the tests with this arrangement were as follows:

Coal fired per hour, pounds	840
Coal fired per square foot of grate surface per hour, pounds	44.2
Temperature of gases in combustion chamber, degrees Fahrenheit	3000
Temperature of gases leaving brick plug, degrees Fahrenheit	1200
Temperature of gases leaving evaporator, degrees Fahrenheit	620
Temperature of gases leaving economizer, degrees Fahrenheit	140
Temperature of feed entering economizer, degrees Fahrenheit	70
Temperature of feed leaving economizer, degrees Fahrenheit	270 to 340
Temperature corresponding to boiler pressure, degrees Fahrenheit	340
Draft at fan suction, inches	23½
Draft at bottom of economizer, inches	23
Draft at top of economizer, inches	7
Draft at back of water drum, inches	6½

It will be observed that the temperature of the waste gases fell to within 70 degrees of that of the entering feed. Compared with a boiler plant in which the waste gases reach the chimney at 540 degrees, this corresponds to an increased evaporation of about 1½ pounds per pound of coal. The transmission through the heating surface surrounding the plug was,

$$840 \times 15 \times 0.25 \times (3000 - 1200) = 5{,}670{,}000 \text{ B.t.u.}$$

per hour, or 48,000 B.t.u. per hour per square foot of heating surface. In a similar manner it was found that the rate of heat transmission in the economizer was 2785 B.t.u. per square foot of tube surface per hour.

The effect of gas speed in promoting rapidity of heat transference was definitely established, as plotted in Fig. 1, and there seemed to be a possibility by its use of greatly reducing the ratio of heating to grate surface without causing a diminution in efficiency which heretofore has always been associated with forced rates of combustion and evaporation.

It was accordingly decided to keep the boiler in operation for several months, making regular temperature observations and weighing the coal and feed water. Some little difficulty was experienced at first with the fan, but slight alterations enabled it to successfully hold up under the severe service. The principal object in making this continuous test was to ascertain whether the narrow gas passages would become choked with soot, and to observe what would become of the sediment and gases contained in the feed water when set free in the narrow water channels of the economizer and evaporator.

As feared, the passages around the economizer tubes did become choked with soot, and in order to burn the required quantity of coal it was found necessary to remove about one-third the number of economizer tubes (which were 7/8 inch in diameter and pitched 1 1/4 inches center to center) and repitch them. With this change the temperature of the waste gases no longer remained at 140 degrees, but rose to 240 degrees with a thin layer of soot upon them.

As regards the water spaces of the economizer (that remaining after a 1/2-inch square rod had been inserted in a 3/4-inch pipe) no deposit was found upon either the rods or the pipe and there was practically no corrosion. Below the water level, however, the evaporator tubes had become partially obstructed by a white sediment. This was accounted for by the fact that during the night the water-circulating pump was always shut down owing to lack of current; consequently the only circulation through the evaporator was that due to gravity.

The results of a test after fifty-one days' steaming without overhauling, except for the removal of some of the sediment below the water level of the evaporator, are given in the accompanying table.

RESULTS OF CONTINUOUS RUN.

Coal burned per square foot of grate per hour	37.8	35.0	23.9	26.1	46.5	40.7
Water evaporated per pound of dry coal from and at 212 degrees	10.342	10.278	10.790	11.005	11.416	11.640
Evaporation from and at 212 degrees per square foot of boiler and evaporator surface	16.24	14.02	11.87	12.41	22.77	22.18
Evaporation from and at 212 degrees per square foot of total heating surface, including economizer	10.63	10.1	8.98	8.24	12.16	12.72
Thermal efficiency of boiler, per cent	77.4	76.8	79.1	77.9	73.8	74.0
Net efficiency, deducting steam for fan, per cent	89	88.8	88.3	89.1	84.4	86.1
Chimney loss, per cent		6.7	6.7	6.3	9.4	5.8
Loss by incomplete combustion, per cent		2	2.8	0.2	1.1	0.0
Loss due to coal dust blown away, radiation, etc., per cent		15	11.9	15.2	16	15.9

In conclusion it may be said that the tests show:

1. That the rate of evaporation in pounds per square foot of total heating surface per hour increases directly with the gas speed.

2. This increased evaporative power can be attained without any sacrifice in evaporative or thermal efficiency.

3. The scouring action of the high-speed gas is sufficient to prevent choking by the accumulation of soot to such an extent as to affect materially the rate of heat transmission.

4. With continuous running, and a high rate of flow of the feed water in small-bore tubes the deposit of sediment is avoided, and corrosion due to pitting is eliminated; that is, if the water is passed through the narrow spaces at a high speed while throwing off its impurities, and is then led into a large space where these may settle without danger of trouble before being passed through the evaporating tubes, the incrustation difficulty which has been advanced against the adoption of small tubes is obviated.

5. High drafts do not necessarily involve high rates of burning on the grate.

6. That the drop in temperature between the furnace and the stack does not depend upon the mere magnitude of the heating surface, but upon the ratio of the total heating surface to the cross-sectional area of all the flues through which the gases pass.

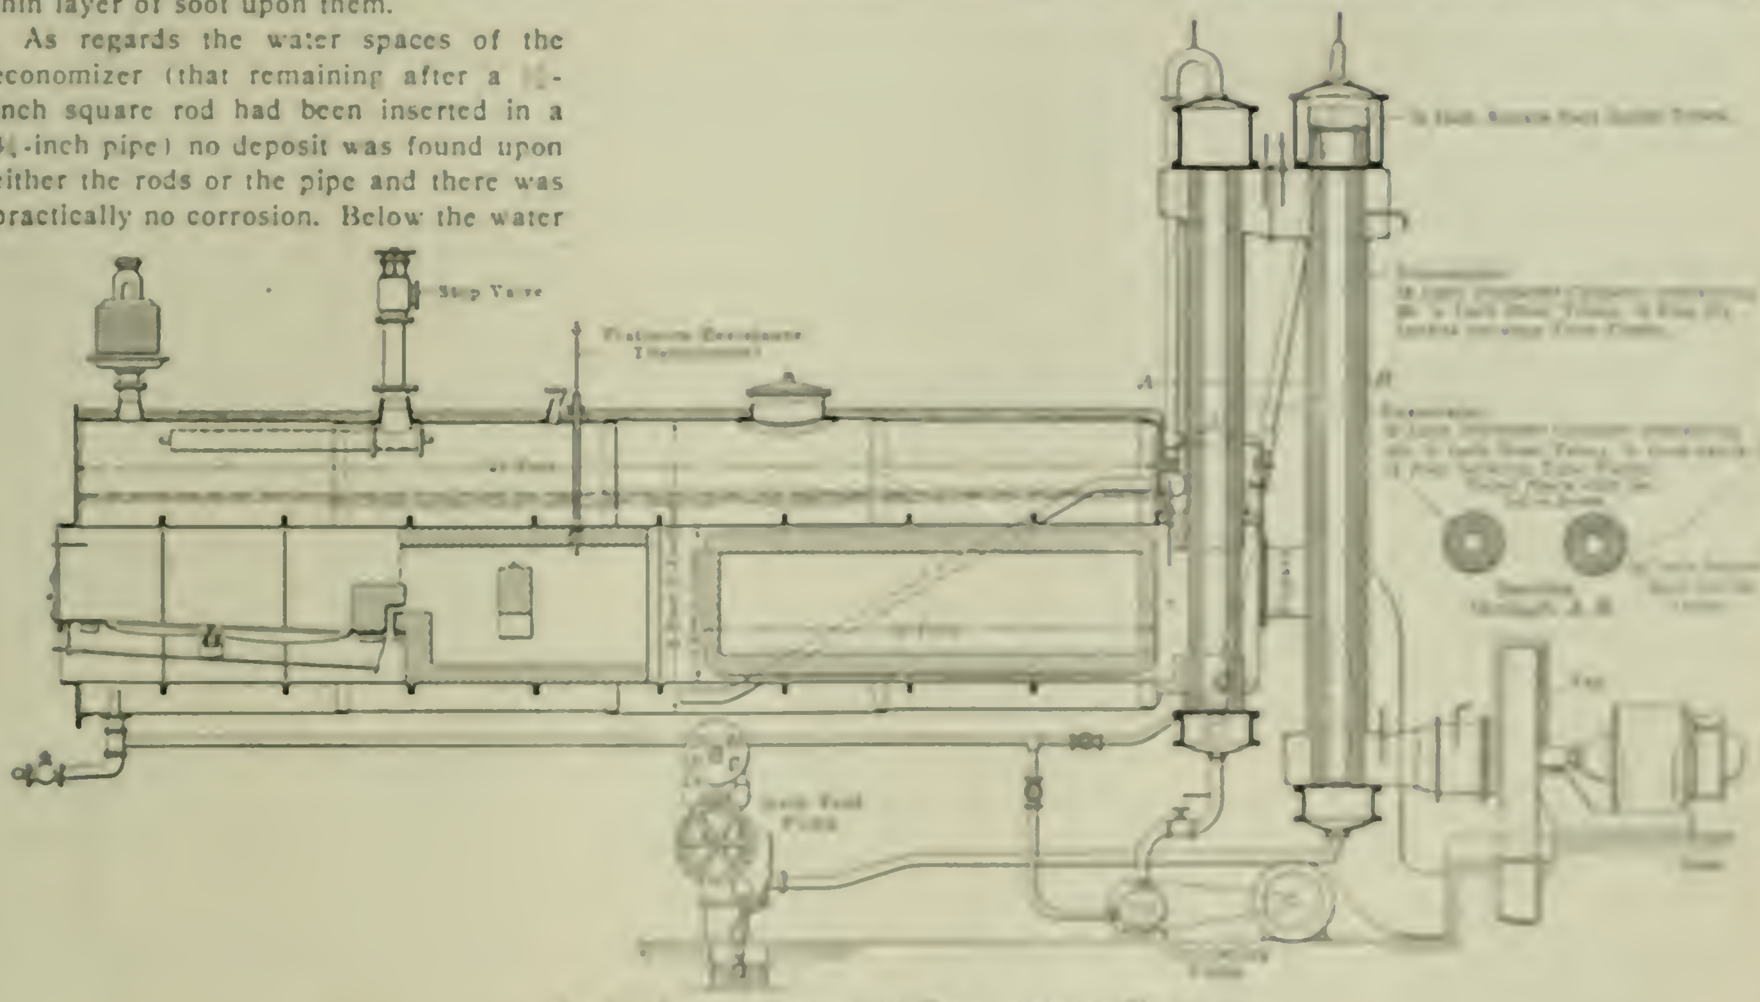

Fig. 2. Section through Experimental Boiler

Petroleum Competition

The Royal Dutch Shell group, according to the *Daily Consular and Trade Reports*, has entered into competition with the Standard Oil Company and is placing oil in France, and, it is reported here, has also determined to sell benzine in the United States, and four big tank steamers carried cargoes of this commodity some time ago to Boston.

Heretofore the Dutch combination has disposed of its products in the vicinity of production and consequently placed its oil on these markets at a very cheap rate. It will be another thing to transport oil 13,000 miles and face a great competition in its home markets, but the Dutch group seem to believe that they have sufficiently developed to succeed in the wider field, and this makes the situation interesting.

Oil is very cheap at Singapore with the price under competition going slowly down from day to day, so that 14 cents would buy as much oil at the end of October as 20 cents would in August. The result of the bitter fight between the great oil interests in the Far East is a reduction of prices to such an extent that the Chinamen are laying in good stocks at very low prices in hope of future profits, while the native consumers enjoy the luxury of plentiful light.

The Steam Turbine in Germany

By F. E. Junge and E. Heinrich

The thermodynamic efficiency as a measure of comparison of steam turbine economies and an outline of the development of the Allgemeine Elektricitäts Gesellschaft turbine.

Before entering into the details of the discussion it is necessary to agree upon a common measure of comparison. Formerly the thermodynamic efficiency was used exclusively, this being the ratio of the energy actually utilized to the energy theoretically available, in other words, the ratio of the theoretical steam consumption of an ideal engine to the actual steam consumption. Those German firms which build only the steam end of the unit, generally base their steam-consumption figures upon the actual work transmitted, measured at the coupling between the turbine and generator shafts. In most other cases, however, the thermodynamic efficiency includes the electrical output of the generator.

Let

H_o = Theoretical heat drop, that is, the amount of heat which is available in an ideal engine per pound, or kilogram, of steam introduced into the cycle (adiabatic expansion);

H_e and H_{el} = Available heat per pound of steam, corresponding respectively to the work delivered to the generator coupling, and the electrical output;

D_o and D'_o = Theoretical steam consumption per horsepower-hour and per kilowatt-hour, respectively;

D_e and D_{el} = Actual steam consumption per horsepower-hour and per kilowatt-hour, respectively;

η_e and η_{el} = Thermodynamic efficiency referred to the output delivered by the turbine and by the generator, respectively.

In accordance with the foregoing the following ratios may be expressed:

$$\eta_e = \frac{H_e}{H_o} = \frac{D_o}{D_e} \qquad (14)$$

$$\eta_{el} = \frac{H_{el}}{H_o} = \frac{D'_o}{D_{el}} \qquad (15)$$

and if η_g represents the efficiency of the generator, then

$$\eta_{el} = \eta_g \times \eta_e$$

When making an efficiency test of a steam turbine, the values D_e and D_{el} are found by the test, the amount H_o being taken either from the Mollier or the Stodola steam tables. In this connection it should be noted that one metric horsepower-hour = 75 meter-kilograms per hour = 632 French units = 2510 B.t.u. per hour, and one kilowatt-hour = 632 ÷ 0.736 = 860 French units per hour = 3410 B.t.u.

In one kilogram of steam only H_o heat units are available; therefore,

$$D_o = \frac{632}{H_o} \textit{ kilograms}$$

of steam are theoretically required in order to produce one horsepower-hour. Similarly,

$$D'_o = \frac{860}{H_o} \textit{ kilograms}$$

is the theoretical steam consumption per kilowatt-hour. Furthermore, expressed in French units,

$$\eta_e = \frac{632}{D_e H_o} \qquad (16)$$

$$\eta_{el} = \frac{860}{D_{el} H_o} \qquad (17)$$

or in English units,

$$\eta_e = \frac{2510}{D_e H_o} \qquad (16a)$$

$$\eta_{el} = \frac{3410}{D_{el} H_o} \qquad (17a)$$

The comparison of two steam turbines on the foregoing basis alone is not free from objections and needs supplementary data. For the economic efficiency of steam turbines the ratio of the circumferential velocity of the blades to the jet velocity is essential. For a single stage the most favorable value of this ratio is, theoretically, 0.5, but on account of the losses which occur, this is reduced in practice to 0.4 or 0.45. Considering two turbines of the same type and having the same number of stages, one working with high superheat and high vacuum, and the other with a lesser degree of superheat and vacuum, this ratio will be considerably smaller with the former than with the latter, because the jet velocity is higher in the first case; therefore, the thermodynamic efficiency of the former will be inferior to that of the latter, although the steam consumption of the former is superior on account of the additional energy available. Besides the influence of this ratio upon the thermodynamic efficiency, constructive features are apt to affect the efficiency with a high heat drop. With a high vacuum the specific volume of steam grows to such an extent that the cross-sectional areas through the last stages and the length of blades cannot be enlarged so as to utilize the heat drop with the best possible efficiency; hence it is useless to go below a certain vacuum. Furthermore, the high-pressure part of turbines built upon the reaction principle is not capable of safely withstanding high working temperatures. If such turbines are destined to work with high temperatures the clearances between the fixed and the rotating parts must be considerably larger than when the working temperature of the turbine is low; hence the leakage losses increase and the thermodynamic efficiency decreases. Summing up, it may be said that the thermodynamic efficiency alone does not give conclusive evidence of the all-round economy of a turbine, but that the rate of energy drop which is utilized in the turbine must be taken into account.

The A. E. G. Steam Turbine

The steam-turbine factory of the Allgemeine Elektricitäts Gesellschaft, in Berlin, is the largest concern of its kind in Germany, employing more than 3000 workmen who are exclusively engaged in this specialty. On October 1, 1910, the total number of Allgemeine Elektricitäts Gesellschaft turbines built and ordered was 1339, representing a total capacity of 1,514,418 horsepower, and prior to 1902 the company had not taken up the manufacture of steam turbines. There were at that time two systems on the market which had given fair results and had proved their usefulness for general power work even in large units; these were the Parsons and the Curtis types. The De Laval turbine, which was to be found in nearly all markets on the continent, could not be used as a model for the manufacture of large steam turbines, on account of its limitations in capacity, it being incapable of producing, economically, greater outputs than 300 horsepower. Therefore the Allgemeine Elektricitäts Gesellschaft adopted an entirely novel system, known under the name of the Riedler-Stumpf turbine. The basic idea was to build a turbine wheel which could utilize the whole energy of the steam in a single stage, at speeds which were to remain within the limits of direct generator drive. Tangential impinging of the steam upon the blades, which were milled with a cutter from the solid wheel-disk, was a special constructive feature of this type; and for low speeds and heavy loads, velocity staging and, when necessary, pressure staging were provided. Although this system is no longer on the market, it possesses historical value, representing the attempt to utilize the single-stage principle for high capacities without having recourse to transmission gearing. The highest possible number of revolutions for turbines driving electric generators—at 50 cycles, such as is used in Germany—is 3000 revolutions per minute, for a generator having two poles. In order to obtain an economic ratio of circumferential velocity to steam velocity, which is essential for steam economy, very large wheel diameters had to be adopted.

Fig. 19 shows a wheel 0.57 feet in diameter, built for 3000 revolutions per minute, corresponding to a circumferential velocity of 314 meters per second or 1003 feet per second. Such extremely high speeds had never before been used in practice and, therefore, necessitated very careful construction of the wheel as well as the employment of first-class material. A high stress upon the material was allowed for and with the best material (nickel steel) a factor of safety of three to four was deemed sufficient. The guide blades for large capacities and low speeds, serving to conduct the steam back to the wheel to impinge upon it again, are shown in Fig. 20. A turbine of this type of 2000 horsepower capacity and single stage was erected at the Moabit central station of the Municipal Electric Works, of Berlin, and was subjected to a careful test in 1903 by F. Rötscher. (For details see "Research Work, Heft 50, Verein deutscher Ingenieure.")

In order to show the essential working conditions of the Riedler-Stumpf turbine the following figures are selected from the various tests:

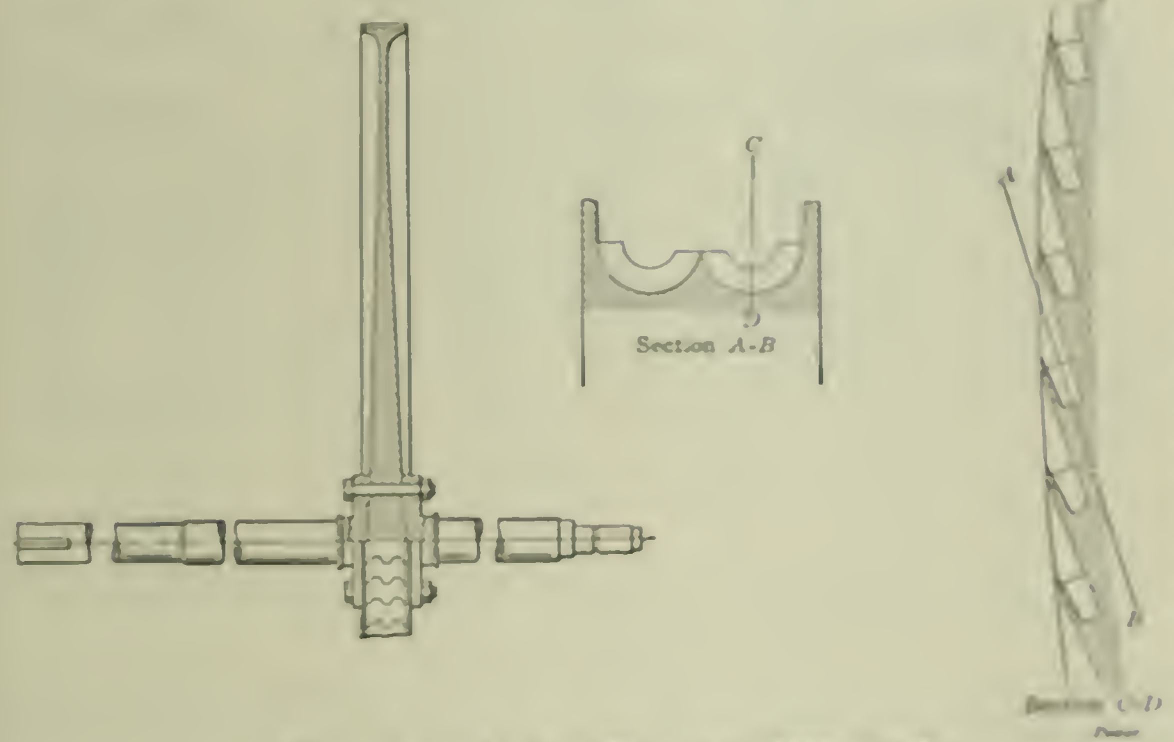

FIG. 19. LARGE DIAMETER, HIGH-SPEED WHEEL

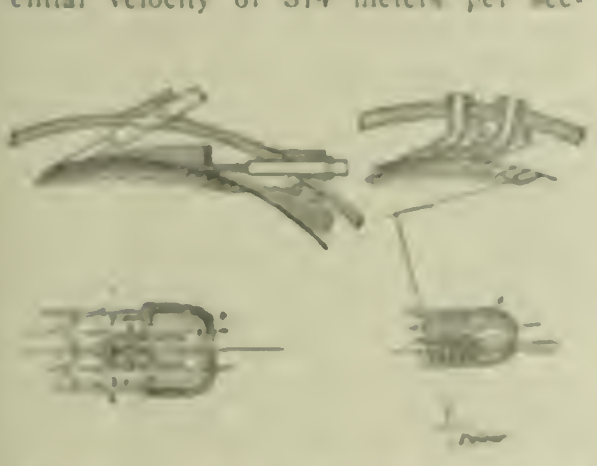

FIG. 20. GUIDE BLADES USED FOR LARGE CAPACITIES AND LOW SPEEDS

	Steam Pressure		Exhaust Pressure—Vacuum		Steam Temperature		Steam Consumption	
Load, Kilowatts	Kilograms per Square Centimeter	Pounds per Square Inch	Kilograms per Square Centimeter	Pounds per Square Inch	Degrees Centigrade	Degrees Fahrenheit	Kilograms per Kilowatt-hour	Pounds per Kilowatt-hour
1241	12.61	164	0.16	2.28	290	554	8.98	19.75

Therefore,

$$H_a = 183\ WE$$

$$H_a = \frac{860}{183} = 4.70$$

and

$$e_d = \frac{4.70}{8.20} = 0.573$$

Supposing e_g to be 91 per cent., then e_t would be 0.577 per cent.

The theoretical velocity of efflux at the nozzle is

$$c_0 = 91.5\sqrt{183} = 1240$$

meters per second = 4070 feet per second. The actual velocity, assuming a coefficient of loss in the nozzle of ϕ = 0.93, is

$$c_1 = 1150$$

meters per second = 3775 feet per second. This gives as the ratio of circumferential to efflux velocity

$$\frac{u}{c_1} = \frac{314}{1113} = 0.282$$

These figures show at once the weakness of the single-stage type. The value 0.282 is far below the most favorable value of this ratio. But considerations of strength forbid further increasing the wheel diameter so as to attain better efficiencies. The number of revolutions is fixed. Moreover, the drop of 183 heat units is very small, on account of the bad vacuum; but a higher drop would only decrease the efficiency, even if the steam consumption were better. The losses in the nozzles and blade pockets were very high in this turbine.

It will be remembered from the preceding articles that with Rateau stages, efficiencies as high as 67 per cent. were attained, while in this case the corresponding figure (including all additional losses through bearing friction, conduction and radiation) is only 58 per cent.

FIG. 21. RELATIVE SIZES OF FOUR TURBINES OF EQUAL CAPACITY AND SPEED

Therefore, the underlying idea of single-stage action for high capacities could not be realized in practice, so that the Allgemeine Elektricitäts Gesellschaft was forced to adopt another system. However, the attempt proved that circumferential velocities of from 300 to 400 meters per second can be safely used. Also, it might be mentioned that American designers of small turbines have readopted the characteristic blade form of the Riedler-Stumpf turbine.

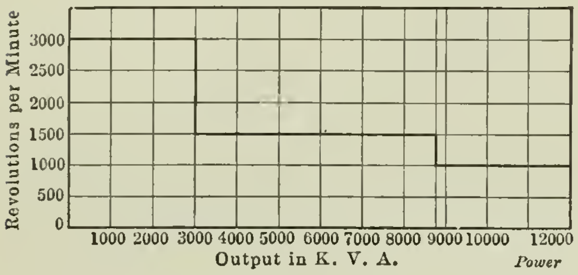

FIG. 22. LIMITS OF OUTPUT OF THREE-PHASE 50-CYCLE GENERATORS

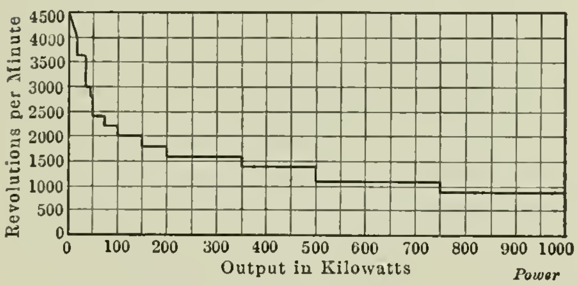

FIG. 23. VARIATION OF SPEED WITH LOAD IN DIRECT-CURRENT GENERATORS

As early as October, 1903, the Allgemeine Elektricitäts Gesellschaft had come to an agreement with the owners of the Curtis patent in America, especially with the General Electric Company, and by this agreement a sort of community of interests, scientific technical exchange, mutual exploitation of patents and a division of the markets, preventing the products of one firm from competing with those of the other in certain territories, was established. As regards the Curtis turbine, the German manufacturers preferred an independent course of construction, adopting the horizontal instead of the vertical type, the main reasons being that for the sake of steam economy in the larger types, the Rateau stages were adopted for the low-pressure portion, and as this necessitated a greater number of stages and therefore a greater total axial length of turbine, the vertical construction was rendered difficult.

Another problem to be considered was that of attendance. The same arguments which make the horizontal construction in steam engines, except in a few special cases, superior to the vertical type, hold true also for the turbine. The horizontal construction affords better accessibility to all parts and a better survey over the whole plant, especially easier control of bearing, governor, safety devices, etc. It also permits the machine to be dismantled and the interior exposed for inspection with much less trouble than with the vertical type. In view of the necessity of ease in dismantling, the pipe fittings, governing mechanism, etc., should be connected preferably to the lower part of the casing. The step bearing of the vertical type of turbine, which now seems to give satisfactory service, was regarded in the early days as a sensitive organism which was likely to give trouble. So it was deemed wiser in this respect by the builders to profit by the tests of Lasche

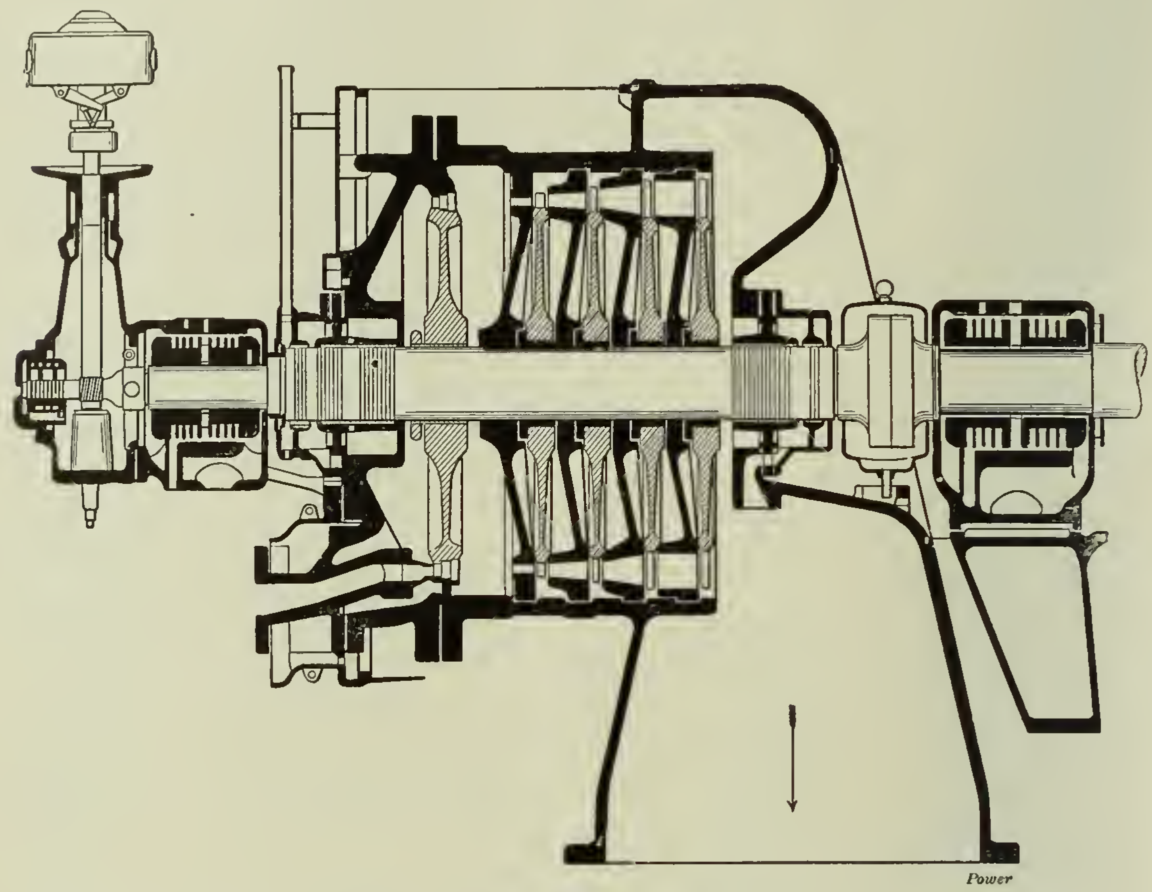

FIG. 25. A. E. G. TURBINE OF 3000 REVOLUTIONS PER MINUTE AND OUTPUTS GREATER THAN 1000 KILOWATTS

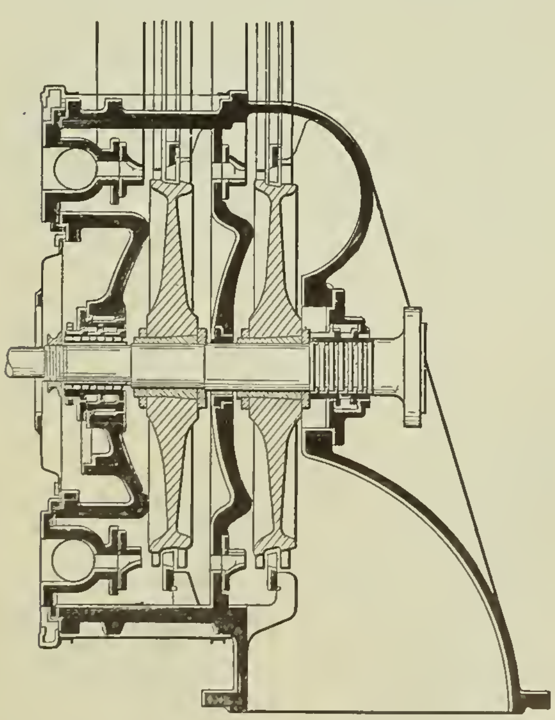

FIG. 24. A. E. G. TURBINE FOR SPEEDS OF 3000 REVOLUTIONS PER MINUTE AND LOADS UP TO 1000 KILOWATTS

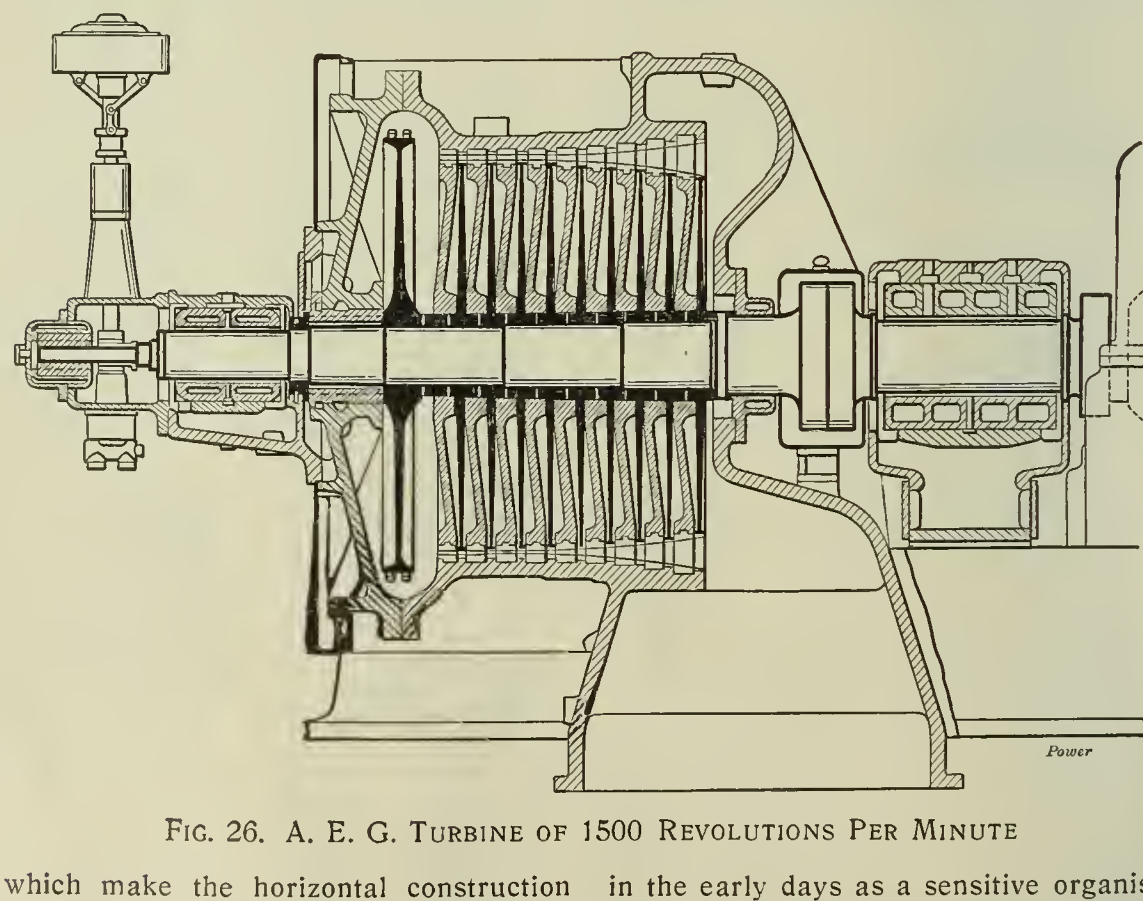

FIG. 26. A. E. G. TURBINE OF 1500 REVOLUTIONS PER MINUTE

and by the good results attained with horizontal bearings in the high-speed electric-railway trials.

As to bulk of plant, the floor space required is approximately the same for both types, if the condensing plant is taken into account (which has the same dimensions in both cases). Considering a turbine room containing several units, the centers between two units become somewhat greater with the vertical types; hence, the length of the plant is greater, while the width of the room will be smaller with vertical turbines than with horizontal ones. However, the hight of the room will be considerably greater for vertical than for horizontal turbines; hence it is safe to assume that the cost of the building for vertical units is greater than for horizontal units.

These and other considerations made it advisable for the Allgemeine Elektricitäts Gesellschaft, instead of copying the General Electric style of the Curtis type, to develop an entirely new and original form of horizontal turbine. With the style once agreed upon, the dimensions of turbines are dictated by three main considerations: First, reliability of operation; second, fuel economy; third, cost per horsepower. These three points of view do not exactly coincide. For instance, in reaction turbines safety of operation and economy stand in direct contrast, in so far as economy requires very small clearance between the guides and the rotating parts in order to keep the leakage as small as possible, while reliability of operation demands larger clearances. On the other hand, with impulse turbines this does not hold true, and in designing these there is only a compromise between economy and cost.

It is obvious that turbines can be built cheaper if the specifications for steam consumption are less stringent. In one of the preceding discussions it was shown that, beginning at certain capacities (somewhere around 100 kilowatts) the Curtis and Rateau systems in the high-pressure portion are approximately on a par, as far as economy is concerned, there being only a slight superiority of the Rateau system, while, in the low-pressure portion, even for smaller outputs, Rateau wheels seem superior.

A common feature of all Allgemeine Elektricitäts Gesellschaft turbines, regardless of capacity, is the employment of the Curtis wheel in the high-pressure portion. Experience leads us to believe that for very large capacities the Rateau action principle is superior whenever a high economy is to be attained, although the building cost is higher. For medium outputs of from 700 to 1000 kilowatts the combined Curtis and Rateau turbine seems the more favorable. For very small capacities, of about 300 horsepower, the Curtis principle (wheels having two rows of blades) is preferable, especially if low speeds are desired for driving direct-current generators. Another point of division lies in the change from wheels having two to wheels having three rows of blades.

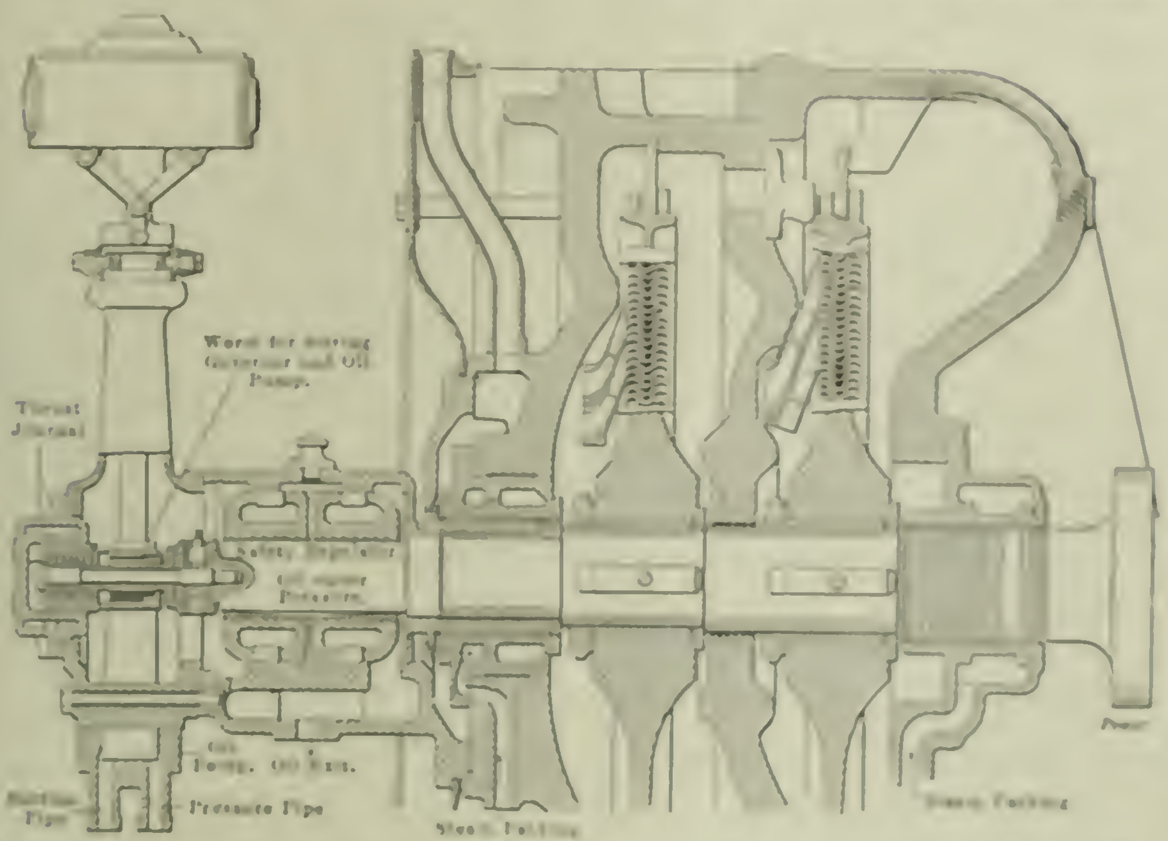

Fig. 27. Sectional Elevation through A. E. G. Turbine Having Two Pressure Stages to One Velocity Stage

One of the problems which the Allgemeine Elektricitäts Gesellschaft had to solve is indicated in Fig. 21, which represents the utilization of a certain heat drop through four turbines of equal capacity and equal speed, and affords an illustration of the size and proportions of these turbines. There will be a certain (very low) capacity for which the efficiencies of the four are equal.

The number of revolutions, at the maximum output for a certain speed, is, as a rule, not determined by the turbine but by the generator. The rotor of the generator is a much more complicated mechanism as regards strength and dynamic conditions than are the rotating wheels of the turbine. The former is an unhomogeneous part, containing besides the iron of the shaft and the iron of the magnetic field, copper and insulating materials, which in the course of operation are subjected to dislocation, necessitating careful and repeated balancing and careful treatment.

Fig. 22 shows the limits of output for 50-cycle three-phase generators at the respective speeds of 3000, 1500 and 1000 revolutions per minute. The units running at 3000 revolutions per minute are built up to the limit of 3000 kilovolt-amperes. The limit of the 1500-revolutions per minute

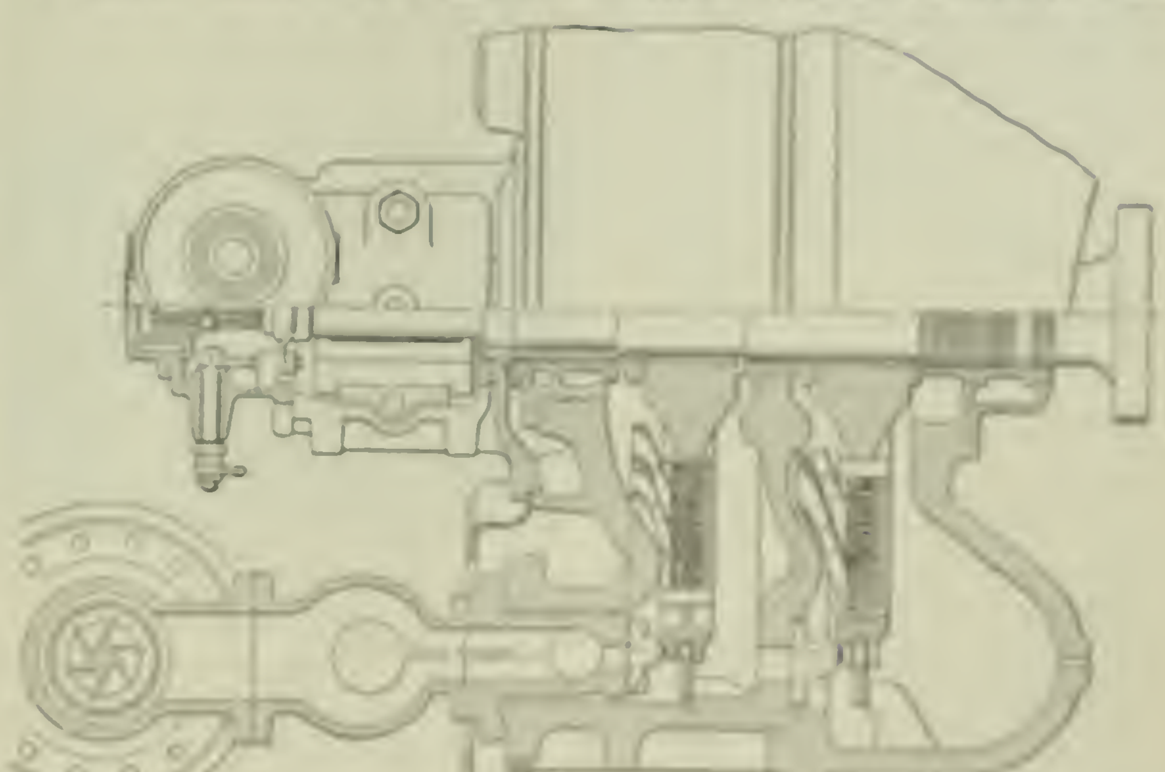

Fig. 28. Sectional Plan of A. E. G. Turbine

ute type lies at 8800, and that of the 1000-revolutions per minute type at 12,000 kilovolt-amperes. The capacities at high speeds increase year by year. In 1905 it was considered a risk to build a generator of 1000 kilowatts capacity running at speeds of 3000 revolutions per minute; today they are built up to 3000 kilowatts for the same speed. Considering that the specifications and guarantees are becoming more stringent year by year, whereby larger and larger wheel diameters are made necessary, and that higher vacuums are being employed, whereby the blades of the last wheels are subjected to heavy stresses, it goes without saying that designers are forced to approach very close to the limit of safe load.

In the Riedler-Stumpf turbine a wheel of 2000 millimeters, or approximately 79 inches diameter, running at 3000 revolutions per minute, was possible only by avoiding the employment of separate blades set in the rim, using instead, pockets milled in the rim. But in the case under consideration we have to deal with inserted blades of considerable length, exercising great additional centrifugal force on the circumference of the wheel.

Direct-current generators afford greater elasticity of speed but have a very sensitive makeup, the collector and the brushes militating against building direct-current generators beyond outputs of 1000 kilowatts. Fig. 23 shows how the normal speeds of direct-current generators vary with the change of load. It is seen that driving direct-current generators requires a greater variety of turbine types than driving three-phase generators. Comparatively small outputs, such as 600 kilowatts, are to be attained at 1200 revolutions per minute. Figs. 24 to 26 show the normal construction of the Allgemeine Elektricitäts Gesellschaft turbine in its various characteristic forms. Fig. 24 is the 3000-revolutions per minute type for outputs below and up to 1000 kilowatts, having the Curtis principle with two pressure stages to one velocity stage each. For higher outputs than 1000 kilowatts at 3000 revolutions per minute the action wheel in the low-pressure part is replaced by four or five Rateau wheels; see Fig. 25. The same holds true for the 1500-revolutions per minute type with the difference, however, that from nine to twelve Rateau wheels are employed in the low-pressure part, as shown in Fig. 26. Figs. 27 and 28 show the first named type of turbine, 3000 revolutions per minute up to 1000 kilowatts, in sectional elevation and plan with details of design to be discussed later.

The Mason Mechanical Laboratory

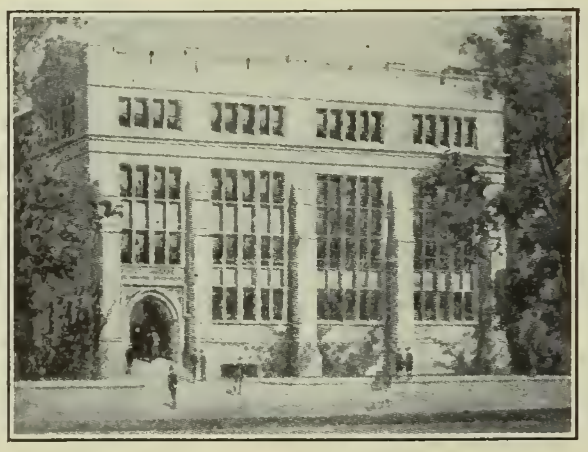
A three story building, 85 by 200 feet, donated to the Sheffield Scientific School of Yale University. The entire space will be devoted to laboratory work; no recitation or drawing rooms.

The accompanying illustrations show the new mechanical-engineering laboratory which is now being built for the Sheffield Scientific School, Yale University, New Haven, Conn. The funds for this laboratory were given to the Sheffield trustees by two graduates of the school, George Grant Mason, of New York City, and his brother, William Smith Mason, of Evanston, Ill., both of the class of 1888.

Work on the building is now in progress and the contract calls for its completion in the early summer of 1911. The frontage is about 85 feet and its length 200 feet. The architect, Charles C. Haight, of New York City, has worked out a very pleasing design, as Fig. 1 will testify. The long windows at the right are at the end of the testing floor, above which is a clear head room of 35 feet; at the left the smaller windows indicate the location of the main gallery and the mezzanine floors—which are possible on this side of the building throughout a greater part of its length. The building will have three stories above the basement. The front rectangle will be of Indiana limestone, and the extension will be of brick, with suitable stone trimmings. The entrance from Temple street will be sufficiently large for the admission of a team so that heavy pieces of machinery may be delivered directly under the traveling electric crane which will extend the entire length of the building with a span of about 40 feet.

An examination of the floor plans will indicate, in a general way, what is to be the distribution of the equipment and the arrangement of the rooms for offices, lectures, computation, research and general experimental work. No provision for recitation or drawing rooms has been made in the building—the entire space being devoted to instruction in experimental work for undergraduates and for research work in engineering science for graduate students, research fellows and special investigators.

The main floor of the laboratory will contain the larger part of the equipment —especially the heavy pieces of machinery—such as machines for testing the strength of materials, steam engines and gas engines of various types, steam turbines, steam and centrifugal pumps, air compressors and refrigerating machinery, together with the auxiliary equipment of condensers, fans, electric motors, scales, tanks and smaller appliances for testing. This equipment will be erected under the crane. The units will, for the most part, be small and self-contained. A large part of the floor under the crane will consist of heavy concrete, suitably arranged with parallel grooves for bolting the equipment at any point. The steam, water, gas and other pipes will be run in the basement below, provision being made for their extension to the testing floors through a series of auxiliary tunnels which occur at frequent intervals. All testing-floor areas are suitably drained so that an abundance of water may be used whenever it is necessary or desirable.



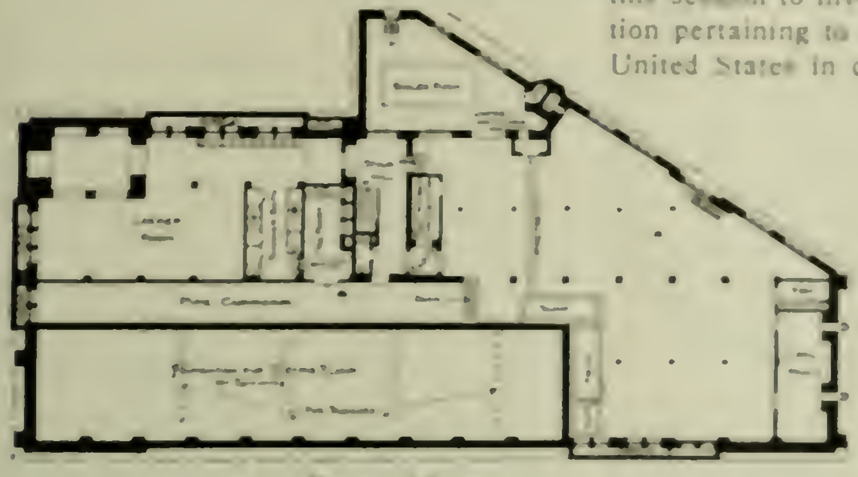
Mason Laboratory of Mechanical Engineering

In the front basement will be located the toilet and locker rooms. There are several shower baths. The boiler-room extension provides for the heating and power boilers. An auxiliary power plant, both steam and gas-electric, will be located near the boiler room. Tanks of concrete will provide water storage and a large sump below the level of the street drains will receive all drainage not otherwise provided for. The sump will be automatically emptied by an electric centrifugal pump. Coal-storage bins and ash-elevating machinery will be located at the Temple street end of the building. Access to the basement is provided for heavy machinery through a large trap door suitably located under the crane, as well as by the electric elevator which connects all floors.

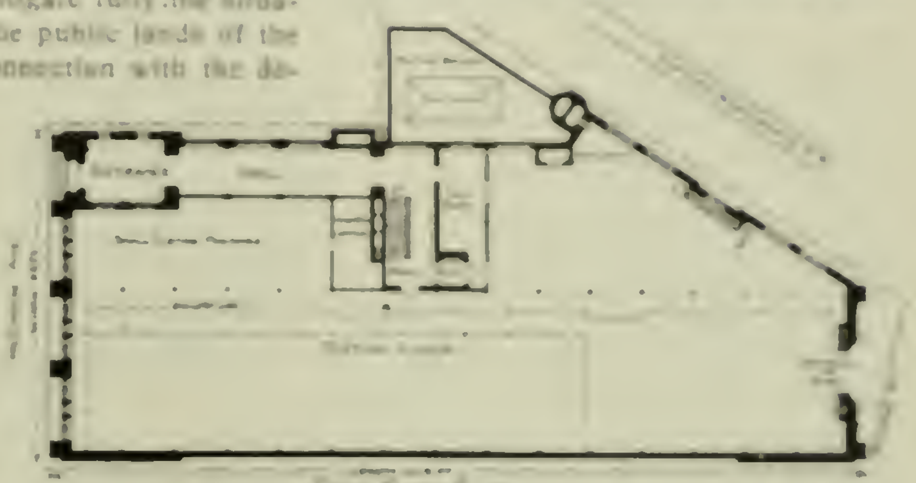
No attempt has been made to provide mechanical ventilation for any of the rooms except the lecture room and the computing room directly above it. For these rooms the fresh-air supply will be furnished through the ducts as shown. A gravity circulation will frequently be sufficient to provide the ventilation required, but a motor-driven fan will be installed to augment the natural circulation at such times as it may be necessary.

The gallery floor contains considerable space available for lighter machinery, several small offices and the general lecture room, with a seating capacity for 150. There are two landing platforms on this floor so that the traveling crane may deliver heavy pieces under a trolley rail extending through the lecture room or across the open floor space at the east end of the laboratory.

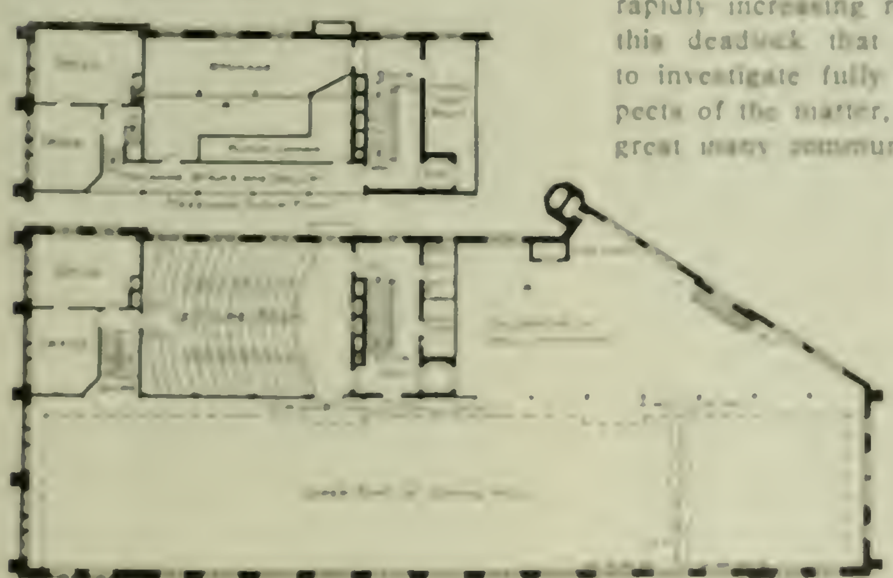
The distribution and use of the space on the third floor are sufficiently evident from an inspection of the plan of that floor. The room devoted to mechanical technology will be used as a laboratory for instruction in machine design, machine construction and mechanism. It is planned to have, not a museum, but an exhibition of modern machines of special and complex design. Power will be available for the operation of such machines as may be placed here for study. In many instances the machines may be on exhibition for only a short time and a representative of the company furnishing the machine may be asked to demonstrate its working.



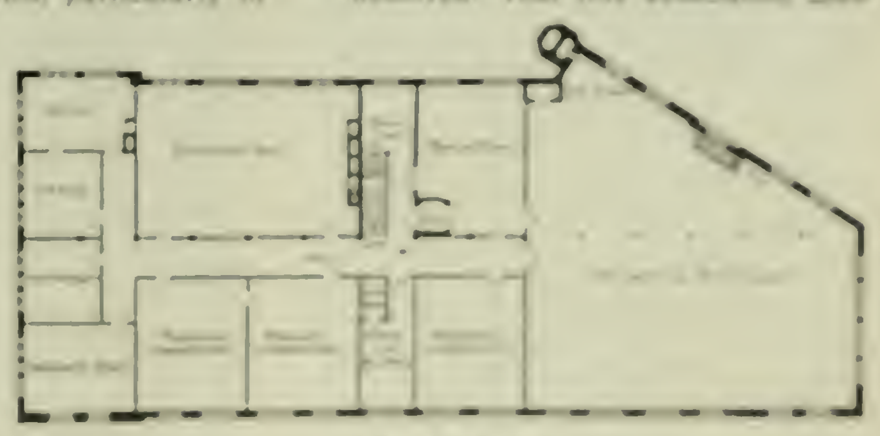
Basement Plan



First Floor Plan



Second Floor Plan



Third Floor Plan

The completion of this laboratory will give to the Sheffield Scientific School many needed facilities available for all its engineering departments, and it will give to mechanical engineering what the Hammond laboratory gives to the students of mining engineering.

It will be remembered that the gift for this laboratory included $300,000 for the building and its equipment, and $100,000 for its endowment.

The general contractors for the construction of the building are P. C. Stuart & Co., New York City.

Congress Urged to Investigate Water Power Question

At the January 12 meeting of the executive committee of the National Electric Light Association, a set of resolutions were adopted urging that a joint commission of Congress be appointed at this session to investigate fully the situation pertaining to the public lands of the United States in connection with the development of water powers. The association represents about two billions of investment in central stations for electric light and power and the apparatus they employ, with 100,000 employees, and includes within its ranks 90 per cent. of the investment and capacity for public service thus represented. There are already nearly 1000 central stations in this country using water powers, but under the present conditions that have tied up such development very few new water-power plants can be undertaken, and the result is that for lack of such utilization of such water power, the consumption of coal and other fuel goes on at a rapidly increasing rate. It is to relieve this deadlock that Congress is invited to investigate fully at once all the aspects of the matter, with the idea that a great many communities, particularly in the West, which are seeking to advance the development of unused water power sites, may be enabled to gratify their natural wishes in this respect.

The resolution reads as follows:

"Whereas the condition of the laws and regulations relating to the public lands of the United States Government is so complicated, unsatisfactory and unsettled that the financing and commercial development of new enterprises in connection with public lands is rendered practically impossible; and

"Whereas the immediate development of the idle water powers of the nation is of importance to the whole people in that it brings to immediate use an indestructible natural resource that would be otherwise lost or idle and conserves coal, oil, gas and other fuels that are limited in amount and subject to replacement; and

"Whereas the National Electric Light Association is particularly interested in the situation pertaining to public lands of the United States in connection with the development of water powers; and

"Whereas much of the difference of opinion upon the subject of water powers arises from the difficulty of obtaining a clear comprehension of all the facts.

"Now, therefore, be it

"Resolved: That this association does respectfully urge that a competent commission, composed of members of the Senate and House of Representatives of the United States, together with persons familiar with the financial and other practical aspects of the situation, be appointed with full authority to collect the evidence, and for that purpose to hold full and complete open hearings in different sections of the country, and be it further

"Resolved: That this association does respectfully urge that such commission be appointed at as early a date as possible, to the end that its meetings may be held between the adjournment of the present session of Congress and the reassembling of the new Congress in the hope that such commission should report upon such reassembling and Congress be thereby enabled to take prompt action in the enactment of such laws as will permit the development of the natural resources of the country in such a manner as shall render them of the greatest possible use to all of the people."

Especially conducted to be of interest and service to the men in charge of the electrical equipment

Hand Controllers for Multi-Speed Induction Motors

By R. H. Fenkhausen

The present article is devoted to a practical consideration of the principal types of apparatus now available for controlling the speed of induction motors. The motors themselves have already been explained in a previous article (June 9, 1908); the present article, therefore, is restricted to the controllers alone.

The controlling apparatus for any induction motor of the wound-rotor type provided with external resistance must consist of two separate and distinct devices; namely, a line switch, by which

Fig. 1. Simple Oil-break Starting Switch

the current supply to the stator windings may be cut off or on and, in the case of a reversing motor, reversed; and a drum controller by which the resistance in the rotor circuit may be varied to obtain different speeds in the motor.

When the secondary resistance is for starting duty only, a controller of the type shown in Fig. 1 will often fill all requirements. A knife switch, preferably of the oil-break type, is used to close and open the leads from the supply circuit to the stator or primary, and when reversal of the motor is desired, the switch may be double-throw.

Owing to the short duration of the starting period the resistance does not need to be of large capacity and is therefore inclosed within the same case with the drum controller, making a very compact outfit and one that requires the least possible labor to install, as all the connections between the controller and the resistance are permanent. For large motors an independent short-circuiting switch should be installed near the motor in order that the resistance of the collector rings, controller contacts and wiring will not cause too large a full-load slip in the rotor.

When the secondary resistance conductor is used for speed regulation, the resistance is in circuit at all times, and in order to obtain sufficient ventilation to keep the temperature rise within a safe limit, the resistance is usually mounted separate from the controller. Fig. 2 shows a set of resistance grids suitable for this service. Flexible cables are attached to the various taps, which connect to similarly numbered cables from the controller.

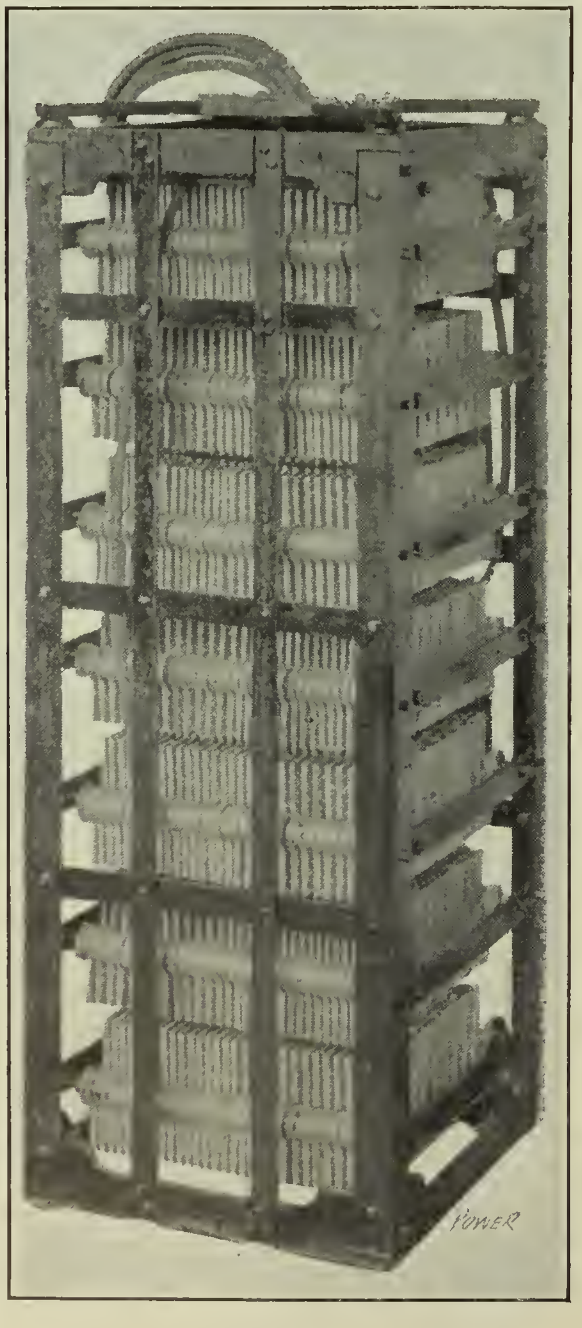

Fig. 2. Resistor Grids in Frame

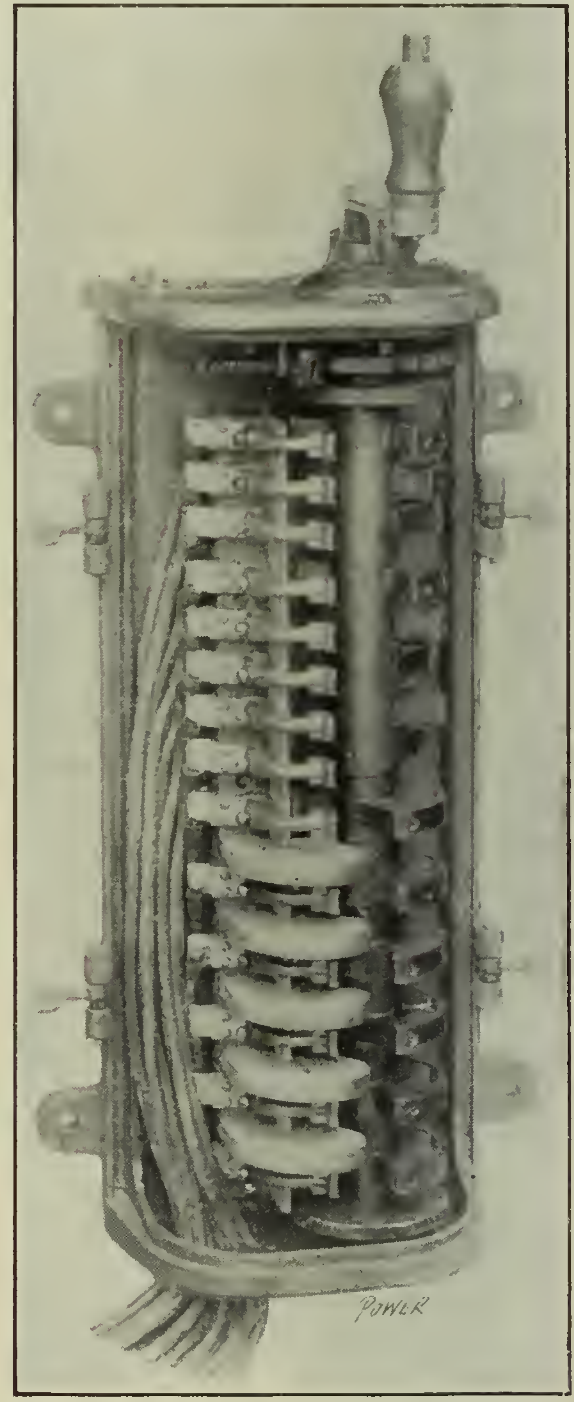

Fig. 3. Stator and Rotor Control on One Spindle

In a previous article attention was called to the fact that wound-rotor motors equipped with independent primary and secondary switches were liable to damage by the line switch being closed by a careless operator when the secondary resistance was cut out. While separate switches are permissible for starting service only, for varying-speed service it is essential that the primary and secondary switches be mechanically interlocked. This is especially necessary where the motor is to be frequently reversed. This mechanical interlocking may be accomplished in several ways. The simplest method is to mount the primary and secondary controlling drums on a common shaft, as shown in Fig. 3, and arrange the connections so that the stator circuit cannot be connected to the line except when all the rotor resistance is in circuit.

The principal objection to this method is the unnecessary wear of the primary switch. After it is closed on the first notch, no further movement is necessary during the various speed changes until the motor is again stopped, but, as the primary and secondary switch drums are mounted on a common shaft, a corresponding movement of the primary switch

FIG. 4. SPEED CONTROLLER WITH CAM-OPERATED STATOR SWITCH

is made for every speed change made with the secondary drum. This not only results in unnecessary wear of the primary contacts, but increases the effort necessary to move the controller, owing to the extra number of fingers bearing on the drum. In large controllers this entails considerable additional exertion on the part of the operator. In order to get rid of these objectionable features, the primary switch is often so arranged that a cam on the operating shaft of the controller closes it for the desired direction of rotation when the controller lever is moved to the first notch and does not again move it until the controller is returned to the "off" position. Such a controller is illustrated in Fig. 4, and a detail of the reversing mechanism is shown in Fig. 5. The primary contacts are submerged in an oil tank to suppress the arc.

It is not desirable to carry high-voltage leads inside the controller case; for high-voltage motors, therefore, the controller is provided with an external oil switch operated by a lever projecting through the rear of the controller case, as shown in Fig. 6. The lever is operated on the

FIG. 5. REVERSING MECHANISM OF CONTROLLER IN FIG. 4

first notch by a cam on the controller shaft similar to that shown in Fig. 5. This arrangement makes it possible to adjust the secondary fingers and drum contacts without danger of a shock from exposed parts of the primary switch.

Controllers are made for both reversing and nonreversing service, the only difference being that on the nonreversing controller the "off" and full-speed positions are at opposite ends of the travel of the handle and the primary switch simply closes and breaks the main-line connections, whereas on the reversing controller the "off" position is in the center of the travel of the handle and the primary switch is arranged to reverse one phase of the primary leads when the controller handle is moved to the "reverse" side of the "off" position.

CONTROLLER REQUIREMENTS

Controllers and resistances are customarily supplied by the motor manufacturer, but in case the motor is an old one, or is bought of some company that does not make its own controlling apparatus, the following information must be supplied to the company furnishing the controller and resistance:

1. Number of phases, voltage, horsepower and frequency.

2. Secondary current per phase of rotor winding.

3. Secondary voltage or ratio of primary to secondary turns.

4. Kind of service. Continuous or intermittent at reduced speeds.

Even when all the apparatus is furnished by one maker it is desirable that the secondary current of the motor be known in order that the leads from the controller to the collector rings may be made of ample size. If this is neglected an objectionable increase in the full-load slip of the motor will result, with evil effects on both the efficiency and speed regulation at normal speed.

The secondary currents vary in motors of different manufacture, but the figures in Table 1 may be considered as fair averages for wound-rotor induction motors. This table also shows the difference in motor ratings for continuous and intermittent service.

As stated in a previous article, the rotors of motors designed for continuous operation at reduced speeds are made of high resistance and the secondary current

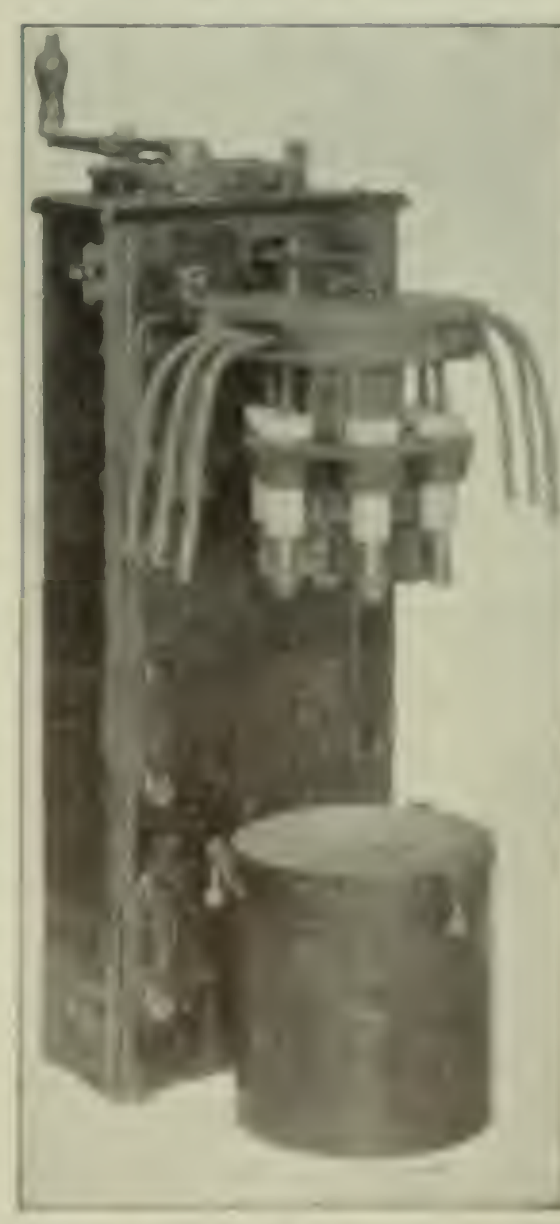

FIG. 6. STATOR SWITCH OPERATED AS LEVER NEAR MAIN CONTROLLER

is small; motors designed to run mostly at full speed and only occasionally at reduced speed are equipped with low-resistance rotors, and the secondary current is relatively large. The resistance grids for the latter type of motor are necessarily quite large and for convenience are usually mounted in two or more frames; one such frame is shown in Fig. 7. The grids designed for the higher resistance motor are smaller and may be mounted all in one frame, as in Fig. 2. In cases where a regular multi-speed controller is used for starting duty only, the resistance grids carry current only for a short time and may be made proportionately smaller.

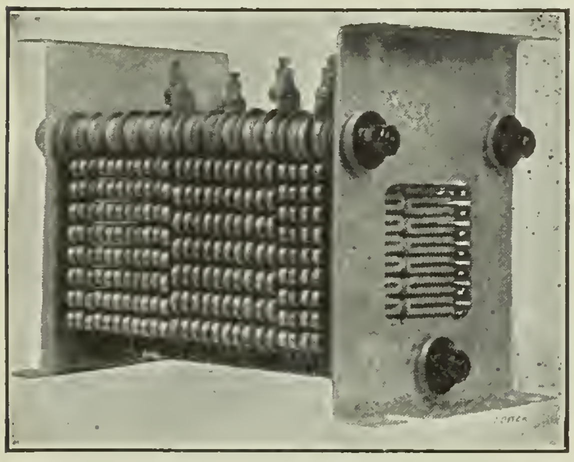

FIG. 7. HEAVY-DUTY RESISTOR GRIDS

There are two methods of varying the resistance in the rotor circuit. In the first method, the connections of which are shown in Fig. 9, resistance is cut out of each phase of the rotor in turn. This method is employed in the controller shown in Fig. 3, and, although it results in the rotor currents being out of balance on two speeds out of each three, this disadvantage is more than offset by the reduction in the number of controller contacts required for a given number of speeds, and the resultant saving in wiring and controller maintenance. In the second method resistance is cut out of all three phases of the rotor circuit simultaneously. This method is used on the controllers shown in Figs. 4 and 10. The connections for this method are illustrated in Fig. 8 and, although the rotor phases are kept in perfect balance, it is apparent from the drawing that the number of drum contacts is considerably greater than is required when the method shown in Fig. 9 is employed.

For elevator service a controller similar to the one shown in Fig. 10 is used. The primary switch is operated by the elevator rope and the secondary switch is operated by a spring which is compressed by the movement of the primary switch. This spring turns the drum against the retarding influence of a dashpot, and by adjustment of the dashpot the rate of movement of the secondary drum, and consequently the acceleration of the motor, may be regulated independently of the will of the operator.

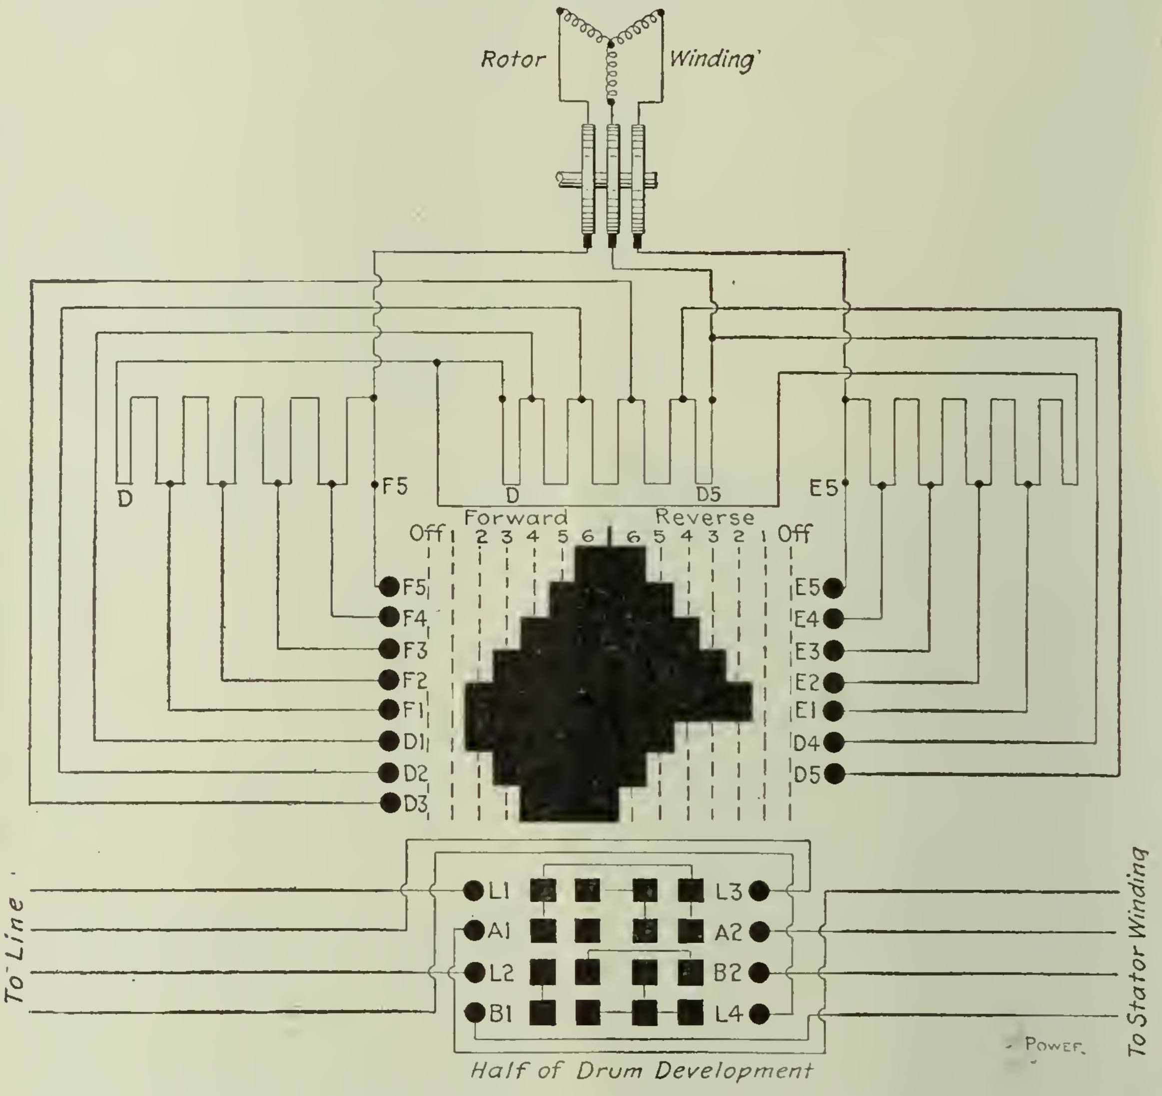

FIG. 8. CONTROLLER FOR CUTTING OUT ALL THREE RESISTORS SIMULTANEOUSLY

"CASCADE" CONNECTION

The greatest disadvantages of the wound-rotor type of induction motor are its inability to maintain constant speed when the load varies, except at full speed, and its poor efficiency when running at reduced speeds. These difficulties cannot be overcome by any commercial control method when one motor is used, but where two motors are connected to the same load, two or more constant and efficient running speeds may be obtained by the use of the so called "cascade" connection. Fig. 11 shows the simplest form of this connection. The rotor circuits of the two motors are connected and the stator of one motor is short-circuited. If the stator of the other motor be connected to the line, both motors will run at a speed corresponding to that of one motor having as many magnetic poles as both of the two motors. The motors shown have equal numbers of poles, so the resultant speed will be one-half that of either one operating alone. This speed will be maintained practically constant under widely varying loads, and the efficiency will be quite high. This control method is similar in principle to the series-parallel method of direct-current control, and, in common with it, requires that both motors be rigidly connected to the load, either by direct coupling or gearing. If this is neglected, one of the motors may run

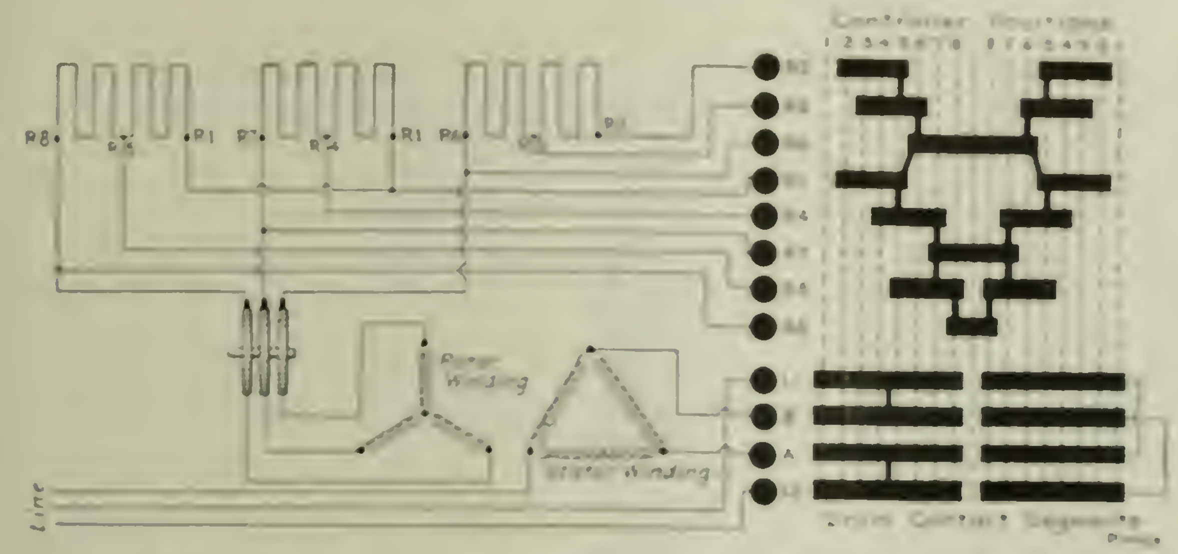

FIG. 9. CONTROLLER FOR CUTTING OUT THE RESISTORS SUCCESSIVELY

up to full speed and the other one stop the first time the division of load between the motors is disturbed.

This method of control may be extended by the use of two motors having a

FIG. 10. HORIZONTAL CONTROLLER FOR ELEVATOR SERVICE

different number of poles, in which case four constant running speeds are obtained. For example, if an 8-pole and a 12-pole motor are installed, the following speeds are obtainable on a 25-cycle circuit:

	Revolutions per Minute
1. Motors in direct "cascade"....	150
2. 12-pole motor alone........	250
3. 8-pole motor alone..........	375
4. Motors in differential "cascade"	750

In differential cascade the motors are connected for opposite directions of rotation and the resultant speed is equal to that of one motor having a number of poles equal to the *difference* between the numbers of poles in the two motors.

The "cascade" method of control is quite expensive to install, as a double motor investment is required owing to the fact that either one motor alone is in use or else the two motors are working at greatly reduced capacity.

For the control of high-resistance squirrel-cage motors in which the speed is regulated by varying the primary voltage, a controller of the type shown in Fig. 12 is used in connection with an autotransformer. There are twice as many contact segments as there are autotransformer taps, and every other segment is connected to a resistance in such a way that the controller brush in passing from one autotransformer connection to the next one, never rests upon two segments connected to different taps at the same time, but always bridges one "live" segment and one resistance segment in such a way that there is always a dead resistance in circuit while taps of different voltage are connected. This obviates the necessity of "killing" the motor while passing from one segment to another.

FIG. 11. CONNECTIONS FOR "CASCADE" CONTROL

LETTERS

Line Disturbance by an Induction Motor

In a recent number, Louis J. Gorilla asks why an induction motor makes the lamps flicker. I will cite an experience that may help him.

I am operating a 150-horsepower induction motor equipped with a starting resistance mounted on the rotor. I was troubled with a brush eating into the short-circuiting ring, and upon taking the bolt out I found that it was loose where it screwed into the rotor; it was also a loose fit in the spool. The bolt was wrapped with shellacked paper to fit the spool and screwed firmly into the rotor, and the machine has been running two years without giving any more trouble.

Tustin, Cal. W. N. GULICK.

FIG. 12. CONTACT PLATE FOR AUTOTRANSFORMER CONTROL

While removing a broken set screw, it was nearly drilled out, when the drill refused to cut. Applying more pressure and sharpening the drill did not help matters. The puzzle was solved when the point of the set screw was found on the end of the drill, with which it was revolving.

Gas Power Department

Everything worth while in the gas engine and producer industry will be treated here in a way that can be of use to practical men

Reducing Motion for Gas Engine Indicators

By Robert G. Brown

The attempt to apply to a gas engine of the inclosed type an indicator reducing motion usually develops several difficulties. To convert the rotary motion of the flywheel and shaft into a reciprocating motion corresponding to the movement of the piston and of a length that will give a good indicator diagram, generally requires a crank and connecting rod of a small scale but of the same ratio as those of the main engine. Such an apparatus has several joints which are subject to wear and lost motion; and if the engine is a large one a special arrangement will probably have to be attached to the outside of the flywheel to carry this gear. The custom of using a pin in the end of the shaft to which is attached the indicator cord is inaccurate mechanically and is not easy to connect to when running at 300 revolutions or over.

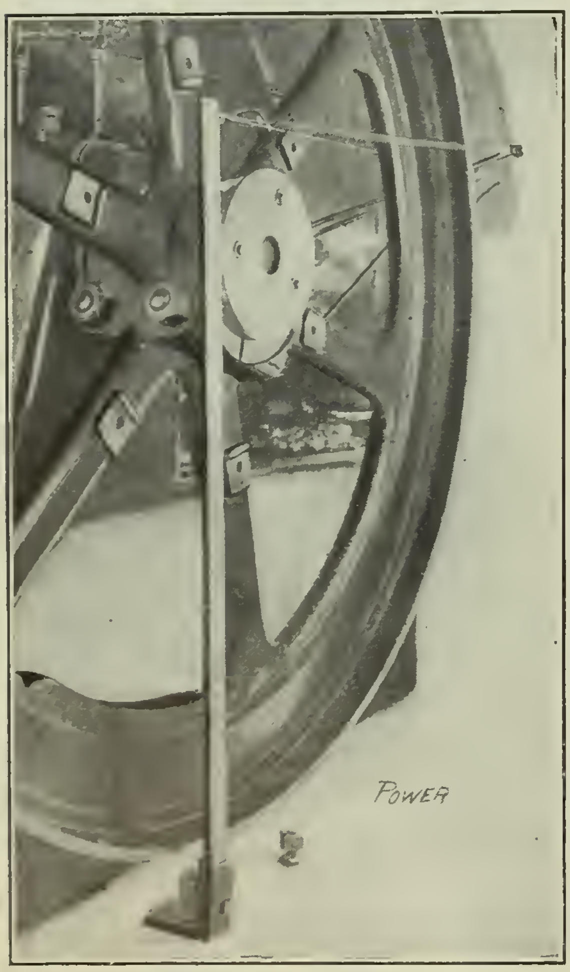

Fig. 1. Eccentric and Oscillating Bar

In the effort to overcome the difficulties mentioned, the cam reducing motion here illustrated was designed. The cam is most simple to make—only requiring a simple turning operation in a lathe. It is attached with two or three cap screws to the end of the shaft or the hub of the flywheel. In some cases it may be necessary to bore it large and slip it over the shaft.

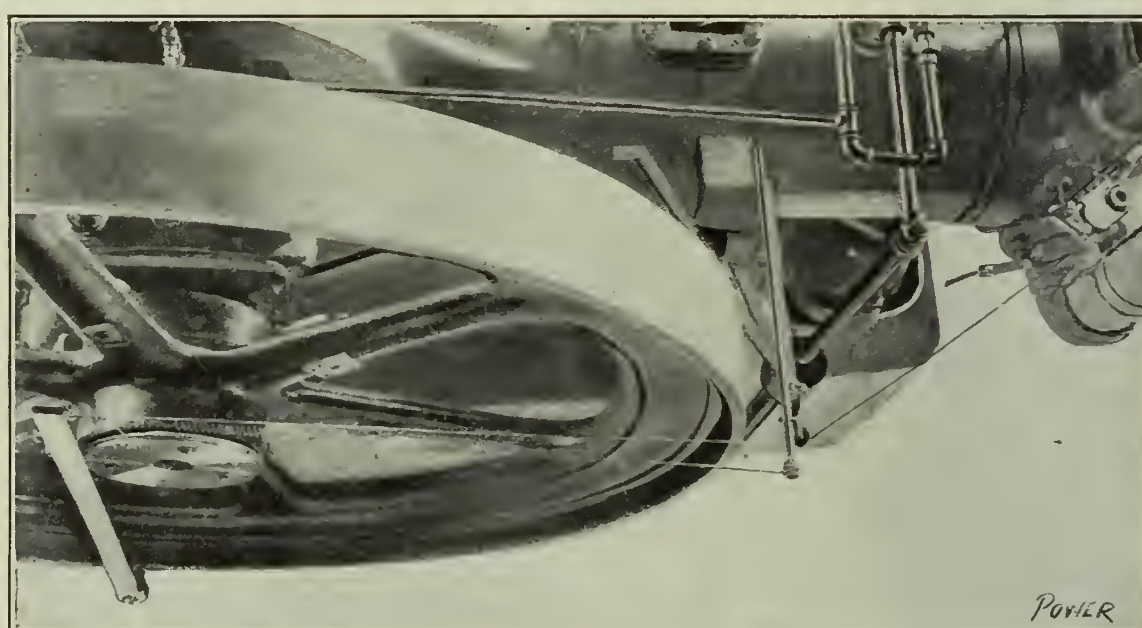

Fig. 2. Looking Down on Engine Equipped with Reducing Motion

Fig. 1 shows a reducing motion of this kind applied to a Fairbanks-Morse Type L producer-gas engine. The flywheel is six feet in diameter. The cam plate bolted to the hub of the flywheel, and a cherrywood bar, hinged to a floor bolt, constitute all the parts. The cam has a V-shaped groove around its edge and a roller on the wooden bar runs in this groove. Unfortunately the indicator could not be shown from the viewpoint of Fig. 1. Fig. 2 is a view looking down on the engine and this shows the location of the indicator at the engine cylinder. The guide pulley for the lead is supported by a tripod of light metal bars.

The indicator lead should be of wire for such a length, and sharp turns should be avoided. The wire should not be carried around the small pulley and drum of the indicator, because it will soon break; a short piece of cord is attached to the end of the wire for this purpose. The wire must run in a direction at right angles to the wooden bar when the latter is midway of its travel. The lead can be hooked and unhooked in any convenient way, to suit the ideas of the operator. The coil spring attached to the end of the bar serves to make the bar follow the cam, thereby relieving the indicator drum spring of this work; on engines which run at less than 200 revolutions per minute, this spring will not be necessary.

A suitable length of diagram can be had by attaching to different places on the bar. The cam itself gives a perfectly accurate motion, but the use of the oscillating bar introduces a slight theoretical error. However, by making it as long and light as possible, the error cannot be detected.

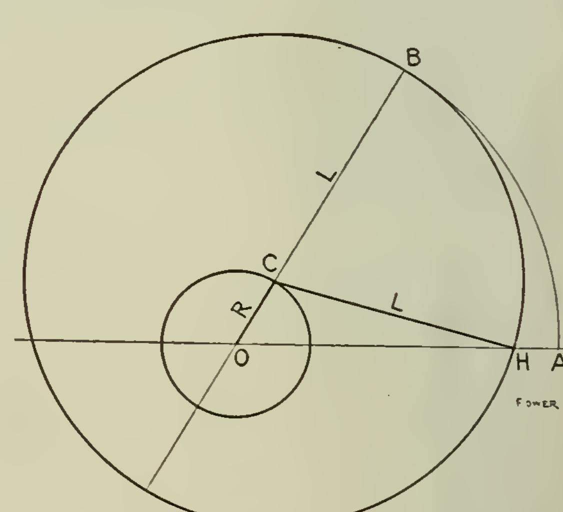

Fig. 3. Graphical Proof

The correctness of the cam motion can be proved mathematically, but the graphical one given in Fig. 3 is sufficient. The lines *R* and *L* represent to scale the lengths and positions of the crank and connecting rod of the engine; L also represents, to a different scale, the radius of the cam circle. The center of the shaft is at O and C is the center of the cam disk, $O\,C$ being the amount the cam is set eccentric. Since C is the center of the cam circle, $C\,H = C\,B$ and $B\,O = O\,A$. Therefore, when the cam and the crank have moved through any angle, such as $B\,O\,H$, the roller has traveled the distance $A\,H$, which is evidently proportional to the motion of the engine piston. The curve $B\,A$ is the path followed by the point B during the travel from B to A.

In laying out the cam for a reducing motion of this kind for a given engine, all that is necessary is to find the ratio of crank to connecting-rod length for that engine. For example, if this is 1 to 5, the cam may be made 5 inches radius and its center set 1 inch off the center of the shaft in line with the crank axis; then it will give the correct motion and the length of the indicator card may be chosen as explained above.

Gas Engine Equipment

By H. W. Jones

As my whole interest in the gas-engine industry is to improve the standing and applicability of the engine, I feel free to discuss the above topic without being accused of "knocking."

I wish to suggest, not alone on the basis of my own experience but on that of others, that it is about time to consider the difference between the cost and the value of the auxiliary equipment of gas engines and, further, to consider what it really should mean when a gas or gasolene engine is installed *complete*. From my price book, which gives the cost of various makes of gas engines, I find that an engine of 20 horsepower can be sold "complete" at a fair profit for $650, and the same engine can also be sold "complete" for $750, keeping the profit exactly the same, the difference in the cost being $100. It all depends on what "complete" means. With some builders the selling price includes a set of engineer's oil cans, also a full set of wrenches, foundation bolts and special washers, an ignition battery, spark coil and switch.

Now, the price of these extras and auxiliaries may be $2.50, or it may be $22.50, and the $22.50 outfit may be the cheaper. The cutoff switch in the ignition circuit may cost $1.80 per dozen or $1.80 each; a set of six battery cells can cost $1.50 or $18; a spark coil for a make-and-break system can cost 50 cents or $3, while the coil of a jump-spark system can be bought for either $2 or $10, or almost any intermediate figure. Some jump-spark coils are very expensive at $4, while others are cheap at $14.

When a man buys a gas engine he seldom considers or knows anything about these points. He may be a master mechanic of the very top grade and yet not realize the value of a switch that changes the direction of current flow across the igniter points. Although he knows full well that experience is valuable, he will not pay cash for it as embodied in gas-engine accessories, but will buy it by shutdowns, engine troubles, experts, repair bills, etc., and probably wind up by damning the gas engine, wholesale. I have seen a three days' shutdown caused by a defective igniter that caused a loss of $300, and the user of the engine utilized all of the modern profanity in abusing gas power when his trouble was due entirely to his efforts to buy *cheap*.

The difference between cost and value is of more far-reaching importance and more promptly manifested in the equipment of a gas engine than in any other thing I know of. Simplicity is very desirable, but do not overdo it.

When you buy a gas engine, insist on having everything on that engine that will add to its effectiveness and reliability of operation, and, further, insist that every attachment, auxiliary and appliance be of the best quality that is obtainable. Do not let anyone try to talk you out of it by the simplicity game; if you do, you lose.

Remedy for Lap Seam Boiler Explosions

By the Oil Drummer

Riley laid down his kit of tools, oiled up the flue expander and asked Kelly, the engineer, if he had read the details of the Pittsfield explosion. Kelly replied he had been so busy keeping track of the lap-seam explosions that he hadn't time to follow the others.

Then Riley remarked that the Pittsfield affair was due to a "lap-seam engineer" screwing down the safety valve, which resulted in killing nineteen men, not counting the engineer himself. The engineer, he said, had got a bath-tub expert to test his steam gage. Kelly retorted by reading the account of nine men being killed by failure of headers on a boiler in the battleship "Delaware" and laid the blame on boilermakers for this and the lap-seam explosions.

Riley grinned, and said, "Even so, the lap-seam engineers have beat the record as agin the lap-seam biler," and mentioned the explosion on the gunboat "Bennington" in 1905, when sixty men were killed. Kelly offset this with the Brockton explosion wherein fifty-eight persons were killed by a lap-seam boiler.

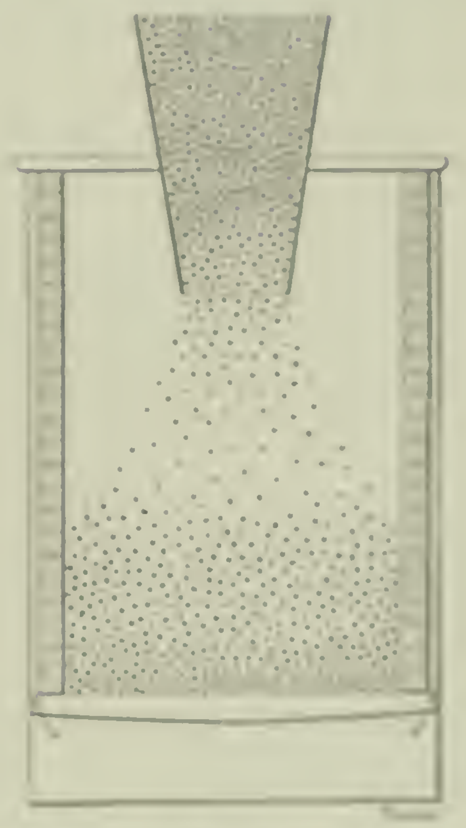
The "old man" blew in at this stage of the argument and settled it by saying that he was figuring on throwing out the steam plant and putting in a gas engine, as he could not take chances on lap-seam boilermakers and lap-seam engineers too.

Honest, do you blame him, the way things are going?

Generator Linings

By C. R. McGahey

A good deal of trouble may be caused by an improperly installed generator lining. If the firebrick is set hard against the metal shell, this is likely to cause trouble because it allows no room for expansion of the brick. Under such conditions it is only a matter of a short time when the brick will begin to crumble and



Air Space behind the Lining

crack, allowing air to pass up through the lining instead of going up through the fire zone. This reduces the capacity and efficiency of the whole equipment. On the other hand, if the brick is not set tightly against the shell, provision must be made to keep the air from passing up between the brick and the shell, as indicated by the arrows in the sketch.

In putting in the lining it is a good plan to allow about 1½ inches of space between the shell and the brick and, as the brick is being put in, to fill this space with asbestos or magnesia. This latter portion should be well tamped in between the brick and the shell. This not only forms a cushion for the expansion of the brick but serves as a packing to prevent the flow of air up behind the brick lining. A lining put in with a backing of this kind will last many times longer than one put in without it, and make the generator more uniform in its operation.

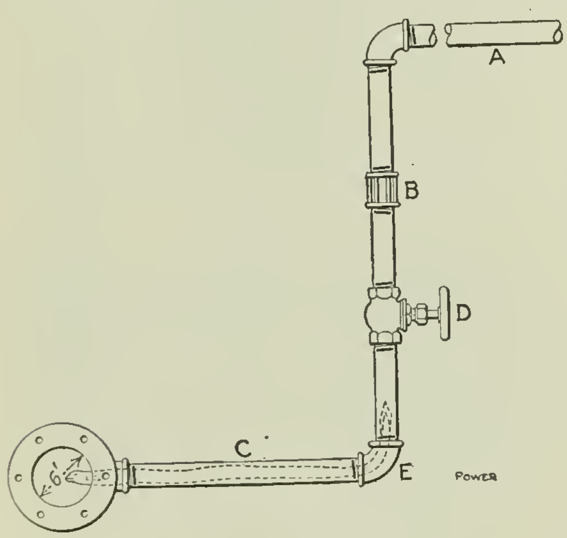
Eel in Water Pipe

One summer evening, about a half hour before it was time to start up and put on the lights, the telephone in the engine room rang. I answered the call and was informed that there was no hot or cold water in the kitchen. This was in an industrial school for boys, and I was the only engineer on duty, as the chief was off and my alternate was home. A relief took my place in the engine room until I could locate the trouble and, if possible, remedy it. I tried all the faucets about the kitchen, and the valves in the cellar, but there was no water. It was evident that there was an obstruction in the pipe somewhere and to locate it was the difficult part of the task.



Eel in Water Pipe

The main 6-inch pipe, which was under the cellar floor, was tapped for a 2-inch pipe to supply the part of the building in which the kitchen was located, and this pipe was fastened to the stringers in the cellar. As this pipe was about 80 feet long, it would be a big job to take it all down to look for the stoppage.

Finally a scheme presented itself to locate the cause of the trouble without taking down the pipe. I got a breast drill, a 1/8-inch drill, some wire nails of a size to fit snugly in the 1/8-inch hole, that was drilled at *A* in the illustration, but there was no water. One of the nails was driven in the hole about one-half inch and cut off with the pliers. This operation was repeated several times, until the stop valve at *D* was reached. It was then plain that the trouble was between the stop valve and the main.

As the chief had arrived, he suggested drilling a hole at *C*; this was done, and when the drill went through the pipe, I felt something soft and springy and said, "It's an eel." The main 6-inch valve that controlled that section of the building was closed and the 2-inch pipe cut at *B* and unscrewed at the ell *E*. The eel's tail stuck out of pipe *C* several inches and, putting a wire through the tail of the eel, it was pulled out.

A union was put in at *B* and the line connected again. A 3-foot eel was brought to the engine room alive in a pail, and when skinned and cleaned made a good breakfast for three men.

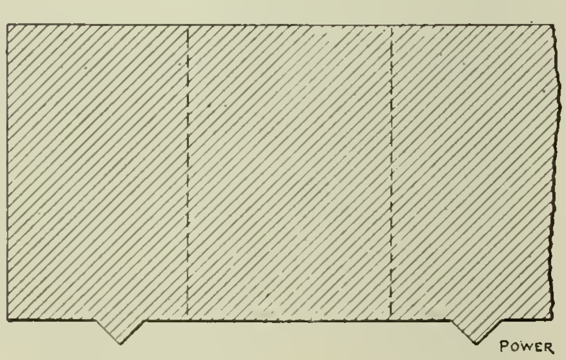
Repairing a Pump Seat

This work consisted in reseating the brass delivery deck of a four-valve air pump, of which the cast-iron valve seat had been partially eaten away by the action of salt water.

It was decided to make repairs with lead as the old seat formed a part of the main housing.

First, the delivery-valve deck was put in a lathe and faced up, both on the valve and under side, leaving a 1/4-inch V-shaped ridge on the bearing surface on each side of the stud holes, as shown in the accompanying sketch. The idea was to embed the ridges in the lead seat, this method being considered better calculated to give a proper joint, and also to dispense with the use of a gasket. The lead surfacing was about 3/8 inch thick.



How Valve Seat was Faced

Indicator Cord Adjusting Device

Among the many tedious tasks connected with rigging up an indicator none is as bothersome, takes as much time and tries the engineer's patience as much as the adjustment of the length of the indicator cord.

In all cases where the stroke of the piston is longer than the motion of the indicator drum some device is needed to produce a motion within the limits of the indicator drum which is parallel to and in proportion to the travel of the crosshead at all points of the stroke. To accomplish this numerous devices are used and each has its advocates.

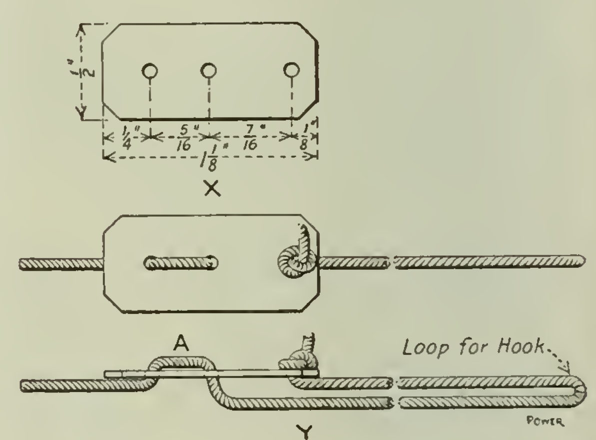

Fig. 1. Sheet Brass Plate

The most common are the pantograph and the reducing wheel, which is considered a part of the indicator outfit. But no matter what device is used the first requirement in taking a card is to see that the drum shall not knock at either end of its stroke. This latter requirement depends entirely upon the length of the indicator cord and demands that it shall be in full tension at all points of the stroke. A cord at its crosshead end is generally fastened to a hook and this hook is simply knotted, a slip knot or bowline being the most satisfactory. In nine cases out of ten when the first adjustment is tried the drum will knock at one end of its motion. Then the knot must be untied and retied a number of times before and during the time of taking a set of cards. All this demands valuable time and in reality is quite unnecessary if the device described herewith is used.

Take a piece of sheet brass not less than 3/64 inch in thickness and cut it to the size shown at *X*, Fig. 1. File off the corners and drill the holes on the center line as indicated. These holes should be just large enough to allow the cord to pass through freely. Be sure to file all around so that no sharp corners or edges are left to cut or scratch the hands. Be sure also to have the holes smooth so that the cord passing through them will not be cut when the string is in tension. This is best done with a very fine strip of emery cloth. Pass the indicator cord through the holes as shown by Y, using a plain knot at the end to prevent it from coming out.

When the cord is disengaged it is an easy matter to slide the plate back and forth by pulling the cord slightly at A in the direction desired, but when the loop and cord are in tension it will not move. If it is desired to move out the end of the loop on which the cord is attached a distance of $\frac{1}{4}$ inch, slacken the cord and move the plate $\frac{1}{8}$ inch toward the hook. If the hook is to be brought further back, slide the plate back twice the required distance in the same manner. In this way it is an easy matter to make a fine adjustment in a few seconds without touching a knot. The size of the plate shown is right for a reducing-wheel cord, but for regular indicator cord increase all dimensions about 50 per cent.

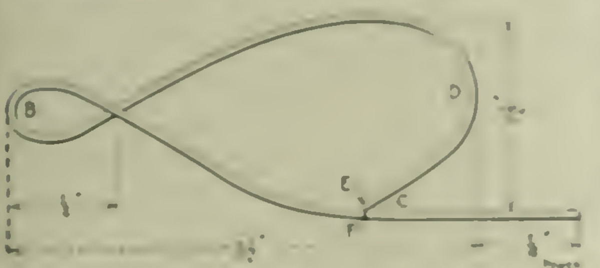

FIG. 2. BRASS-WIRE HOOK

Plates like these are supplied with some indicator outfits and are usually nickel plated, but engineers who do not have them can readily make them in a very short time.

In cases where a reducing wheel is used and the end of the cord is hooked directly to a rod (about $\frac{1}{4}$ inch in diameter and not more than 8 inches long) screwed into the crosshead, and where the stroke is not over 48 inches and the speed not more than 100 revolutions per minute, a very good hook to use at the end of the cord is shown in Fig. 2. It is made out of brass wire of about No. 10 Brown & Sharpe gage and is attached to the loop of the cord at B.

To hook on, hold the hook so that it will be about 2 inches back of the rod when it is at the cylinder end of the stroke, and in line with the travel of the rod; then gradually move it toward the rod until it is in such a position that it will strike the hook at C and then slip in between E and F and rest in D, thus carrying the hook along. To unhook, stand about one foot back of the hook when it is at the cylinder end of the stroke and, facing the crank pin, put the hand nearest the piston rod around the moving cord, but not touching it. Then gradually move the hand toward the crank until the end of the hook is felt at each stroke. Then close the hand around the cord in back of the hook, but do not grip the cord, and with the fingers of the other hand quickly pull the hook off the rod in a direction *away* from the crosshead in a line parallel to the rod. Be sure to do this when the crosshead is as near the cylinder as it is possible to determine. Thus, the second hand will slip the hook off the rod and the first hand will prevent it from flying back and allow the indicator to come back hard with a sudden knock.

Before hooking in it is a simple matter to hold the hook up to the cylinder end of the travel of the rod and then up to the crank end without engaging it to see if the length of the cord is properly adjusted so that the indicator drum will not knock at either end of its motion.

To one who has never tried this method it is advisable to practice when the engine is starting up or stopping, when it is running very slowly, before making experiments when the engine is running at full speed. Three or four trials are quite enough to get the knack of hooking in and out.

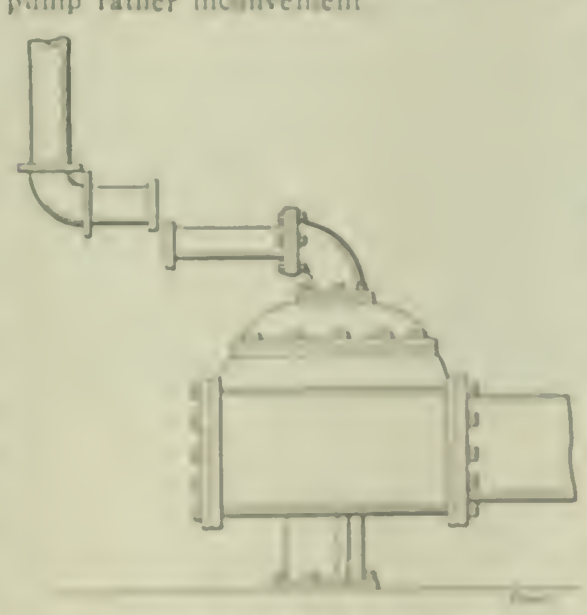
Difficult Pipe Fitting

One time when pumping out a mine the manager decided to use a horizontal steam pump that was on hand. The volume of water to be pumped was large and if the pump were shut down for a few minutes the water accumulated very fast, which made the handling of this pump rather inconvenient.



DISCHARGE PIPE OUT OF LINE

Each time the pump was lowered a platform had to be set up on the next landing. Once when the pump was changed the connections on the discharge pipe came together as shown in the accompanying illustration. As the pipe could not be lowered and there was not time to cut a new one, one end of the pump was blocked up and the pipe sprung together.

On moving the pump again, arrangements were made to place the coupling in the vertical pipe. This gave a better chance to make connections in case the pipes did not come together when the pump was moved to a lower level.

There was never any time to spare when shifting this pump, and on one occasion a new piece of pipe was lowered into the mine with the union on the wrong end. As tools were not at hand to change the union, the pipe had to be sent to the surface to be turned around, and by the time the connection was made the pump was submerged.

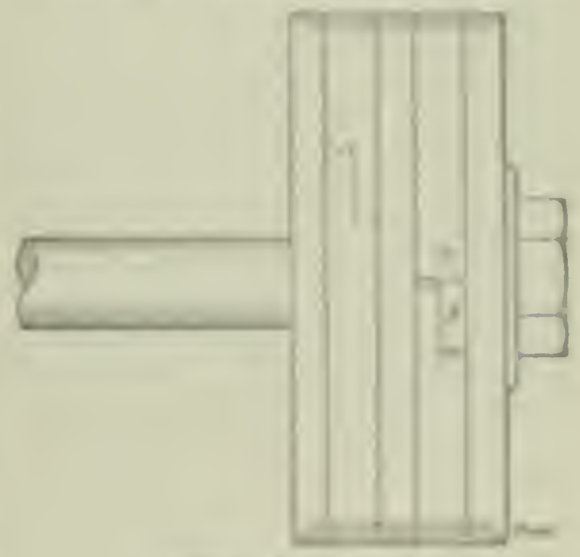
Higley, Ariz.

Broken Piston Ring

One of several large Corliss engines had behaved beautifully for several years, and everything was in good order so far as those interested knew. Then, all at once, the engine began pounding. The braces were sprung and everywhere that anything could possibly budge was strained. An examination indicated that the trouble was internal.



PISTON AND RING

After taking off the cylinder head, an attempt was made to turn the engine over. The piston moved easily through most of the cylinder, but when it approached the head end where the diameter was slightly less, the piston got tighter and tighter until the aid of jacks was necessary to force the piston over to the counterbore. Drawing the piston from the cylinder until the first packing ring showed, the cause of all the trouble came to view.

The accompanying sketch shows the slotted end A of the packing ring, and the line B indicates where this end had broken off. The break was an old one and the continual movement of the small piece of metal, confined in the small cavity, had worn one of its ends wedge-shaped. Finally this wedge slipped under the end of the ring, expanding it at the limit and preventing any contraction. The result was that the piston filled the largest cylinder area and was made a driving fit in the smaller area where less wear had taken place.

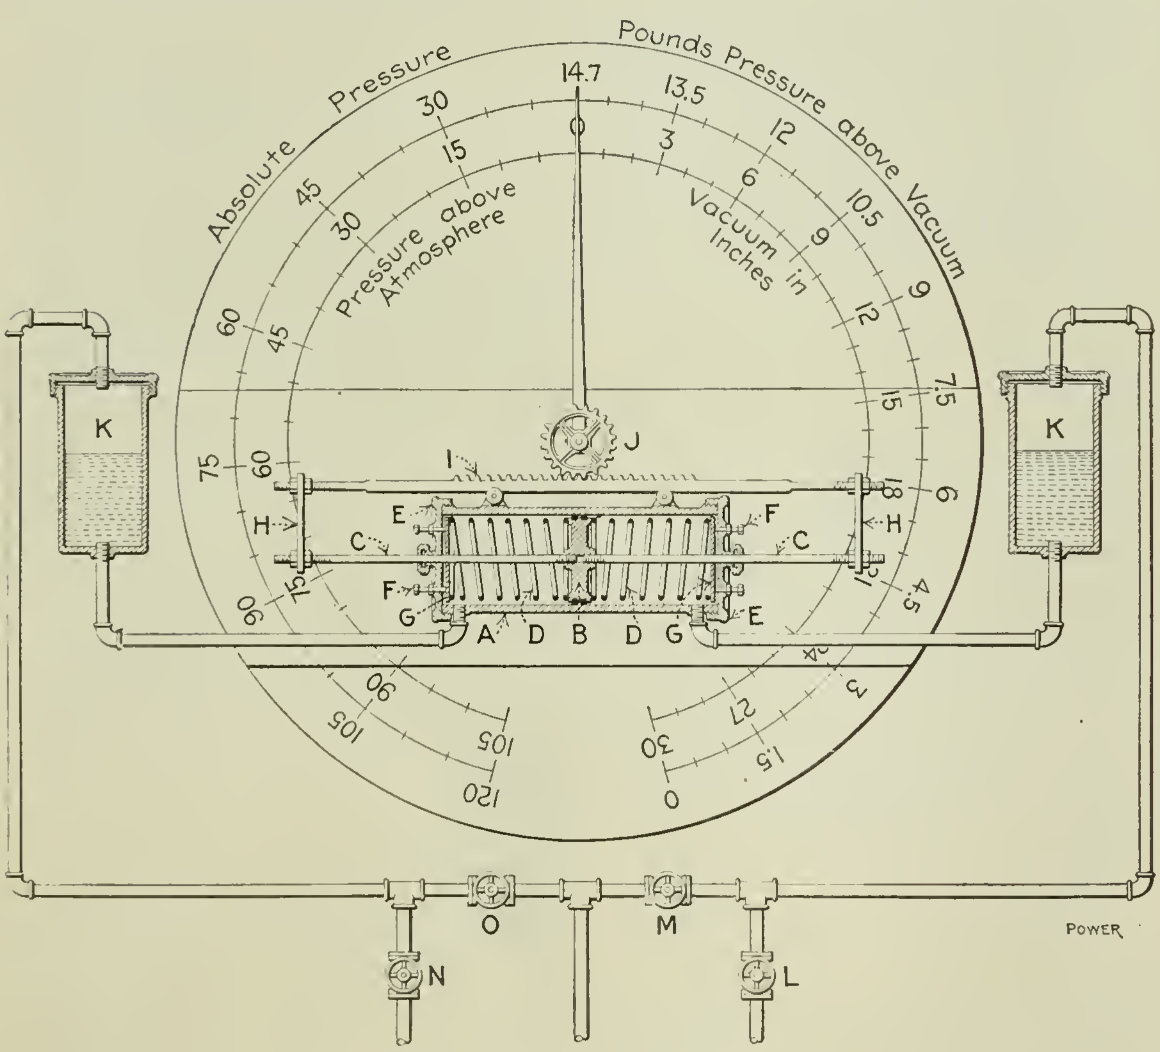
Combination Pressure and Vacuum Gage

Following is a description of a combination pressure and vacuum gage: It consists of a brass cylinder *A*, piston *B*, two piston rods *C*, two spring of different tensions *D* and two cylinder heads *E*. Each cylinder head has four holes for the screws *F* of a very fine thread to prevent leakage which, when screwed in or out, moves the two plates *G* and thus adjusts the tension of the springs. The piston rods are connected by two short rods *H* to a flat, brass gear rack *I*, and the gear engages with the gear wheel *J* to which the pointer is connected. The two drums *K* are to prevent the oil from flowing away.

This gage shows the absolute pressure when connecting the pipe *N* to the live-steam main and the pipe *L* to the exhaust steam. Closing the valve *L* and opening the valve *M* to the atmosphere the gage will register the live-steam pressure, and by closing the valve *N* and opening the valve *O* it will register the exhaust-steam pressure. With condensing engines it is only necessary to connect the pipe *L* to the condenser and the gage will show the mean effective pressure, live-steam pressure and vacuum. If used as a vacuum gage alone, connect the pipe *N* to the vacuum and open the valve *M* to the atmosphere. The pointer will then show the vacuum in inches and pounds pressure above a vacuum.



Details of Combination Gage

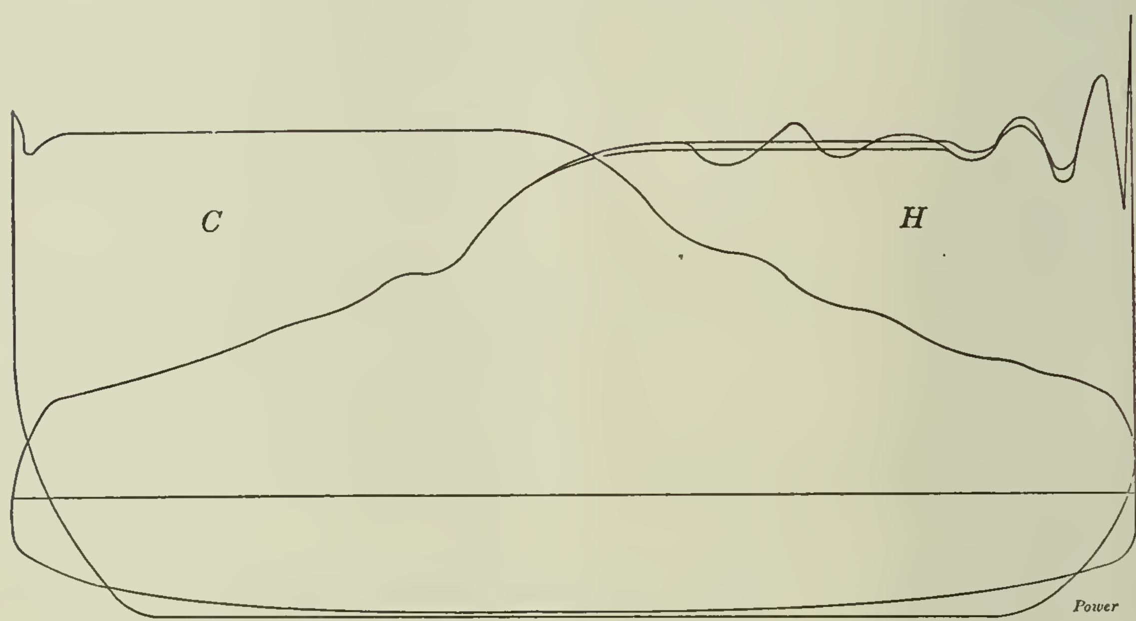
Indicator Diagram Defects

The indicator diagram shown herewith was taken from the low-pressure cylinder of a Porter-Allen engine, and diagrams taken from three other engines of the same type show the same lines. These engines are all run compounded in the summer season only. The low-pressure cylinders are disconnected and the engines are run simple for the sake of exhaust-steam heating during cold weather.

The irregularity of the diagram at the point of admission has puzzled the engineer in charge, particularly as several different indicators have been used on these engines.

The speed of each is 157 revolutions per minute and the initial steam pressure in the 24x30-inch low-pressure cylinder is 30 pounds. A vacuum of 21½ inches is maintained. Why do not the same defects show on both ends of the diagrams?



Why Are Not Both Diagrams the Same?

Philadelphia, Penn.

Disposing of Back Numbers

This seems to be an opportune time to say a few words in regard to disposing of the technical magazines of 1910. Some engineers allow them to accumulate until they are in the way, and then destroy them. Others clip such portions as are of special interest, and destroy the remainder.

These methods are a more or less shameful waste of valuable literature. I have had POWER for 1909 bound in two volumes, by a local bindery, and I am going to have the numbers for 1910 bound in the same way.

To prepare the paper for the bindery, I remove the advertising matter, retaining the editorial page in the front and the page entitled "Moments with the Ad Editor," at the back of the paper, also the pins.

Several engineers with whom I have discussed the subject, and who formerly destroyed their papers, are having them bound. To some this may seem expensive but I think it pays, for in these papers we have accounts of interesting experiments and tests, letters from practical men who give us the benefit of their experience in getting out of difficulty and relate all kinds of stunts and kinks, some one of which may just fit an individual case.

Inquiries of general interest, with answers, are always instructive, also many illustrations of new things for the power plant, and valuable information relating to their construction and operation. This subject as a whole comprises a reference library which can be obtained in no other way, and which, if properly bound, makes a pleasing addition to any engineer's bookcase.

Greenfield, Mass.

Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

Leakage through a Piston Valve

In the issue of November 29, Mr. Allen's criticism of Mr. Mitchell's article dealing with the matter of leakage through a piston valve is interesting.

For some time it was quite the fashion to discredit this type of valve. But now, thanks to the experiments of Messrs. Callendar and Nicolson, and to the subsequent efforts of designers and makers of this valve, it has quite rehabilitated itself and it is remarkable that the world's records for economy on two different types of engines were obtained with this valve.

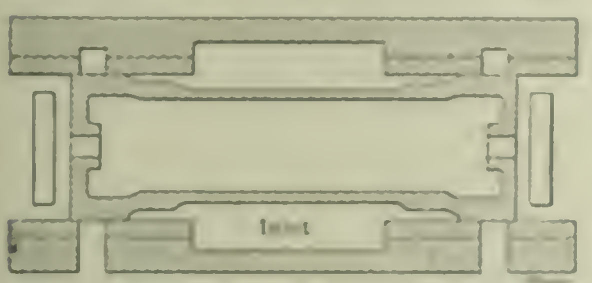

FIG. 1. DIAGRAM OF ORIGINAL VALVE

Mr. Allen's remarks on the advantages of the piston valve are quite in agreement with the experience of makers in England, and, as indicated above, there are some who are prepared to go further than he on the matter of economy if the valve be used with superheated steam.

In Mr. Mitchell's description of his experiments he stated that many schemes have been devised for measuring the amount of the leakage, but in general they are crude and for many reasons the results cannot be regarded as accurate; he then mentions the most important defect common to all of them and straightway embodies it in his scheme.

Had he read the literature on this subject he would have come across Messrs. Callander and Nicolson's experiments and would have seen how inaccurate his statement is, and the study of the subject might have been benefited by his attempting to improve upon the methods of these experimenters.

That there is a great difference between the leakage of a valve or piston when standing and when running seems to be quite understood, yet the first tests were taken with the valve and piston moving, and in order to separate the leakage of the piston from that of the valve the tests were taken with the piston standing.

The fit of the valve when it was tested was stated to be perfect; if this were so, then a great opportunity for taking a valuable test has been neglected; however, what was this fit? Was the clearance measured in ten-thousandths or in thousandths of an inch? Or, was steam turned on and found not to leak past the valve when it was standing?

The fit of the piston was not stated; if it had been an ordinary commercial fit then, when standing, steam would not have leaked past it; the fact that it did leak when standing showed that it was not a good fit. It is improbable that the tests would have been taken had the experimenter considered that this was not a good fit, so possibly his idea of a perfect fit was little better, and the extraordinary amount of leakage is explained.

It is difficult to see why it was decided to have a special valve for these tests;

FIG. 2. SAME VALVE WITH SOLID LINER AT ONE END

the preparations would have been much cheaper and the tests carried out much more accurately and expeditiously if the arrangement shown in the accompanying figures had been adopted.

This arrangement obviates the plugging up of any port, which is a very desirable feature, as it was stated that the plugging up of the cylinder port was not successful and it is probable that the plugging up of the exhaust port from the valve was equally unsuccessful, but in this instance unnoticed.

Fig. 1 shows the original valve and its liners. During the tests this valve was replaced by one which admitted steam to the head end of the cylinder only, and the exhaust port at the crank end was plugged up.

Fig. 2 shows the original valve and one original liner, the other liner being new and without ports so that steam cannot get from it either into the cylinder or into the exhaust pipe; the liner in the head end is easily replaced without dismantling the cylinder and the new liner should be inexpensive.

A pipe can be led from a hole in the head-end valve cover to the condenser and so all the leakage from that end of the valve can be measured; another pipe could be led from the relief-valve hole in the head end of the cylinder to another condenser and so the leakage from the piston measured.

It is seen that with this arrangement it is possible to take very accurate tests of the valve and of the piston leakage separately and simultaneously, and it is hoped that Mr. Mitchell, or anyone who is able to, will use this idea or an improvement on it and repeat the experiments.

If experiments could be made with various types of valves, the results would be most interesting and valuable. When making the tests it should be kept firmly in mind that one assumption vitiates the whole of the test, and that the full data of the tests should be published.

A. VINCENT CLARKE.

Gainsborough, Eng.

Washing Boilers Externally

A correspondent in the December 27 issue inquires as to the advisability of washing the fire surface of the boilers under his charge.

With one battery of boilers I did this for several years with no ill effects. The external washing was done, of course, only when the boiler was down for cleaning and, as the correspondent says, there was heat enough to dry off the surfaces.

I cannot say that I advise external washing, though, for the conditions vary so much; because it proved to be all right in one case does not insure it to be so in all cases.

Filling a boiler with cold water after cleaning is something I much dislike to do, on account of the severe contraction strains set up and the corrosive effect of the oxygen that water gives; the temperature of the water does not need to be high to prevent this; 140 degrees or more will do.

J. O. BENEFIEL.

Anderson, Ind.

Setting Us Straight

Method of Banking Fires

Regarding the question under the above caption in the December 20 issue, M. B. F. makes no explanation as to how thick the grates are covered with fuel or the method employed regarding the fuel on the grates.

Closing all doors and dampers is, of course, right, but in addition the fires should not be left on the grate bars or given an ordinary covering of coal. The proper method of banking fires is to push back the fuel from the front of the grate and then cover the live fuel on the rear of the grate with fresh coal to a depth of not less than 3 inches. Closing all drafts will result in finding the fuel ready for work the following morning, when it can be set into active combustion by simply opening the drafts, pulling the fire over the whole grate and adding a little fresh coal.

I would strongly oppose the suggestion of opening the flue doors to overcome any air leak that may be in the damper, because opening the flue doors means that a current of cold air is being continually drawn through the tubes, causing a chilling of the boiler, which is opposed to engineering practice. Furthermore, flue doors are seldom any too secure or tight and if they are opened at night the chances are that they will leak in the day time. Any plant operating with natural-draft conditions will be subjected to an intake of air at any leaky flue door, greatly to the detriment of the economy of steam production and also to the welfare of the boiler. M. B. F. will do well to leave his flue doors closed both day and night and to see that there are no leaks at that point. On the other hand, he should study the matter of leaving a part of the grate surface exposed, covering the fire a little heavier on the rear end as suggested above.

Steam for Preventing Clinkers

In the December 13 issue the following inquiry and answer are given:

"I have been told that a jet of steam under the grates will prevent the formation of clinkers. Is this true, and is it an economical practice?

"S. P. C.

"Clinkers are caused by the melting and running together of the incombustible in the coal by the heat of the fire. If steam enough is passed through the fire to keep the temperature below the melting point of the ash, clinkers will not form. It is certain that there is no economy in using steam to reduce the temperature of the fire under the boiler which makes the steam."

It is very evident that the answer given was hastily and thoughtlessly furnished, as it is entirely misleading and a very incorrect opinion might be formed by anyone reading it who is not thoroughly conversant with the subject.

What are the facts? Strictly speaking, ash does not melt at all. Clinkers are caused by the fusing of certain elements in the fuel; these elements may be sand, silicate, sulphur, etc.

In coal, the formation of clinker shows different characteristics; in some cases the clinker is very easily broken up and is not in any sense of the word a detriment; in others, it fuses and becomes a part of any firebrick with which it comes in contact and cannot be broken off except at the expense of the firebrick to which it adheres; in still other instances, clinker is so serious a trouble as to compel a cessation of the use of the fuel which produces it.

The detriments of clinker are well known. If the clinker only causes extra labor in the manipulation of the fires, just that excess is a cost. On the other hand, its presence may result in loss of brickwork or loss of active grate surface in the fire.

How, then, is clinker to be prevented? The only successful means of preventing clinker is the use of a steam jet under the grates. In doing this, careful study should be given so that the steam will be uniform under the entire grate surface and yet not of sufficient volume to reduce the temperature of the fire. It is quite unnecessary that the temperature of the fire be materially reduced in order to prevent clinker; in fact, if the temperature were materially reduced by the use of steam jets there would be loss of economy, as the actual steam used and the excess fuel burned would more than offset any cost due to clinker.

How, then, should the steam jet be applied? Its most common and only successful application has been in the form of steam-jet blowers, and it has been the constant aim of the manufacturers of steam-jet blowers to reduce the amount of steam that they use for motive power and reliable manufacturers are now placing on the market blowers which are guaranteed on this particular point.

The use of a steam-jet blower can be for the purpose of increasing the draft or it can be for the purpose of eliminating clinker, or both. I remember very well a certain plant to which my attention was called by an urgent telephone message to the effect that it was impossible to hold steam. On investigating, I found the plant running under natural-draft conditions, although the furnace was equipped with the Parson steam blower. By inserting a slice bar the fuel was shown to be fused together to an extent that rendered the whole one sticky mass, as might be evidenced in a pan of taffy. With the means of a slice bar and a common two-prong hook, I had the fire torn apart and then the steam blower was set in operation. Using the same fuel and with the steam blower in operation, inside of a half hour I had a thoroughly satisfactory fire and the boiler was developing its full requirements of steam and this without objectionable clinker from the fuel.

Such an experience as this, together with hundreds of others of similar conditions which I have personally investigated, would absolutely disprove the statement made in the answer under discussion, that the temperature of the fire must be reduced in order to prevent the formation of clinkers.

By the use of a pyrometer I have found that the amount by which the temperature is reduced when using a proper steam-jet blower is almost negligible, whereas the formation of clinker is eliminated or certainly reduced to a point where it is not objectionable, using fuel which clinkered badly with fan or natural draft.

Again referring to the item under discussion, the statement therein made that "It is certain that there is no economy in using steam to reduce the temperature of the fire under the boiler which makes the steam" is one that would suggest the conclusion that there is no economy in using steam jets or steam blowers.

I can cite hundreds of cases where the use of a steam jet has not materially reduced the temperature of the fire, although it successfully eliminated objectionable clinker; therefore, it is quite unnecessary to say that "There is no economy in using steam to reduce the temperature," because steam is not used in sufficient volume to reduce the temperature nor does it materially reduce the temperature of the fire; in many cases it positively improves it.

Using jets made of ordinary pipe has been common practice, but I would suggest that the steam jet used be supplied by means of a proper form of blower as being the most economical and best method of accomplishing two purposes.

Horsepower and Boilers

Another inquiry in the December 13 issue requested the rating of horizontal tubular boilers with respect to the amount of heating surface. The reply given was to the effect that horizontal tubular boilers were rated on a basis of 10 square feet of heating surface per horsepower.

While it is quite true that makers of horizontal tubular boilers at the present time base their rating on 10 square feet of heating surface per horsepower, claiming this type to be fully as efficient as the water-tube type, it is not true that this is a common rule, and for years back manufacturers of horizontal tubular boilers have established rating on a basis of one to fifteen; then, later, they established a basis of one to twelve.

While it is true that horizontal tubular boilers are capable of high overrate, the inquiry was directed by an engineer who had a boiler already produced and not a boiler which was being made at the present time; I therefore suggest the development of this subject so that the engineer asking the information may be in full possession of the subject rather than being given an answer which he would find flatly contradicated by a very large percentage of operating or professional engineers. The real difference between the efficiency of a water-tube boiler and that of a horizontal tubular boiler lies in the difference in the settings.

CHARLES H. PARSON.

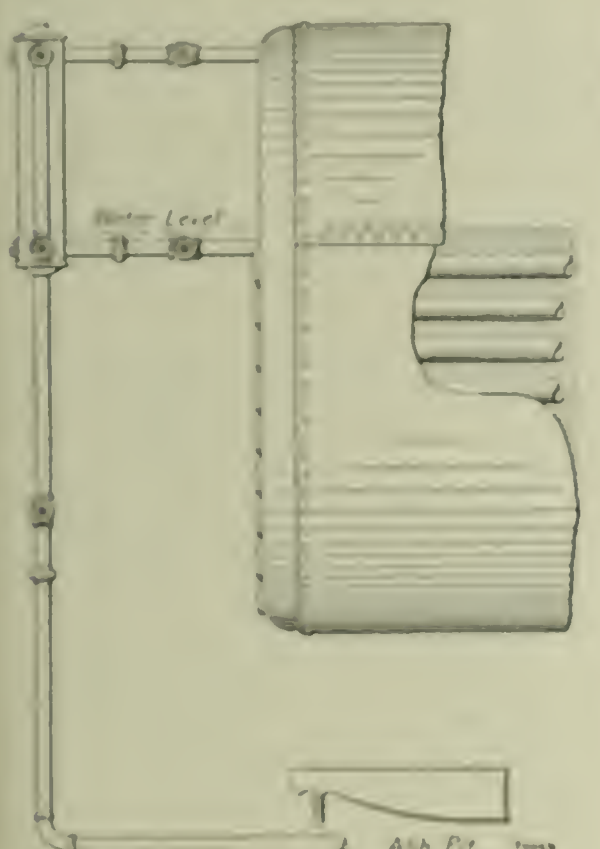
Water Gages

In the December 13 number of POWER Mr. McGahey favors valves in the water-column connections. I think he is right on that point, but his sketch shows a poor way of connecting the column. Also the column is in a bad position in re-



IMPROVED ARRANGEMENT OF WATER-COLUMN PIPING

gard to the water level. I submit the accompanying sketch as showing an improved layout. The sketch is self-explanatory. With the blowoff piping arranged as shown, the column can be blown down with even greater convenience than in the case where the column is arranged as per Mr. McGahey's sketch.

L. JOHNSON.

Exeter, N. H.

If there is anything worse than no water column on a steam boiler, it certainly is one arranged as shown by C. R. McGahey in the December 13 issue of POWER. No doubt a good many readers would like to have Mr. McGahey lay out a front view of his column arrangement, as it probably would enrich their conceptions of the fourth dimension. I have always been under the impression that a gage glass should show the hight of the water *above* the tubes and not *below*. Another thing I consider to be poor engineering is the use of gate valves on columns, where impurities are liable to clog the pipes.

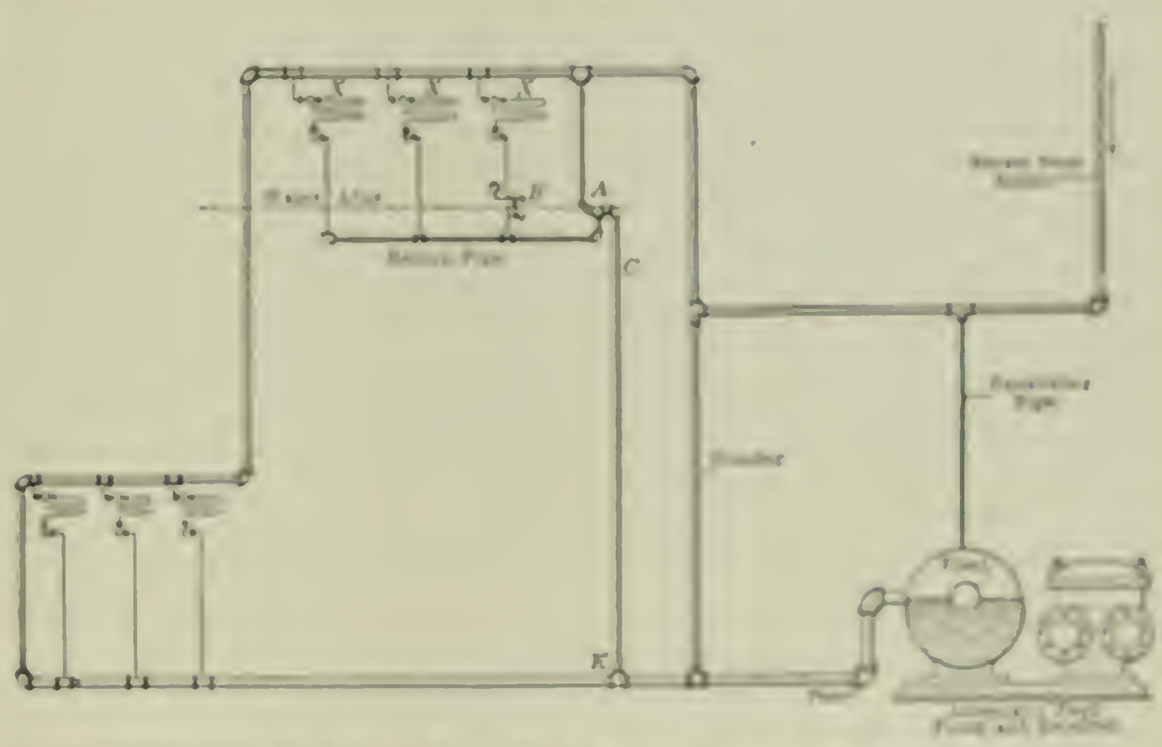
H. F. HAYSOM.

Bridgeport, Conn.

Trouble with a Heating Plant

In regard to Mr. De Saussure's problem, as described under the above heading in the January 10 number, in my opinion the equalizing pipe on top of the receiver tank, if properly connected, serves mainly to facilitate the work of the pump and guard the tank against a vacuum; hence, this equalizing pipe has no effect on the distant group of radiators.

Since he has a seal at *A*, the water line in the returns must be about where the dotted line is; but what causes the seesaw is the steam pipe at *A* running from the main to the seal trap, which "buck"



REPRODUCTION OF FIG. 1, SHOWING ARRANGEMENT OF HEATING SYSTEM

against the regular flow of water from the horizontal return until the water line *A B* is high enough and the pressure in the radiators sufficiently equalized to start a sudden rush of steam and water down *C*, the arrangement at *A* acting as an injector for the time being.

I am not of the opinion that the pressure in *C* ever drops; further, I do not think that the gage is at the proper point to indicate any variations in the pressure in pipe *C*. As soon as the siphon-like action ceases on account of lack of water, the pressure at *B* will be at its lowest, and it will gradually increase as the seal *A* becomes full of water.

I should say that the elimination of pipe *A* from the main to the seal would stop the trouble. Then pipe *C* would have the steady drop in pressure necessary to allow a regular steady flow to the receiver.

ALEX DOLPHIN.

Jamaica, N. Y.

Boiler Explosions

In many of the accounts of boiler explosions I see this statement, "The boiler was being limbered up after being idle for some time" or, "The boiler had not been used for some time." I believe that many boiler explosions have been caused by getting the boilers under pressure too rapidly after they had been idle for a longer or shorter period.

When a boiler has been standing cold for some time, the steam gage is more likely to become stuck than at other times. The spring may not throw the needle accurately.

I noticed in the account of the Pittsfield explosion the statement that the steam gage showed only 35 pounds pressure, while there probably was a pressure of 125 pounds or more on the shell of the boiler.

Once, while running a battery of boilers in a plant in New England, I was getting up steam in Nos. 1, 2 and 3, when I noticed that the gages on Nos. 1 and 3 showed 40 pounds while that on No. 2 showed only 10 pounds pressure. I knew by the fires, water, etc., that the No. 2 gage ought to have shown as much pressure as the others. I gently tapped and shook the gage and the needle came right up to the proper mark.

I believe that in every plant that has only one boiler, the boiler should have two steam gages. Then if one happens to stick there is not one chance in a hundred that the other would register wrong also.

West Cummington, Mass.

Boiler Explosions in Germany

The editorial under the heading "Boiler Explosions in Germany," in POWER for December 20, should make one sit up and think. Why have we so many explosions in this country? There must be something radically wrong. Perhaps there may be a few reasons.

Germany has no coroner handy with the whitewash. The officials whose business it is to investigate such accidents are installed and shielded by the government and all stand on their honor, which is worth more to them than mere dollars and cents. They never bow to the dollar sign. They do their duty no matter whom their action hits. They are sticklers in upholding the law; try to bribe one and see how quick the briber goes to jail. When a boiler explodes, killing one or more persons, the district attorney with a circuit judge goes to the scene.

The attorney and the judge conduct the inquest. Experts are summoned, only such men as hold master certificates and are well qualified, also the inspector who last examined the boiler being eligible.

These men sift the evidence and no one dares to block their efforts. They need fear no political wrath, for all hold their jobs for life, unless promoted, and promotion comes according to ability in enforcing the law. If, in their investigation, they find someone negligent, the blame is placed; it makes no difference who the party is or whether he is of high or low rank. And the blame is often found to be with someone "higher up" that is living (not a dead man or a dying engineer; remember Brockton, Mass.).

The man responsible is then placed under arrest immediately. At the trial he is charged with such a crime as the inquest seems to indicate. He must clear himself if he can; nine times out of ten he cannot. Sentence is pronounced if he is found guilty; the penalty usually is not a fine because this only hurts the pocketbook; generally it is a jail sentence.

If we had some of this in our great and glorious United States, what a blessing it would be! Look through the list of explosions and one cannot help but shudder. How many dead men there are with blame resting on them of which they are innocent! But, dead men tell no tales.

A. RATHMAN.

Chicago, Ill.

Metallic Packing

In answer to the question by W. D. Marquest in the December 13 number concerning metallic packing, I would say that if he will indicate his engine he will probably find there is back pressure at the end of the crank-end stroke which is so high as to produce a pressure on the packing greater than that due to the boiler pressure.

If there were back pressure at the other end of the stroke it would not have any effect on the packing or rod, as the piston would be between the pressure and the packing. I still have the first rod that was used in my engine; it is worn tapered at the crosshead end.

The tension of the springs causes but very slight wear.

W. H. PHELPS.

Ellwood City, Penn.

Does the Crosshead Stop?

I have been reading the arguments on Mr. Fryant's question, "Does the Crosshead Stop?" My opinion was that it did. I wanted to know for sure so I made a wooden cylinder and mounted it beside the engine with its axle parallel with the crosshead. I kept it in motion by a string running around the shaft of the engine, around two spools and then around the cylinder. Then, by placing a piece of paper on the cylinder, fastening a pencil to the crosshead so that the point just touched the paper, I was ready to take a diagram. I turned the engine over once by hand and secured the diagram shown in Fig. 1. This diagram proved beyond a doubt that the crosshead does not stop for, if it did, there would be a straight line at *A* and *B*, Fig. 1. As the ends of the diagram are curves, the crosshead did not stop. I took this diagram from a high-speed automatic engine with a 14-inch stroke.

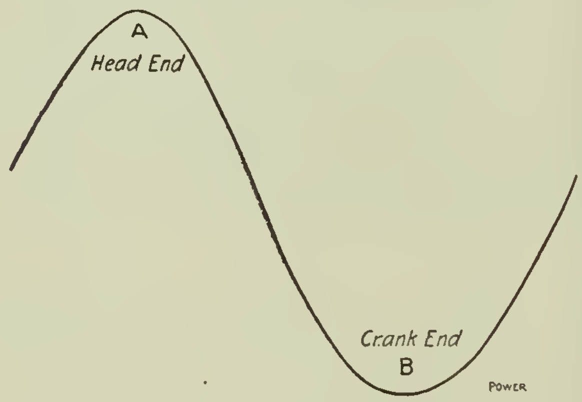

FIG. 1. DIAGRAM OF CROSSHEAD TRAVEL

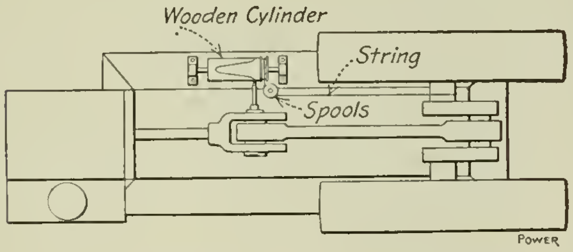

FIG. 2. ARRANGEMENT FOR DRAWING DIAGRAM

The curve at the head end of the diagram is somewhat sharper than that at the crank end on account of the crosshead having a quicker motion during the head-end half of the stroke.

WILLIAM T. KINGSLEY.

Boise, Idaho.

Fusing Temperature of Ash

The discussion by J. V. Hunter in the issue of December 27 of the article on "Fusing Temperature of Ash," which appeared in an earlier issue, is very interesting, and bears out conclusively the contention that the clinkering property of coal bears no relation whatever to the percentage of sulphur in the coal.

All other usual determinations, such as the percentage of iron in the ash, percentage of lime, etc., apparently fail in indicating this characteristic, and the only test which we have found to be consistent is that of determining the fusing temperature of the ash.

Mr. Hunter says that few people are in a position to obtain these data and it is reasonable to suppose that sole reliance must be based upon actual tests conducted in the plant. This is true to a certain extent, for even the proximate analysis of the coal, the B.t.u. determination, the percentage of CO_2 in the flue gas, etc., are only of value when properly interpreted in connection with actual operating conditions. The purpose and value of such tests, however, are that they serve as definite and reliable indications of the suitability of various fuels or conditions for securing the best results in practice.

In the past, the only method of determining the clinkering property of coal has been to burn it, and while it is true that the "proof of the pudding is in the eating thereof," yet it is often very desirable to learn before the pudding is eaten, or the coal burned, whether or not the act is going to result disastrously in either case.

In many of the larger power plants today, capacity is of primary importance. The greatest enemy of capacity, as well as efficiency, is the formation of clinker, and it is certainly very desirable in every possible case to prevent the disastrous procedure of trying out in practice all of the various kinds of coal which may be shipped upon a contract, by providing limitations of the fusing temperature of the ash in the specifications with suitable penalties and premiums, just as are imposed upon variations in the B.t.u., percentage of ash, etc., in many cases today. In other words, the fusing temperature of ash is a short cut to determining before a coal is placed in the furnace, or even before it is delivered to the plant, whether or not it will be suitable, without having to wait until the plant is shut down for lack of steam, due to lack of air with which to burn the coal.

We hear a great deal today about the heat value of coal, and the percentage of CO_2 in the flue gas, but neither can the maximum B.t.u. be developed, nor the best percentage of CO_2 be obtained if the ash forms a clinker which slags over the grate and prevents the flow of air through the fuel bed.

It is true that there is a great variation in the amount of clinker formed in different furnaces, due to the method of handling the fire, and every engineer and fireman should remember that any ash should be kept as cold as possible, thereby preventing undue risk from heating it up to, or far beyond, its fusing temperature. However, under similar conditions, whether they are good or bad, the fusing temperature holds a relation which indicates the comparative values of different coals, and it is comparative quantities that are of value in engineering practice more than absolute or theoretical figures.

Mr. Hunter referred to the practice of mixing coals, and its effect upon the formation of clinker. His conclusions on this are in general correct; in some cases it may be helpful to the more troublesome coal, while, on the other hand, the mixing may cause serious trouble, while either coal burned separately might give satisfactory results.

Mr. Hunter also mentioned the possibility of adding ingredients, such as lime and silica to the ash, in order to eliminate this trouble. This point has already been taken up by W. N. Wing in the November 22 issue of Power and discussed by E. Dixon in the December 27 number. In the case under discussion, Mr. Wing spoke of using oyster shells to remove clinkers from a boiler furnace, and there is no question but that he might have received some benefit from the use of lime in this form, but as to the action of lime, I differ with Mr. Dixon in this connection and do not believe that the lime added lowered the fusing temperature of the ash by fluxing it, but that it increased the fusing temperature of the ash. With a certain composition of ash, lime added, up to a certain percentage, may act as a flux, but as lime itself cannot be fused much below the temperature of the electric arc, it would certainly increase the fusing temperature of any ash if used in sufficient quantity, and this is probably what Mr. Wing did. I have known of other cases where oyster shells have been used in lessening the trouble from clinker. I have also learned that from some mines, coal with a higher percentage of ash due to the admixture of certain kinds of clay and slate which were high in alumina increased the fusing temperature of the ash and lessened the trouble from clinker, and there is a possibility that in the future coal may be treated in order to prevent clinker as feed water is now treated in order to prevent scale. This, however, can only be done by adding other material, the composition of which will depend upon the nature of ash which is already inherent in the coal, and while it may be feasible in the case of coal which has a low percentage of ash, yet where a high percentage of ash exists in the coal a greatly increased percentage of the added material would probably offset any advantage gained thereby.

E. G. Bailey.

Boston, Mass.

Why the Feed Pipes Clog

In regard to Mr. Piper's letter in the January 3 issue under the title, "Why Did the Feed Pipes Clog?" it is my opinion that the trouble is due to iron in the water.

I have had the same trouble. If Mr. Piper will have the water analyzed, he will probably find that it contains iron. This forms a reddish scale.

Peter Elseth.

Crookston, Minn.

Faulty Design and Economic Engineering

In Power for November 22, R. L. Rayburn speaks of the engineers in charge of plants, knowing the plant as no others do, as a reason for not securing the services of a competent consulting engineer. As the general run of chief engineers are usually busily engaged in making necessary repairs and changes, they are left but little time to spend in convincing the management of the necessity of making needed changes or improvement in equipment; while the consulting engineer has little else to do. Moreover, it is well known that a man's personal appearance and standing or reputation has much to do with the consideration given his propositions. Very frequently it is the case that the management does not like to have the engineer become the advisory board. In such cases the consulting engineer can and does play a very useful part, as the engineer can have his plans carried out through the consulting engineer.

A chief engineer in charge of a plant cannot reach the management for an audience until he has risen in their esteem and subsequently in the ranks of men, through his everyday efforts and achievements.

Of course there are consulting engineers and consulting engineers, those of good repute and otherwise. No man would commend the practice of employing a man as chief engineer in charge of plant just because said man had made a failure in some particular plant. I have been wondering what Mr. Rayburn's impressions are of what a consulting engineer really should be capable of; we may call a man a consulting engineer or he himself may assert that he is capable of performing the duties of a consulting engineer, but that does not make it so. To become a successful consulting engineer, it is necessary first to apply the theories, and one's own hypotheses to everyday practice. A man rises to such a position by a gradual process. Perhaps he should first be the chief engineer in charge of a plant before he should consider himself eligible for the duties and responsibilities of the consulting engineer.

There are different types of consulting engineers. Unquestionably, a man should specialize along some particular line of work.

It is only natural to find men terming themselves "consulting engineers" who in reality are entirely unfit to design or lay out a power or heating plant. I have known college graduates to establish offices in cities and term themselves consulting engineers; certainly we would not expect such persons, just out of college, to be capable of laying out a power plant, neither would we expect a good business man to employ such engineers.

I say that the consulting engineer will play a more important part in the operation of light, heat and power plants each succeeding year, as a man of caliber, high standing and achievements will be necessary to make the final determinations and to display sufficient tact in presenting a new layout or proposed change to the management.

Perhaps a great many of the changes, etc., were the ideas of the engineer in charge, but the changes often never would be made if they were presented to the management by the engineer. This is an age of salesmanship, an accomplishment which the engineer does not frequently possess to any marked degree.

In concluding, I assert that the isolated plants cannot expect to withstand the onslaught of the central stations unless they, too, are organized in a concrete body as the central stations are. Also, they are ultimately doomed unless the same high standard of salesmanship is resorted to, in order that the management may be convinced that it would be cheaper and better to operate its own plant. This high-grade salesmanship must be one of the attainments of the consulting engineer, as he is in such standing with the management that the engineer in charge can never attain.

Waldo Weaver.

Middletown, O.

When cutting pipe threads in a lathe it is sometimes difficult to get the exact diameter necessary. When a mistake is made and the threads on a [illegible] pipe are cut a trifle too small, so that it screws right up to the shoulder, then it remains for the workman to get out of the trouble the best way he can. A very good way is to use wire cloth of the brass variety, about 50 or 60 meshes to the inch, similar to that used by the farmer for screening his [illegible]. Wrap a bit of wire cloth around the pipe, daub it with litharge or red lead and screw the pipe home with the wire cloth in the joint. This joint will never leak or come loose.

Inquiries of General Interest

Questions are not answered unless accompanied by the name and address of the inquirer. This page is for you when stuck—use it

To Make Pipe Covering Stick

How can asbestos be made to stick to steam pipes and cylinder heads?

P. C. S.

Give the surface a coat of silicate of soda, sometimes called liquid glass, and before it has time to dry apply dry asbestos as thick as possible by handfuls. The silicate will stick to the surface and hold enough asbestos to serve as an anchor for the following coats to be applied in the usual manner.

Reasons for Compression

What reasons are there for giving compression when setting engine valves?

R. F. C.

Compression reverses the direction of pressure on the pins and main bearing of an engine gradually, takes up the lost motion without shock and allows the crank to pass the centers quietly. It also fills the clearance space with exhaust steam instead of with steam from the boiler.

Safety Valve and Steam Gage

If with a safety valve set to blow at 80 pounds the steam gage should show a pressure of 120 pounds, what should be done?

S. S. G.

The pressure should be reduced, the boiler cooled and both gage and valve tested by a competent man.

Reducing Size of Eccentric

If 1/8 inch is turned off the outside of an eccentric, how will it affect the valves and the speed of the engine?

R. S. E.

In no way whatever.

Capacity of Duplex Pump

How many gallons of water will be delivered by a duplex pump making 30 strokes per minute with 4x6-inch water cylinders?

C. D. P.

The area of the 4-inch piston is 12.56 square inches and 75.36 cubic inches of water will be delivered per stroke. Both pistons will, together, make 3600 single strokes in one hour and the quantity of water pumped will be

$$\frac{75.36 \times 3600}{231} = 1174.44 \text{ gallons}$$

Cutoff with Lapless Valve

If a slide valve has neither lap nor lead, at what point in the stroke will the cutoff take place?

C. L. V.

At the end.

Badly Scaled Boiler

In case a boiler is found to be badly scaled, what should be done?

R. S. B.

It should be thoroughly cleaned at once.

Thickness of Strap Plates

Why are the cover plates or straps of a butt and strap joint made thicker than the shell plates, and why can they not be made thinner?

T. S. P.

They are never made thicker than the shell, but on the contrary are frequently thinner. They should never be less than five-eighths of the thickness of the shell plate.

Center of Shaft

Does the center of a shaft revolve?

C. O. S.

It does not.

Diameter of Steam Pipe

What diameter of pipe 1000 feet long will be required to deliver 200 pounds of steam per minute at a velocity of flow of 100 feet per second with a drop in pressure of only 5 pounds; from 100 to 95?

D. S. P.

No diameter of pipe will fit all the conditions. A 6-inch pipe will deliver 200 pounds per minute with a drop in pressure of only 4½ pounds, but the velocity flow will be only 4000 feet per minute. A 5-inch pipe will give a velocity of flow of 6000 feet per minute for 200 pounds delivery, but the pressure drop will be 11 pounds per square inch.

Increasing Speed of Fan

I have a 7-foot fan running 187 revolutions per minute and I wish to increase the speed to 400 revolutions per minute. The fan is driven by an 8x8-inch engine running 153 revolutions per minute with a steam pressure of 100 pounds. How can I make the change?

I. S. F.

You cannot do it. The power required to drive a fan is approximately as the cube of the speed. A 7-foot fan at 187 revolutions per minute takes about 20 horsepower, which is about the limit of your engine at its present rate of speed at 60 pounds mean effective pressure in the cylinder. To drive the fan at 400 revolutions will take over 90 horsepower, which means an increase in piston speed or mean effective pressure beyond what is possible. The safe speed for the fan will fall below 275 revolutions per minute. These and other reasons, any one of which is sufficient without the others, will show why it cannot be done.

Weight of Boilers

What is the weight of a 60-inch and a 72-inch return-tubular boiler?

W. O. B.

The weight of a 60-inch return-tubular boiler without front or fittings varies according to length, etc., from 10,000 to 13,000 pounds; complete from 17,000 to 18,500 pounds. The weight of a 72-inch boiler will range from 14,500 to 26,000 pounds, depending on length and equipment.

Horsepower of Boiler

What is the horsepower of a horizontal return-tubular boiler, 6x18 feet, containing sixty 4-inch tubes, allowing 12 square feet of heating surface per horsepower?

H. O. B.

The heating surface of a horizontal tubular boiler is the total area of one-half the shell, the inside area of all the tubes and the area of one head less twice the cross-sectional area of all the tubes. One-half the area of the shell equals,

$$3 \times 3.14 \times 18 = 169.56 \text{ square feet}$$

The inside tube area is equivalent to

$$\frac{11.72 \times 18 \times 60}{12} = 1054.8 \text{ square feet}$$

The heating surface in the head would be

$$28.27 - \left(\frac{12.56 \times 2 \times 60}{144}\right) = 17.42 \text{ sq.ft.}$$

The total heating surface in the shell, tubes and heads would then be

$$169.56 + 1054.8 + 17.42 = 1241.78$$

square feet which would give a horsepower rating of

$$\frac{1241.78}{12} = 103.48$$

Reliability of Test Figures

Tests, such as those of engines and boilers, are so flexible that it is an easy matter to deceive oneself as to the results that are obtained. No wonder, then, we are startled now and then by the published reports of such phenomena as a boiler efficiency of eighty-five per cent. and the like. Not infrequently such reports are given out over the signatures of men whose integrity is above the slightest suspicion, in which event the figures are quite startling.

When men whose ability is beyond question and who have absolutely no motive in deceiving themselves about the performance of a given piece of apparatus can induce themselves, by virtue of their faith in the results obtained, to sign reports which indicate performance considerably beyond the ordinary, it is small wonder that a manufacturer or his chief engineer, can persuade himself to believe that his observations are reliable even when they indicate results that border on the impossible.

Results apparently secured are shown by the observations made by the persons conducting the test. These observations depend for their accuracy upon the calibration, precision and manipulation of the instrument used in making the observations. Even after an instrument has been found to be accurate, unless it is used carefully and intelligently, the indications which it makes may be far from the truth, as the following tends to show:

The man in charge of the Orsat apparatus during a certain boiler trial found that the percentage of carbon dioxide as indicated by the apparatus was too high. It would go as high as from seventeen to nineteen and the percentage of oxygen indicated would be nine or ten. Obviously, something was wrong, as the total of the quantities of carbon dioxide and oxygen amounted to from twenty-six to twenty-nine per cent., which is from five to eight per cent. in excess of what is theoretically possible.

For some time the operator was wholly unable to discover where the trouble was. After some searching, he discovered that the time taken in manipulating the apparatus had much to do with the percentage of carbon dioxide indicated. Strange to relate, however, the more rapidly the flue gas was passed back and forth between the measuring burette and the absorption pipette the higher would be the indicated percentage of carbon dioxide. Next he noticed that the rubber gas bag attached to the back leg of the absorption pipette remained distended after the liquid had run back to its normal level, and lo, the "mystery" was solved! In passing the gas rapidly from the burette to the pipette, too much pressure was put upon it and some of the gas was forced down through the glass capillary tubes in the front leg of the pipette, bubbled up through the liquid in the back leg and escaped into the gas bag. When the operation was reversed, the pressure in the gas bag was not great enough to force the gas back into the front leg so that it could be drawn back into the burette again. Hence, the water level in the burette seemed to indicate that more carbon dioxide had been absorbed than really was the case. By varying the speed of the manipulation the operator could obtain any indication for carbon dioxide that he desired.

The moral to be drawn from this incident is that unusual results should be viewed with caution even by the man who has obtained them. Before making them public the methods employed and the deductions made should be subjected to careful investigation and analysis.

"It's better to be sure than sorry."

Professor Nicolson's Experiments

Professor Nicolson's experiments with high gas speeds in boilers, an account of which is given elsewhere in this issue, demonstrate that an enormously high rate of heat transfer through the tubes can be attained if the velocity of the gases is great enough. Beyond establishing this fact, however, they add nothing which would seem likely to revolutionize present boiler practice.

In order to prevent the passages around the economizer tubes from becoming choked with soot, it was found necessary to respace the tubes, and after this had been done, the temperature of the gases leaving the economizer rose to two hundred and forty degrees. This is no better than the results attained in everyday operation in well designed plants equipped with economizers; in fact, it is not uncommon in some plants to have the temperature of the gases fall to two hundred degrees. Another significant fact is that Professor Nicolson's experimental boiler did not show any extraordinary efficiency, such as might be expected from the high rate of heat transmission. True, an efficiency of seventy-nine per cent. was attained on one run, but when the steam required to operate the fan at its high rate of speed, was deducted, the net efficiency fell to sixty-nine per cent.; which is considerably below the results obtained with the best boiler practice.

When it is considered that the goal aimed at in the design of all boilers is to deliver to the water the greatest possible percentage of the heat in the coal, it would seem that the further solution of the problem lies within the furnace.

Gas Poisoning

The narrow escape of an engineer, a few weeks ago, from death by carbon monoxide gas in a producer-gas power plant and the more recent death of a young man and woman in Maryland due to the same gas from a defective stove, bring the subject of gas poisoning strongly to the front. In every producer-gas power plant there is constant danger of fatal "gassing," as our British cousins call it, unless proper precautions have been taken to prevent the escape of carbon monoxide into the building.

The simple suction producer plant is less likely to give trouble in this respect than any other, because the entire system is below atmospheric pressure right up to the engine. But the simple suction plant develops bad operating features as soon as two or more producers are operated in a battery, especially if two or more engines are supplied simultaneously. The induced-draft type of plant comes next in point of freedom from leakage possibilities. The generators, scrubbers and all of the many connections between the generators and the fans are under suction, only the piping between the fans and the engines being under pressure. Moreover, the pressure in this part of the equipment is only a few ounces per square inch and all joints are or should be in plain sight and easily accessible. In such a plant there is much less excuse for gas leakage than there would be for steam leakage throughout the piping of a steam plant.

Even where straight pressure producers are used because of their well known meritorious features, there should not be any great difficulty in preventing the leakage of gas into the building. Of course, there are more points to be protected, but that is merely a routine part of the designing engineer's work.

No matter what the system or the operating conditions, it is just as incumbent upon the builders and erectors to prevent gas leakage as it is upon boilermakers to eschew low-grade steel and lap seams.

Plant or Unit Efficiency

There is a tendency among engineers to judge the economical operation of their plants by the performance of the main engines and boilers. At one plant where the boilers show an efficiency of seventy-two per cent. and the engines a water rate of fourteen and a half pounds per horsepower-hour, it is believed that power is being produced about as cheaply as possible for the size and type of installation; whereas a neighboring plant of similar equipment, in which the boilers show an efficiency of only seventy per cent. and the engines a water rate of fifteen and a half pounds, may, in reality, be producing power much cheaper than the first plant.

Although a determination of the individual efficiencies of the boilers and engines is useful for comparison with other engines and boilers they cannot be taken as a criterion upon which to base the economy of the whole plant. One engine may attain a lower water rate as a result of a half inch higher vacuum, yet the extra power required to produce this additional half inch may more than offset the economy due to the lower water rate. Similarly the other auxiliaries have a direct bearing upon the cost of generating power as do also the labor and fixed charges, and these must be included in the plant efficiency.

The prominence given to the main units is no doubt due largely to the fact that competition among the builders has kept their performances continually in the limelight, and also, in a lesser degree, to the fact that tests of individual units are more common than plant tests.

Concealing the Facts

Accidents are frequently the results of mistakes the careful and intelligent analysis of which will usually bring much to light that will be of great value in showing how the repetition of the mistakes may be avoided.

Refusing to give information and denying access to such information to those whose business it is to search for and find the cause, if possible, is to deliberately seal a source of knowledge to which the public has an unquestionable right, even down to the smallest detail; every factor in an accident which has endangered or destroyed life or property is vitally important to those interested in related lines of work, and they have a moral right to such information. That which is a menace in one situation is also a menace in another, if the conditions are similar, and an error in construction or operation of machinery in one case may be repeated over and over in other localities if detailed information be refused in the first case. Full publicity in every case of accident, therefore, will do much to reduce the number that occur.

Dissatisfaction and even resentment are often if not always shown by all who are in any way connected with an accident if the investigation indicates that it was caused by ignorance or carelessness. This attitude, while perfectly explained on the ground of selfishness and absence of consideration for the safety of others, is wholly inexcusable. That the public has a right to protect itself from polluted water, adulterated food or contagious disease is unquestioned. Power-plant owners and operators do not seem to realize that it has the same right to protect itself from the danger of an accident that ignorance or carelessness may cause.

There is another side of the question that seems to have escaped due attention also. That is the fact that the refusal to give out information concerning an accident will always arouse a natural suspicion that there is a foundation for the uncharitable criticism and gossip which are so general concerning matters of the kind under discussion. It is a good deal better to tell the full truth about an accident than to encourage sinister suspicions and possibly the publication of a garbled story based on partial information and guesswork by a reporter, against which the editor of a periodical is almost always defenseless.

We are hearing so much of late regarding the conservation of our national resources. What about the conservation of time? The average man would be surprised if he realized the amount of time he wastes annually through lack of a systematic way of doing things. System is one of the greatest of time savers.

Balzac said that "Cruelty and fear shake hands together." In steam engineering, ignorance and death walk hand in hand.

A California man who tickled a lion under the chin is now minus three fingers.

A Massachusetts engineer who screwed down a safety valve burst a boiler, killed himself and nineteen others. One act was just as foolhardy as the other.

A certain type of engine runner is disappearing. He is in a class with the old tiddle-de-winks and ping-pong outfits—out of date.

While a man was thawing out a frozen oil pipe, gas, which had accumulated in a receiving tank, was exploded by the torch that was used. The man was blown 150 feet and killed. It pays to be careful.

The man who rigs up an appliance from material on the scrap heap, and makes it work, is a genius compared to the man who makes a nice working drawing of an appliance that will not work.

The majority of explosions occur, not while the boiler is in regular service but while it is being started up. The Pittsfield catastrophe is a case in point.

Flywheel Explosion at Lowell, Mass.

By Joseph King

> *The 25-ft. flywheel of a twin simple condensing Corliss engine explodes with disastrous results to mill and machinery. The regular speed of the engine was 58 revolutions per minute and the wheel was evidently safe at 80.*

Shortly after 7 o'clock Thursday morning, January 26, the 25-foot flywheel of the twin 32x60-inch condensing engine at the No. 7 Boott mill, Lowell, Mass., burst with disastrous results to the engine, machinery and building, but without seriously injuring any of the 150 operatives. The wheel, which weighed approximately 56 tons, was eight feet wide and carried three belts.

As no examination of the engine can be made until the tons of wreckage under which it is buried can be removed, it is not possible to give the initial cause of the accident. That the rupture of the wheel was due to excessive speed is well known, as for some minutes before the final crash the looms on the floors above automatically stopped when the speed increased, and pulleys in various parts of the mill burst from the effects of the high speed.

In the light of the little that is known it is thought that perhaps one of the large belts broke and piled itself up on the floor back of the wheel, either breaking the governor belt or forcing it off the pulley.

The governor, not being furnished with safety devices, allowed the engine to take steam nearly full stroke, which soon drove it to a speed so far above the normal that the wheel exploded.

FIG. 1. THE ENGINE LIES BURIED BENEATH THE WRECKAGE

The three belts ran vertically upward quite near the wall and were made to cover a large proportion of the circumference of the flywheel by the use of an idler. As the engine ran "under," it is quite within the limits of the possible that a broken belt following the direction of rotation of the wheel would catch on the floor and pile up between the engine frames and render the governor inoperative.

The engine ran at 58 revolutions per minute, which was only about two-thirds of the safe speed for the comparatively modern design of this wheel.

The fragments of the rim tore through four floors and the wall of the building, making an opening about 50 feet wide, around and over the edges of which hung the ends of machines and shafting supported by the remaining belts and lag bolts. One section of the wheel, weighing nearly 900 pounds, was thrown through the roof and landed on the top of the building where it remained, while another piece went up through the second floor and lay close to the edge of the hole.

Although it is true that probably nothing is certainly known of the cause of the accident, a great deal of street talk and the newspaper reports give the impression that from the time the increase in speed was noticed to the final crash, several minutes elapsed, and that the engine might have been stopped, as the operatives had plenty of time to escape from danger.

FIG. 2. PIECE OF WHEEL ON ROOF AND HOLE THROUGH WHICH IT CAME

During this time, it is reported that the engineer, a new man, was seeking the master mechanic to get permission to stop the engine.

It is estimated that the damage will exceed $50,000, $30,000 of which is covered by insurance. Only one operative, a young Greek girl, was hurt in any way, and she only slightly by running against one of the machines.

Heating and Ventilating Convention

The seventeenth annual meeting of the American Society of Heating and Ventilating Engineers was held on January 24, 25 and 26 at the Engineering Societies building, New York City.

The following papers were presented: "Pipe Line Design for Central Station Heating," by B. T. Gifford; "The Value of Good Ventilation," by Prof. Severance Burrage, Lafayette, Ind.; "Standards of Ventilation," by Dr. W. A. Evans, Chicago; "Ventilation of the Capitol, Washington, D. C.," by Nelson S. Thompson. In addition to these papers a report was submitted by the committee on "Effect of Air Leakage and Wind Velocities on Heating Guarantees." A report was also submitted by the committee on "The Rating of Heating Boilers."

Mr. Gifford's paper on "Pipe Line Design for Central Station Heating" will be printed in abstract in next week's issue.

Value of Good Ventilation

Professor Burrage indicated in his paper on the above topic that the value of good ventilation was found in the good health and high efficiency of the people occupying well ventilated buildings. One of the most important predisposing factors in the spread of tuberculosis and pneumonia is bad air. Not only is health greatly improved and the power of resistance of the body against disease greatly increased by breathing pure air. but much more efficient work can be done by those who study and work in well ventilated rooms.

Standards of Ventilation

Doctor Evans showed that the standard of ventilation must be complex because it must depend on many factors such as the different qualities of air and the different methods of handling air. If a building is so located that it gets lots of sunshine in its interior the standard of ventilation may, possibly, be lowered 20 per cent. while that for a basement or cellar where sunshine seldom enters must be raised 20 per cent. In a hospital the standard must be high because the general degree of health is low. Thus, the standard is influenced by the physical character of the building, the use to which it is put, the class of people occupying it, etc.

After all such factors have been taken into account, the standard of ventilation must provide restrictions as to the dust content in the air, the humidity, the temperature, the carbon dioxide content, odors, the frequency of air change, air current and bacterial conditions.

Ventilation of the Capitol, Washington, D. C.

The paper on this topic consisted mainly of a description of the methods employed and the results obtained during tests to ascertain the quantities of the various constituents, chiefly carbon dioxide, of the air in the Capitol building.

The system of ventilation used in the Senate chamber and that of the House of Representatives is of the up-draft type. Air is admitted by numerous floor openings, and is drawn out through ducts in the ceiling by exhaust fans. The conclusion drawn from the tests is that while the quantities of air circulated are sufficient for excellent ventilation, the distribution of the air is poor and that the system employed is, consequently, unsuitable.

Effect of Air Leakage and Wind Velocities on Heating Guarantees

The report of the committee on the above consisted of a few specific examples in the form of test results obtained at the Harvard Medical College buildings and at the gymnasium buildings at Michigan University.

Due to the dirth of data available to the committee it was impossible to draw any definite conclusions. The committee urged that a future, larger committee be created to acquire more data on these important factors in heating requirements.

Rating of Heating Boilers

The committee on the above recommended that a square foot of direct heating surface be used as the unit of rating, based upon the assumption that a square foot of direct steam heating surface gives off 250 B.t.u. per hour, and that a square foot of direct water heating surface gives off 150 B.t.u. per hour. It was recommended that the rating of heating boilers be based on the number of square feet of steam radiation or water radiation surface having heat radiating values as before stated and that the statement of rating be accompanied by a statement of the rate of combustion and the efficiency of the boiler.

The following were elected to office for 1911: R. P. Bolton, President; J. R. Allen, first vice-president; A. B. Franklin, second vice-president; W. W. Macon, secretary and W. G. Scollay, treasurer, reëlected.

Industrial Accidents

Industrial accidents in the United States take an annual toll of life and limb far exceeding the killed and wounded of several great military campaigns. The statistics given by the *Bulletin* of the Bureau of Labor for 1908, which must be regarded as incomplete because of the failure to report fully these accidents, show a yearly mortality of between 30,000 and 35,000 adult wage earners alone, and the nonfatal injuries inflicted will roll up the total by at least an additional 2,000,000. These and other arresting statements are made by John Calder, manager of the Remington Typewriter Works, Ilion, N. Y., who will, at the New York monthly meeting of the American Society of Mechanical Engineers, 29 West Thirty-ninth street, New York, Tuesday evening, February 14, present a brief for the mechanical engineer and the prevention of accidents. Much, Mr. Calder believes, can be accomplished by a movement on the part of the profession which has to deal so largely with the planning and working of industrial machinery. Prevention, not cure, is the theme of the paper, which analyzes the causes of those accidents regarded as preventable and describes various devices for guarding equipment and processes, drawn chiefly from the writer's experience in plant management. Mr. Calder considers that one-third of the present rate of mortality can and should be eliminated by such devices. The National Civic Federation and the Industrial Safety Association, which have already done much to arouse public sentiment along this same line, will be represented at the meeting and engage in the open discussion which will follow the presentation of the paper. Both before and after the meeting the American Museum of Safety, also located in the Engineering Societies building, will open its exhibit to the public.

Under the head of safeguarding, the author has many interesting views of equipment and machinery, showing the use of such devices on gears, steam turbines, lathes, cotton carders, rolling-mill engines, transmission tubes, belts, etc. He also takes up in detail especially dangerous machines and processes which present difficult safeguarding problems for the engineer.

Advance copies of the paper may be secured for review upon application to the secretary, Calvin W. Rice.

Water Power in British Columbia

According to Consul Frank C. Denison, in the *Daily Consular and Trade Reports,* a plant for the generation of electrical power by water has been successfully inaugurated by a company of Americans at the Bull river falls, 13 miles due west of Fernie. At this point a fall of 273 feet has been obtained by the construction of a flume 9000 feet long, which takes water from the river above the falls and returns it below. A head of 273 feet with a flow of 462 cubic feet of water per second has been obtained. The flume, constructed of wood and built upon a rock foundation, is 30 feet wide by 7½ feet deep at the intake. The width is reduced to 16 feet within the first thousand feet, this width being kept to the end of the flume. The estimated horsepower that can be utilized is 12,600.

The company is now preparing to install the penstock, which is to be of steel, 9 feet in diameter, and will rest upon bed rock the whole length, at an angle of 30 degrees. The foot of the stock will rest upon a natural bed rock, and a tee-shaped cross pipe will be placed at the end of the stock in which the wheels will be placed; three wheels of 4200 horsepower each will be utilized as the demand for power develops.

Within a radius of 30 miles there are now in operation steam plants with an aggregate of 23,650 horsepower. Some of this power is used by sawmills, which will continue to employ steam on account of the cheapness of the mill waste used as fuel, but it is expected that many mining and smelting plants within reach of this new plant will discard steam for electrical power.

Within this radius there is available undeveloped water power to the extent of 30,000 horsepower, the greatest single power being at Elko, on the Elk river, 20 miles south of Fernie. This estimate does not include the possible power to be developed by damming the different mountain streams in their courses, but is confined to the power available at the various natural falls on larger streams.

New Power House Equipment

What the inventor and the manufacturer are doing to save time and money in the engine room and power house. Engine room news

The Merrick Conveyer Weightometer

This device is for the purpose of recording the weight of coal transported on a belt or bucket conveyer.

It consists of a pair of weighing levers *L*, Fig. 1, a steelyard or beam *B*, similar in principle to those of the usual platform scale, but of special design so that a short section or portion of the conveyer can be suspended from the weighing levers.

The weight of the load on this suspended portion of the conveyer, regardless of its distribution, is at any instant automatically counterbalanced by the buoyancy of a cylindrical iron float suspended from near the long end of the weighing beam and partially immersed in a bath of mercury. Any increase or decrease of load on the levers will either raise or lower the float in the mercury until the loss or gain in buoyancy compensates for the variation in load. Fig. 2 shows how the weightometer is placed over a belt conveyer.

The function of this float is to insure that the movement of the beam from its zero position, or position when the conveyer is empty, be proportional to the weight of material at any instant on the suspended portion of the conveyer.

At the extreme end of the weighing beam is connected a totalizing mechanical integrator, which derives its other factor from the travel of the conveyer by means of suitable gearing from a band pulley on the return belt or a sprocket wheel if on a bucket conveyer.

This integrator continuously totalizes the product of two quantities, one proportional to the weight of material suspended and the other to the travel of this material. The result therefore represents the total weight of material and is plainly indicated by a register in units and tenths of units of either a short ton, long ton or metric ton.

For cases where the material handled adheres to the conveyer in a varying amount, an attachment is added that automatically counterbalances the variable weight of the empty conveyer. This avoids frequent adjustment to meet the changes in the weight of the empty conveyer and material that may adhere thereto.

This integrator consists of an aluminum disk, Fig. 3, around the periphery of which are mounted rollers that are free to revolve, and have their axes tangential to the edge of the disk, and form practically a continuous annular roller which cannot move around the disk which is fixed on a shaft that revolves in bearings on the frame. This frame is mounted with a bearing at either end so that it can rotate about an axis coincident with the plane of the disk and at right angles to the axis of the disk. On one end of this frame is an arm the extremity of which is connected by a link

Fig. 1. View of Weightometer on Belt Conveyer

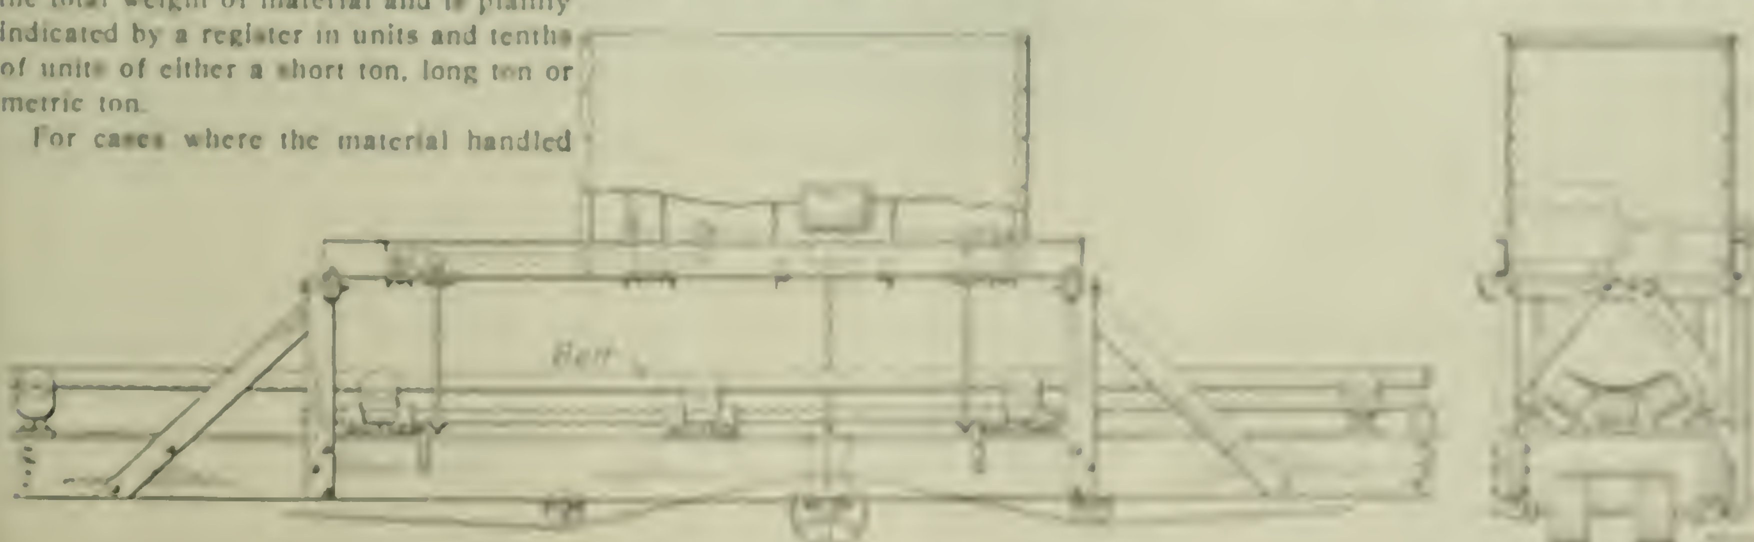

Fig. 2. Side and End Elevation of Weightometer

to the long end of the beam. Thus any movement of the beam, caused by an increase of the load on the belt, tilts the frame through an angle whose sine is proportional to the vertical movement of the float, and again proportional to the load on the suspended portion of the conveyer.

As the rollers cannot slide on the disk they will rotate it around its axis. Consequently the speed of rotation of the disk is proportional to the deflection of the beam, the movement of the float or the load on the conveyer. The amount of its motion is thus a measure of the weight of material carried by the conveyer during the period of observation. Thus the revolution counter mounted on the disk shaft will record and totalize the weight carried in any units for which the mechanism is designed.

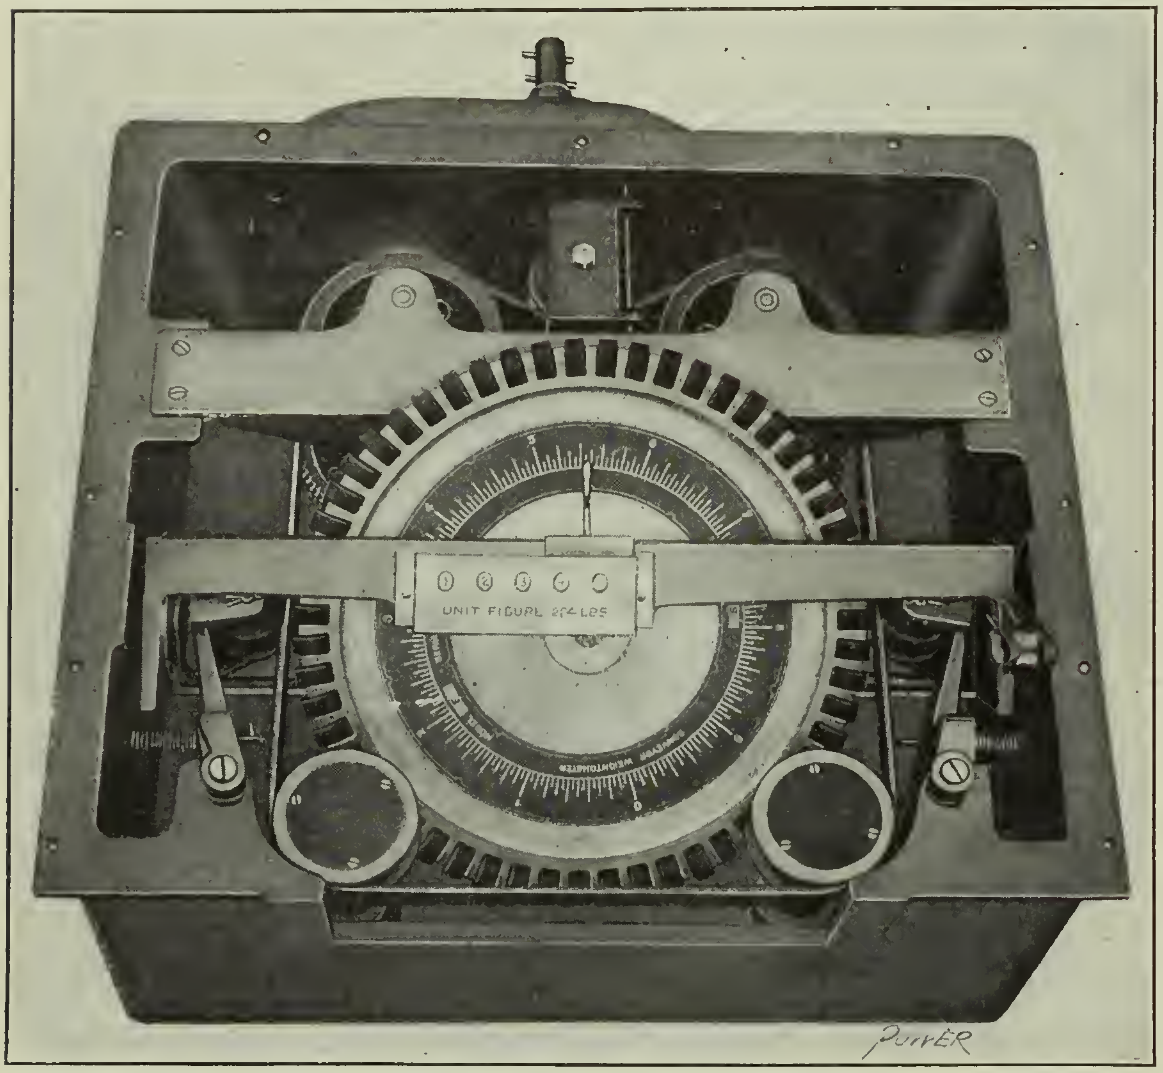

Fig. 3. Details of the Integrator

Four pulleys guide a small endless belt around the disk and touching the rollers thereon at two points diametrically opposite and on the axis of the frame.

Pressure rollers behind the belt keep the belt and disk rollers in contact. A weighted take-up pulley assures an even tension in the belt and takes care of any stretch. The two upper pulleys are geared together and are driven by means of miter gears from a band pulley under the return belt as shown in Fig. 2. The integrator belt thus travels at a speed proportional to that of the conveyer.

So long as the plane of rotation of the roller on the recording disk is parallel to the direction of the integrator belt, the motion of the latter will only affect it to the extent of revolving the roller on its own axis. This condition corresponds with the zero position of the beam or when there is no load on the conveyer. If, however, the beam is deflected by the loading of the belt, the frame and recording disk will be correspondingly tilted. This will incline the axes of the roller with respect to the integrator belt. Then, besides rotating them, the belt will push the rollers sideways across its face at a rate proportional to their inclination.

A glance at the dial when the conveyer is running empty will determine whether the dead weight of the idlers, etc., plus the weight of the belt or buckets is correctly balanced so that the net weight of the material is recorded. Should the dial remain stationary or move back and forth between two constant limits of travel the adjustment is correct. Should the dial make a plus or minus gain the proper balancing is done by means of a weight on the steelyard. This weight is carried on a screw and is similar to that on the ordinary platform scale, as turning the screw moves the balance weight.

A magnetic counter is furnished, if desired, that will duplicate the reading of the scale register in the engineer's office or at any other point distant from the scale itself and present the record right at hand. This is accomplished by a pin on the recording dial closing a circuit, thereby causing an electrical current to pass through a set of coil magnets, the armature of which is attached to a link connecting to the counting device which is located in the engineer's office.

All of the shafts within the casing and integrator turn either in ball bearings or special self-lubricating bushings, but no matter how much looseness there may be in the latter due to wear, the accuracy is not impaired as the travel of the small belt is not reduced. The speed of the integrator belt is only about 30 feet per minute and therefore the pulleys and rollers on the disk rotate slowly, resulting in but very slight wear after long service. Because of the large diameter of the disk, the wear of the rollers on their pins causes only an almost inappreciable error.

As all parts are inclosed in a removable sheet-iron casing, Fig. 4, unauthorized persons are prevented from having free access to the apparatus, and the dust and dirt always present around conveyers, which would quickly impair the efficiency of any exposed mechanism, is thus kept away from the working parts of the device.

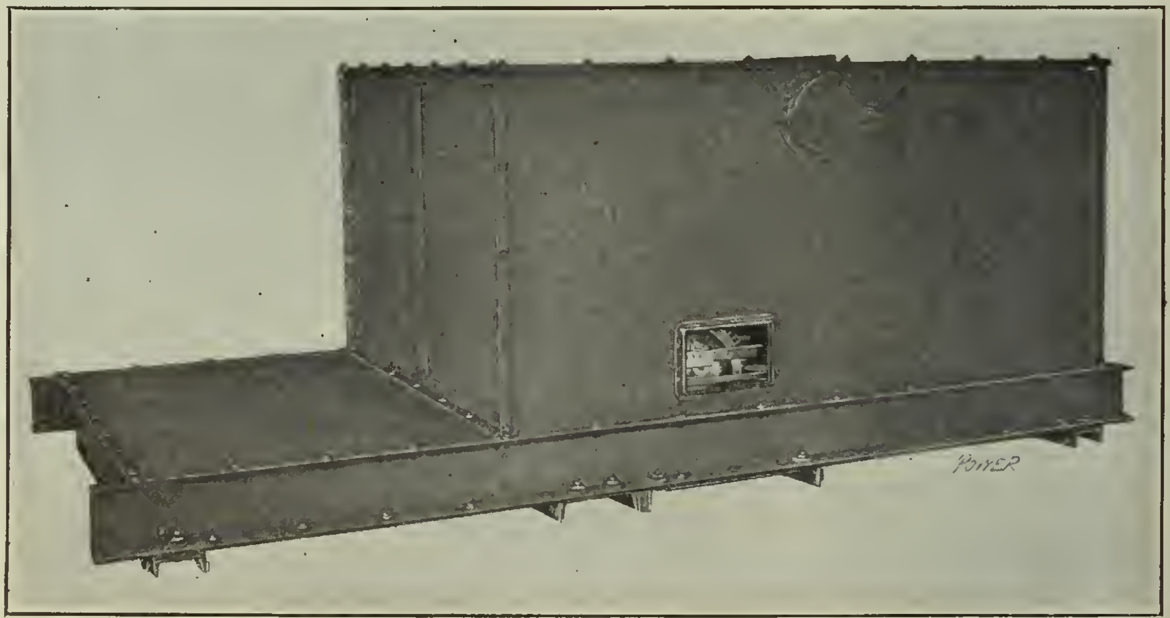

Fig. 4. Weightometer with Casing in Place

This weightometer is manufactured by Herbert L. Merrick, Passaic, N. J.

Correction Note

In the issue of December 20, mention was made of the flow past the seat of the Nelson blowoff valve. One of the special features of this valve is that it has no seat, as may be readily seen from the cut which accompanied the description. In the same article an older form of the Powell blowoff was shown. The latest or "cyclone" self-cleaning valve will be described in the near future.

Mechanical Engineers Give Reception to Captain of "Celtic"

An informal committee of the 1910 transatlantic party of the American Society of Mechanical Engineers entertained Capt. A. E. S. Hambelton, of the "Celtic," at luncheon on January 17 at the Engineers' Club, New York City.

The "Celtic" was the ship upon which the mechanical engineers went to England last summer at the time of their joint meeting with the Institute of Mechanical Engineers at Manchester, Eng.

The luncheon to Captain Hambelton was given as a token of the high esteem in which he is held by the members of the party.

Prof. F. R. Hutton, as director of ceremonies, extended the felicitations of the members to the captain in the shape of a wish that he may continue to meet with the success he so well deserves.

Those who attended are: F. R. Hutton, Capt. A. E. S. Hambelton, Jesse M. Smith, Leonard Waldo, F. B. Gilbreth, John Platt, C. E. Davis, S. L. Moore, G. M. Bond, L. C. Marburg, Augustus Smith, G. A. Orrok, C. W. Rice, E. D. Meier, C. H. Corbett and H. B. McCreery.

Boiler Flue Blows Out

Another boiler accident in Missouri emphasizes the necessity of rigid boiler-inspection laws in that State. It is reported by Albert Dedrick that on January 20, several flues in an old boiler in a flour mill at Union Star, Mo., failed. The engineer had a narrow escape from death, having only a few minutes previous stepped to the rear of the boiler to make some minor repairs. One flue went out through the front flue sheet and landed several hundred feet away. As luck would have it, no one was hurt. An examination showed that the boiler was old and the flues were in such condition that they should have been replaced long ago.

Pabst Brewing Company Wins Boiler Explosion Suit

In the case of the Pabst Brewing Company versus the Hartford Steam Boiler Insurance and Inspection Company, just tried in Milwaukee before Judge A. T. Sanborn, of the western district of Wisconsin, the jury brought a verdict in favor of the plaintiff for $98,400 with interest from December 1, 1909. The case was immediately appealed. Full particulars will be given in a later issue.

BOOKS RECEIVED

AUTOMOBILE MECHANICIANS CATECHISM. Published by Frederick J. Drake & Co., Chicago, Ill. Leather cover; 110 pages, 4[illegible]x6[illegible] inches; illustrated plates; indexed. Price, $1.25.

THE MECHANICAL WORLD ELECTRICAL POCKETBOOK FOR 1911. Published by Emmott & Co., Ltd., Manchester, Eng. Cloth; 208 pages, 3[illegible]x6 inches; 68 illustrations; tables. Price, sixpence.

Valuable Reference to Technical Press

The International Institute of Technical Bibliography is publishing a monthly index to the world's technical press, covering technical periodicals, new books and the proceedings of learned societies. The first volume has now been completed. To create an English and American center, the institute has recently founded a special branch in London, 57 Chancery lane, whence the English and American editions are sent out. The value of the publications may be best explained by reprinting an appreciation of them by E. Wyndham Hulme, chief librarian of the English patent office, which appeared in the *Library Association Record*.

"By some freak of fortune practical England has for the last half century stood out as the champion of the indexing of the periodical literature of pure science, while to philosophic Germany belongs the credit of having maintained for the same period an annual index of the corresponding literature of the applied sciences. Not many years ago the Royal Society's *Catalogue of Scientific Papers* was handed over to the control of an International Council with regional bureaus, and today we have to chronicle a similar reorganization of the "Poole" of technical periodical literature, viz., the *Repertorium* of the imperial patent office of Berlin. This hardy annual has in its turn been transferred to an International Institute of Technical Bibliography, organized on lines similar to those of the International Council. The first step taken has been to transform the publication into a monthly, and to extend it by the inclusion of book notices. From the beginning of the past year the index has been published in six sections dealing respectively with 1, mechanical; 2, civil; 3, electrical engineering; 4, mining and metallurgy; 5, applied chemistry; 6, matter not included in the preceding sections. A further section dealing with the naval, military and aëronautical sciences has also appeared recently. These monthly sectional indexes or *Abstracts*, as they are termed, will be consolidated at the end of each year in one general alphabet. The first of these annual publications for the year 1909 has just appeared in two volumes. The classification of the deceased *Repertorium* was on dictionary principles, the titles, headings and index being in German, English and French, while the entries were compiled in the language of the articles indexed. The new publication follows closely on the old lines, except that the monthly sections have their headings arranged in class order, with a synopsis of the classification prefixed to each number.

"The life of the German edition is practically guaranteed by subscriptions from the state department, professional societies and manufacturing firms of Germany. But the fate of the English edition must be regarded as conditional upon the support received in these countries."

SOCIETY NOTES

The ninth annual reception and banquet of the combined associations of the National Association of Stationary Engineers of Greater Pittsburg was held on Thursday evening, January 26. Over 400 of the members and guests, including both sexes, gathered about the tables in the large dining hall of the Monongahela house and enjoyed an appetizing dinner.

After the banquet was served, an entertainment was given by the Duquesne quartet; J. C. Usher, Crandall Packing Company; Billy Murray, Jenkins Brothers; Frank Corbett, Consolidated Valve Company, and Jack Armour, of POWER. Dancing followed and concluded a most enjoyable and successful occasion.

With the new year the National Electric Light Association has taken another leap forward in membership and on January 21 crossed the 6500 line. This is a gross gain of over 1500 since the St. Louis convention and a net gain of about 1250. The Canadian Electrical Association voted recently to affiliate with this body and this will also bring a large accession; while new company sections are being formed in Pittsburg, Allegheny City, Scranton, Connellsville, Penn., and other cities. H. H. Scott, the chairman of the membership committee, estimated that 7000 members will be enrolled by the end of January and that the number may easily be 8000 by the next annual convention in June. Fifteen months ago the membership was slightly over 3000. A number of smaller central stations are included in the new membership.

Tom Blowoff takes a "leap" with [illegible]. His boss told him that they [illegible] [illegible] [illegible] in a [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible]

Cleveland No. 5 Honors Past President William Powell

It has been the practice of the National Association of Stationary Engineers in recent years to present the retiring national past president with a past officer's jewel. At the last convention it was voted to present such badges to the living past presidents of the association who had not thus been honored.

On Saturday evening, January 28, Cleveland Association No. 5, of which Past National President William Powell is an old and honored member, held a special meeting for the formal presentation of this jewel.

There were present Past National Presidents John W. Lane and Robert E. Ingleson, many State and subordinate officers and State examiner of engineers Haswell. There were large delegations from the two other Cleveland associations, as well as a big representation from the other Ohio associations, justifying the claim of Chairman J. E. Radigan that this was the largest and most important gathering of Ohio engineers that has been held outside of a State convention.

After the adjournment of the regular meeting, the company proceeded to the dining hall, where Mr. Powell was seated at the head of the table and presented with the jewel of past president of local association No. 5, and then with the national emblem. Mr. Powell was visibly affected by this expression of appreciation of his past services, and in his speech of acceptance reviewed in an interesting way the conditions of the engineer before the organization of the National Association of Stationary Engineers, and some of the earlier activities of the association.

Brief remarks from many others in attendance enlivened the proceedings and extended the program well into the night.

NEW INVENTIONS

Printed copies of patents are furnished by the Patent Office at 5c. each. Address the Commissioner of Patents, Washington, D. C.

Pres., G. W. Wright, Baltimore, Md.; sec. and treas., D. L. Gaskill, Greenville, O.

POWER

NEW YORK, FEBRUARY 14, 1911

FOR over a year this page has been a feature of the paper. It was designed to bear a message to the man who is doing things or, at least, trying to do them.

Endeavor is made to make the language as near "human" as possible, and to point a moral or illustrate a truth in a way calculated to be emphatic as well as entertaining.

We are receiving regularly ample, unsolicited testimony that our efforts have met with approval. As soon as this ceases to be apparent this editorial leader will be dragged off to Barren island as a "dead one" and the space which it occupies will be given over to something more desirable to the readers. For, is not this the reader's paper?

Although the editor might get a wealth of comfort and enjoyment out of writing this weekly "whirl," yet would he have to forego it at the instant that the spectators turned down their thumbs on his handiwork.

And don't you know that what is true of the editor's work is just as true of your own, no matter what your work may be? The instant that you stop "delivering the goods" you're on the greased slide and a swift slip to the discard is imminent.

A certain successful member of the race which is noted for business shrewdness was in the wholesale clothing business. One of his salesmen seemed to feel that every time he came in from a trip it was necessary to make elaborate explanations why the orders he had received were not more numerous.

So he would take up an hour or two of his employer's time telling how this man was all stocked up, and wouldn't buy; how that one was putting in a line of cheaper goods, and so on. Always the lack of orders was no fault of the salesman. Finally, toward the end of one of these sad seances, the manufacturer stopped the flow of excuses with the terse remark, "Well, Mr. Lowen, what we want is orders."

He might have said "results" and meant the same thing. Everywhere, in power-plant operation as well as in any other line of work, RESULTS are the things upon which a man's worth is based.

It makes no difference what you might, could, would or should have done, it is what you actually did do that tells.

In the long run you are weighed by your work—not by your words.

Modern Boiler Plant, Holyoke, Mass.

By Warren O. Rogers

A central station, replacing three smaller boiler plants, reduced the operating expenses $75 a day. In the new plant the engineer can read the temperature of the flue gases, of return water from the mills and of the feed water, also the percentage of CO_2 in the flue gases without stepping from his office. The coal consumed is automatically weighed as it is conveyed to coal bunkers, and the weight is registered in engineer's office.

Present tendencies are to centralize the boilers and engines of manufacturing plants and use electric drive, especially where the buildings are scattered over a large area.

To secure the economies available through consolidation, the American Writing Paper Company, Holyoke, Mass., decided to erect a central steam-generating plant, of sufficient capacity to supply all the steam necessary to operate three separate paper mills, which were equipped with separate steam plants of from 600 to 1200 horsepower capacity.

This work was designed and installed by the company's engineering department under the direction of Edward P. Butts, chief engineer of the company. As a result, although aiming to keep the first cost down to a minimum, the plant stands a model for simplicity of design and ease of operation.

By means of this new plant the cost of operation, including labor, fuel and supplies, has been reduced $75 per day, or from $20,000 to $25,000 per year.

The boiler plant consists of six 400-horsepower Babcock & Wilcox boilers, based on 10 square feet of heating surface per horsepower. These boilers do the work formerly done by nineteen small boilers in the old plants. The boilers are operated constantly at 25 per cent. above their rating in order to obtain the best efficiency from them.

Murphy stokers are used, the grate area being 80 square feet, with a ratio of fifty to one. There has been no trouble in burning 30 pounds of coal per hour per square foot of grate surface and the plant operates practically with no smoke.

These boilers are set in three batteries, of two each, as shown in Fig. 1. A permanent iron stairway and rail has been placed at one end of the boilers and, as a platform extends the length of the boiler settings, the firemen can easily get at the coal chutes or fixtures on the front of the boilers.

In order to eliminate air leakage into the furnaces through the brick settings, the side walls of each battery have been lined with a magnesia covering. The tube blow-hole plates are fitted with a sheet-iron cover which prevents air leakage at these points. These features are shown in Fig. 2.

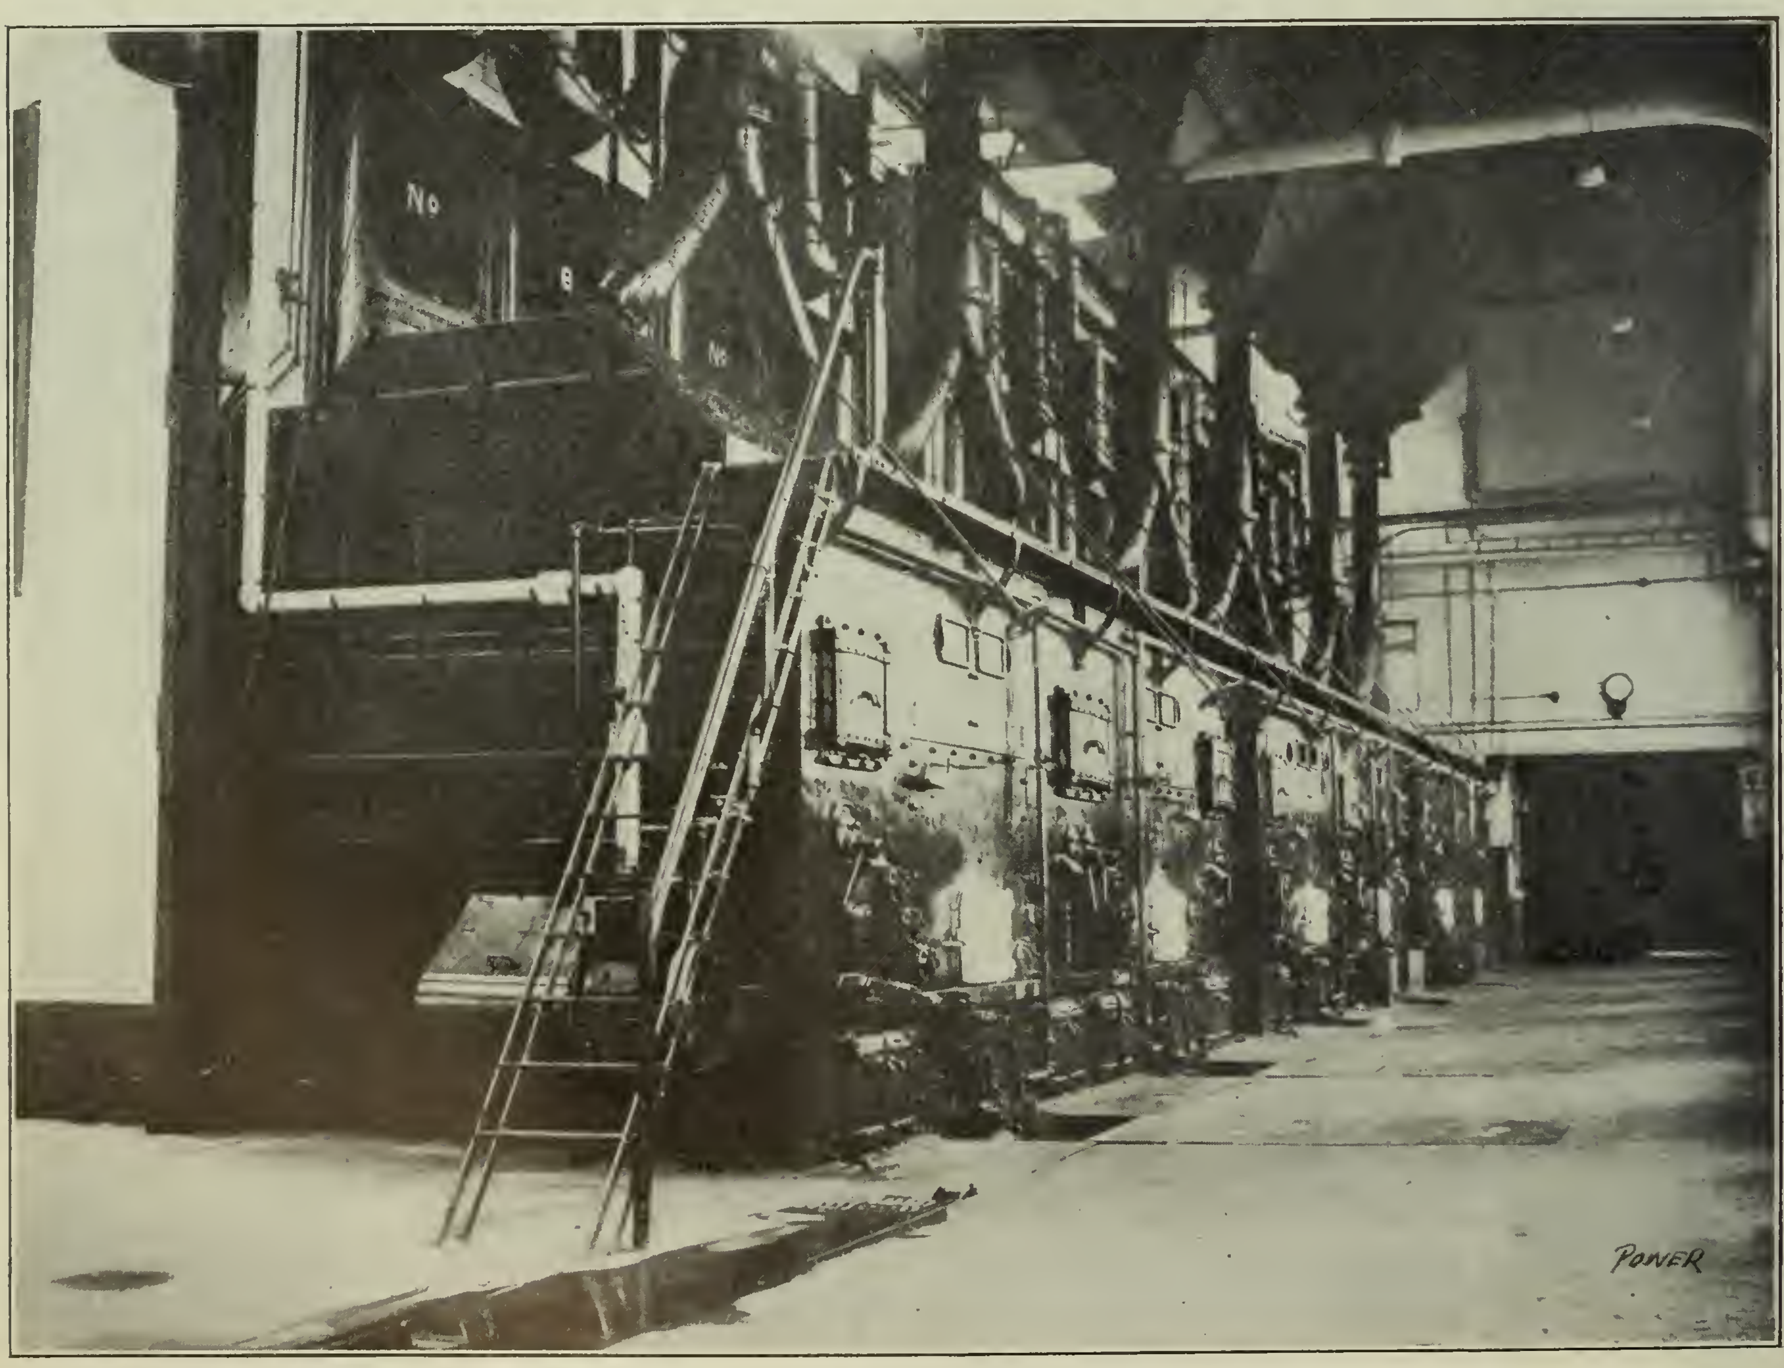

Fig. 1. New Boiler Room of the American Writing Paper Company

Each boiler smoke flue is fitted with a damper, but the draft is controlled by a main damper placed in the main smoke flue, between the stack and the junction of the individual smoke flues. This damper arrangement is peculiar, but effective. Instead of having a bearing on both sides of the smoke flue, the damper is suspended by means of an iron beam, placed crosswise over the top of the flue, an eyebolt, three large iron links and a short length of chain. The details are shown in Fig. 3.

FIG. 2. SHOWING MAGNESIA COVERING ON BOILER SETTING

The damper is connected to the damper regulator by means of a rod, as shown. Suspending the heavy damper on rings and chain has the advantage of allowing it to turn on a very small bearing point, thus eliminating friction and permitting free operation. In order to prevent the damper sticking to the side and top of the smoke flue, a clearance of 1½ inches at the top and bottom has been allowed.

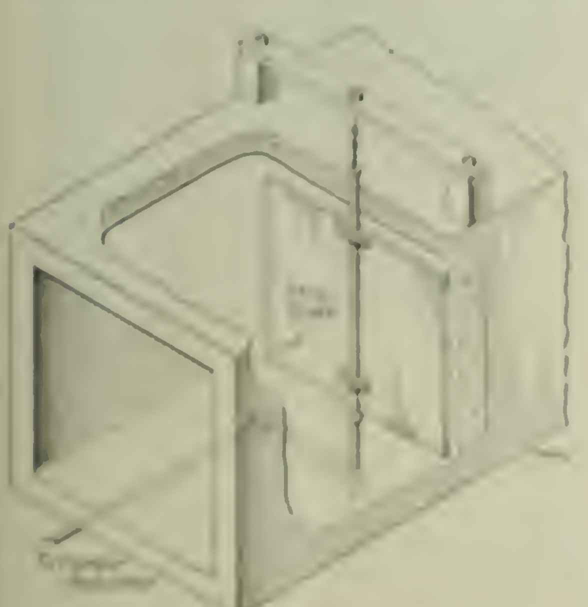

FIG. 3. DETAIL OF DAMPER ARRANGEMENT

FIG. 4. VIEW BACK OF THE BOILERS

An iron stop is secured to the side of the smoke flue, and so placed that the damper rests against it before it is entirely closed. These precautions prevent any possibility of the damper sticking when closed and shutting down the entire plant.

Fig. 4 presents a view of the alley back of the boilers, showing the arrangement of the smoke flue, damper regulator on the wall and blowoff pipes, of which there are two lines for each boiler; double blowoff valves are used. An iron spiral stairway gives easy access to the top of the boilers.

These boilers generate saturated steam at 150 pounds pressure per square inch, although designed for 200 pounds with provision for using superheaters at some future time, should it be deemed advisable. Considerable thought was given to the subject of superheating the steam, which is carried to the mills several hundred feet distant, but as the steam was to be reduced to 100 pounds pressure for factory uses there was but little benefit, if any, to be derived from superheating at the boilers, and it was decided that the steam in passing through the reducing valves into receivers would be superheated to some extent. As it is, the steam goes to the factory in a dry state.

The ashpit of each boiler is made with a semi V-shaped bottom. This enables the fireman to hoe the ashes out into the 6-inch inlet pipe of the Darley vacuum ash-conveying system. The main ash tube, which is 5 inches in diameter and 170 feet long, empties into an ash tank located at one end of the building and above the top level of the boilers. A 14-ounce [illegible] carried on the system is maintained by a fan direct coupled to a Curtis steam turbine.

As the 6-inch inlet ash pipe is placed under an iron section of flooring outside of the furnace fronts, it is necessary for the men to hoe the ash from the ashpit into the cement opening over the ash pipe. This pipe could have been placed under the ashpit, but it would have added to the cost of installing the system and also loss of draft when the system was in operation, and with no additional saving in labor. This system was put in on a guarantee to handle 300 pounds of ash per minute, and it will handle anything that will go through a 6-inch pipe.

Figs. 2 and 5 give a good idea of the piping layout over the boilers. The flanges are screwed onto the pipe; the ends of the pipe are then peened over and faced. A walkway at the rear of the boiler extends the length of the boiler settings, and there are steps leading to the top of the steam drums.

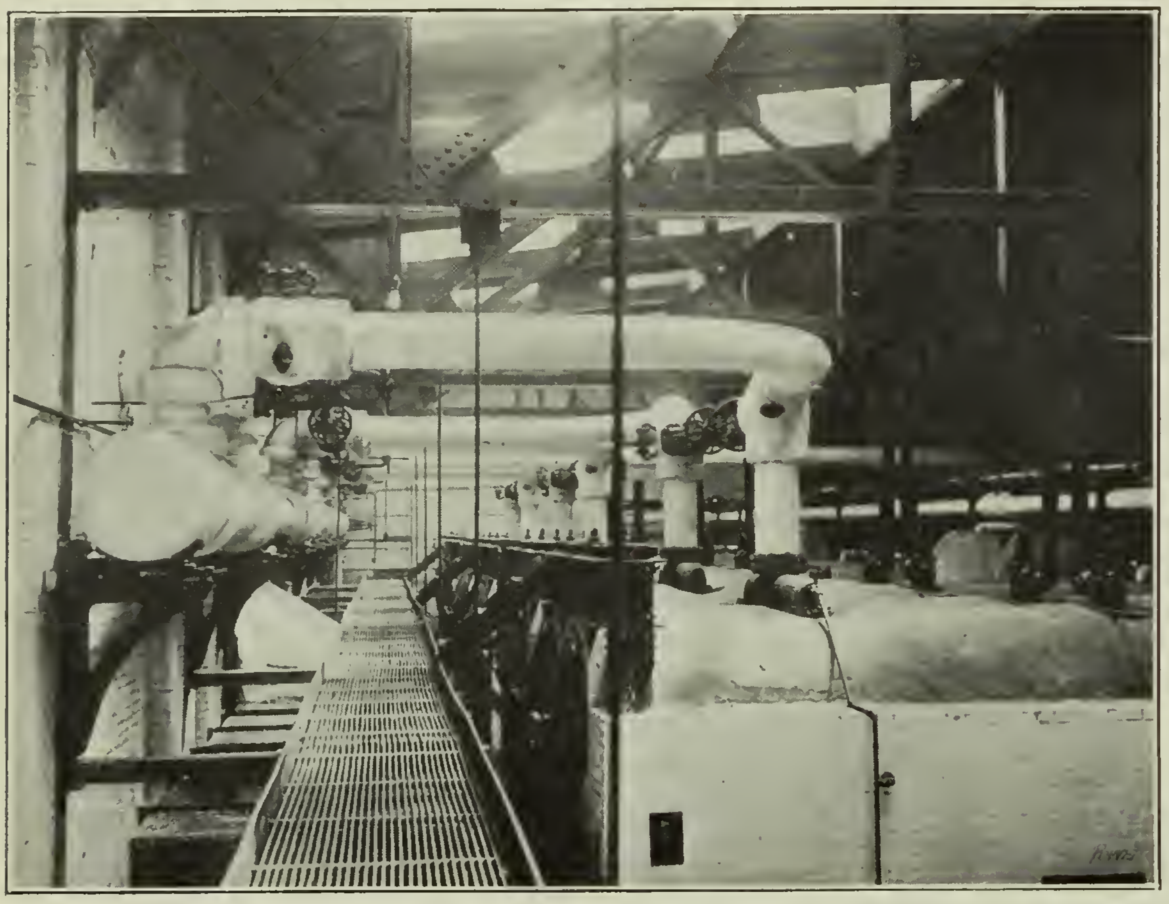

Fig. 5. Layout of Piping Over the Boilers

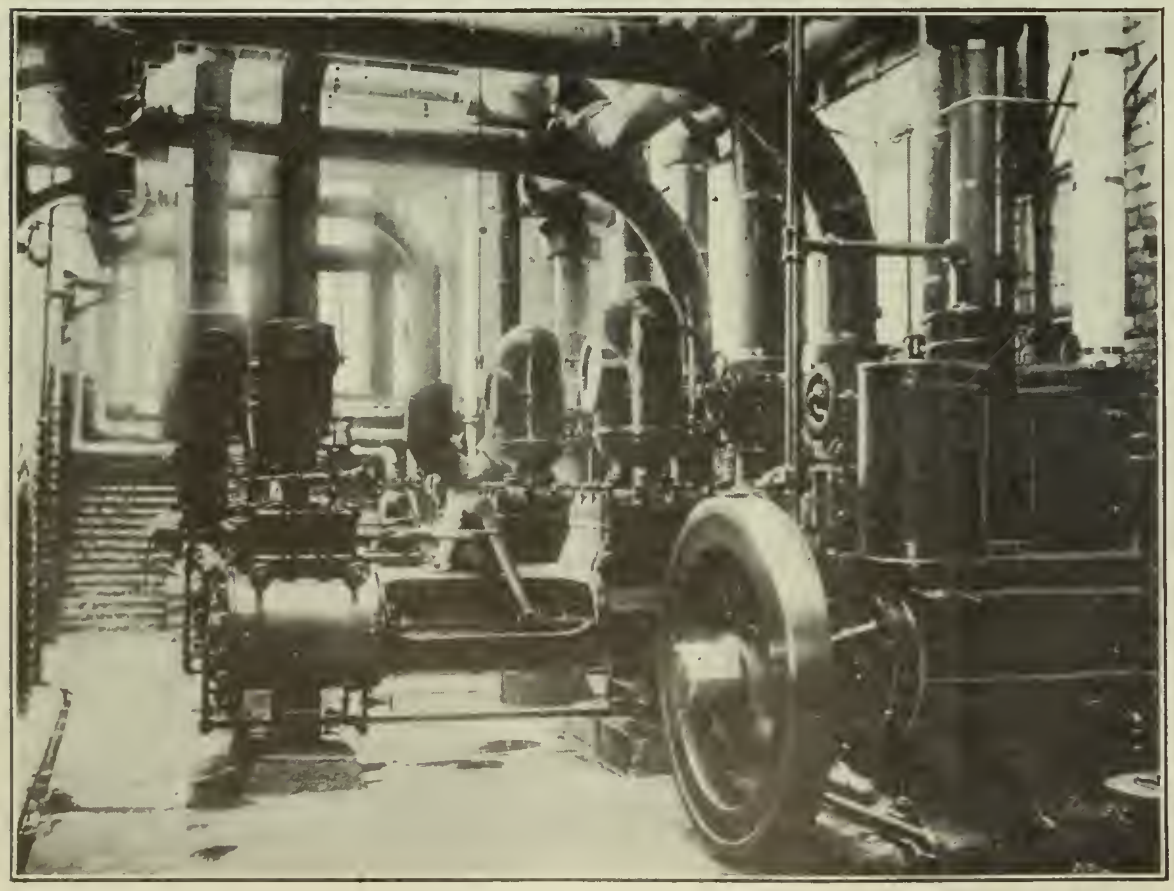

Fig. 6. Auxiliary Units

Water may be fed to the boilers by means of either one of the two Deane 12 and 7 by 12-inch duplex pumps. Each is fitted with an air chamber to prevent pulsation in the Venturi meters. There is also a Worthington four-stage centrifugal pump, direct coupled to a Terry steam turbine, which runs at a speed of 2000 revolutions per minute. The turbine-driven pump is used 24 hours a day with an occasional shutdown while the duplex pumps are being tried out to be sure they are in running condition; they are kept as emergency units. A Westinghouse engine furnishes power to operate the coal-conveying system. These auxiliary units are shown in Fig. 6.

There are six concrete-lined steel coal bins over the boilers, each having a capacity of 20 tons. The construction of the lining of these bins is rather interesting. Owing to the deteriorating action of moisture and sulphur on steel, these bins are lined with cement. Channel irons are placed on the inside of the steel casing and held in place by bolts and nuts, as shown in Fig. 7. On the outside of the channel iron is placed a layer of wire lathing which is held in place by nuts. Over this iron lathing, and filling up the space between it and the outside steel casing of the bin, is a thick coating of concrete made of a one to three mixture of cement and sand, worked hard in order to get a smooth surface.

Fig. 7. Construction of Coal Bunker

Coal is delivered to these bins from either coal cars or from the reserve supply in the yard by means of a Robins belt conveyer. Fig. 8 illustrates the method of handling the coal. This belt conveyer is 250 feet long and is driven by means of a shaft which is belted to the 60-horsepower Westinghouse engine located in the pump room. The shaft is placed underground and also supplies power for the coal-crushing rolls. Fig. 8 also shows a coal car in position over the chute and hopper leading to the crushing rolls. After the coal is crushed it is elevated to the top of the conveyer tower and is either carried to the coal bins over the boilers or is discharged onto the reserve pile in the yard, where about 2000 to 3000 tons are kept on hand for emergency. The coal flowing from the bins to the stokers through iron chutes regulates itself, as the supply banks up in the spouts as soon as sufficient coal has run down.

When it is desirable to discharge the coal into the yard, the *A* frame controlled from the yard level and shown in Fig. 8, is placed above the point where it is desired to dump the coal, and the unloading device on the conveyer set so that the coal will be discharged on both sides of the belt. Under the conveyer shed is a line of hoppers leading to an underground conveyer so that the supply in the yard can be elevated and carried to the boiler room. When the coal in the immediate vicinity of the opening has been used the outlying coal must be shoveled into the underground hopper or moved in some other way.

To reduce this labor to a minimum a portable conveyer, made something as shown in Fig. 9, is used. It consists of a long framework set on a pair of iron wheels. A 3-horsepower motor is suspended and boxed in under the frame. The belt conveyer and supporting rolls are placed on top of the framework, the belt running over rollers placed at each end of the frame. One roll shaft is fitted with a sprocket wheel which is belted to a similar wheel on the motor shaft. A stationary hopper is fixed at one end of the frame into which the coal is shoveled.

When in use, the hopper end is placed farthest from the underground conveyer and the portable conveyer set in a horizontal position. Six men can shovel into the hopper and the belt will take care of the coal without trouble. This device saves considerable labor in case coal from the outer edge of the coal pile must be used. The belt runs at a speed of about 300 feet per minute.

The coal is weighed on a Merrick scale or weightometer and a Merrick coal-weight recorder is placed in the operating engineer's office, each dial representing 200 pounds, 2 tons or 10 tons. A record is made by a pin on a revolving disk on the scale, closing a circuit and causing an electrical current to pass through a magnet coil which draws an armature down and revolves the first unit of the counter, and for every contact made the register is advanced one number, as in the case of a revolution-counting recorder. The accuracy of this combination scale and record is apparent when it is stated that a difference of only ½ of 1 per cent was found in weighing thirteen million pounds of coal as invoiced by the shipper. An average of 15,000 tons of Clearfield coal, containing 14,000 B.t.u. per pound, 9 per cent. ash and 1½ per cent. sulphur, are burned per year.

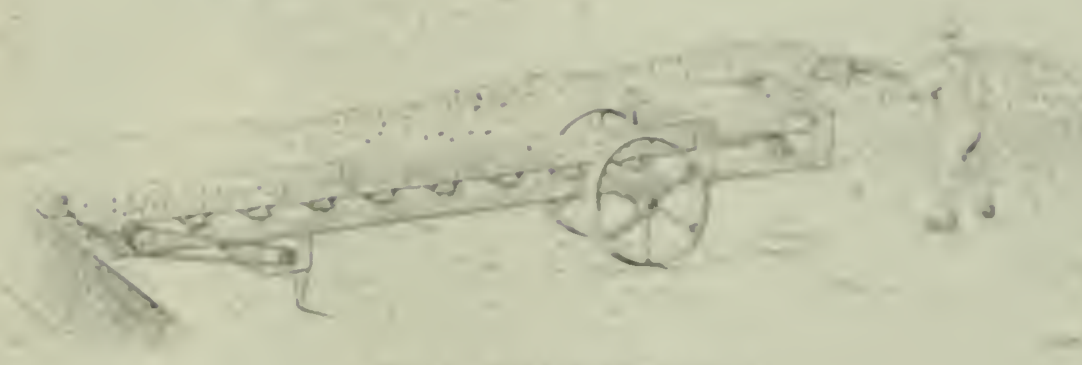

Fig. 9. Portable Conveyer

Above the boiler and overlooking the firing alley is the operating engineer's office. Here are placed the recording instruments which enable him to tell at a glance the temperature of the flue gases from each boiler and also of the gases in the main flue, temperature of the return water from the coils through the various pipe lines, the steam pressure carried and the amount of water being used.

Fig. 10 shows one corner of the office and the board on which the temperature-recording instruments are mounted.

The top central dial is the clock; the two small gages at each side are the feed-line pressure gage and vacuum gage on the ash vacuum system. At the left is shown a combination steam and recording gage, and at the right of the board is shown the draft-recording gage. The switch arrangement at the bottom of the board represents an arrangement that is unique in every detail. The switches are for the purpose of closing a circuit between the electric couples on the return hot-water line, feed-water lines, uptake for each boiler and the main smoke flue. These switches are of the double-throw type because it is the intention to install continuous recording instruments at some future date.

The Wilson-Maculen Company designed the present system. It consists of two Wilson electric indicating instruments, shown just below the two larger recording gages. One terminal of each instrument is connected to a line leading to the electric couple, the other terminal of each instrument is connected to the upper contact jaw of the switch of the couple to be tested. The center or pivot post of the switch is connected to the grounded end of the electric couple.

All that is necessary in order to ascertain the temperature of any return line or uptake temperature is to throw the switch corresponding to the right electric couple so as to form an electric circuit through the indicating instrument. No two couples can be connected to the instrument at one time, so the chances of error are entirely eliminated in case two or more switches should be thrown at the same time. The couples on the water lines are of the compound type; the temperature of the flue gases is obtained by simple couples. There are three return water lines from the coils and two feed lines to the boilers, one being used as an alternative line. The thermo-couples for the flue gases are located in the smoke flue at the rear of each boiler. The average temperature of the main-flue gases is 500 degrees Fahrenheit.

A feed-water temperature of 190 degrees is obtained after passing the feed through a heater. With a temperature of 80 degrees on the grounded end of the thermocouple the readings for the various boilers vary but 25 degrees the

Fig. 8. Coal Conveyer and Coal-storage Yard

all seasons of the year, but simple adjustments for season change reduce the variations in the readings to 5 degrees.

The water consumption for the six boilers runs as high as 100,000 pounds per hour, this volume fluctuating with the stage of water supplied to the water-wheels, with which the three mills are equipped.

The amount of water consumed in the plant is recorded by a Venturi water meter that is located in the office. The chart scale is graduated into thousands of pounds per hour, and the total amount is measured by a planimeter on daily charts. Each feed line is equipped with a Venturi meter and a third meter is connected to a bypass feed line, as shown in Fig. 11. This allows running any one boiler on a test, and the amount of water used is metered without interfering with the total amount of water passing through the meter in the main feed line. For instance, suppose all of the water being used by the boilers is being passed through the meter on feed line No. 1. If a test is to be made on a single boiler, the valve on feed line No. 1 between the meter and the boiler to be tested is closed and the regulating valve on feed pipe No. 2 opened. The valves *A*, *B*, *C* and *D* are open and valves *E*, *F* and *G* closed. The flow of water to the boiler being tested would be through the main feed line No. 1, the meter *M* and valves *A* and *B*, meter *N* and valves *C* and *D*

REMARKS:

to the feed line No. 2 and into the boiler. This allows the entire amount of water used in all boilers to pass through the meter M, but the water used in the boiler being tested passes through meter N, so that its water consumption can be accurately measured. The mercury gage for the small Venturi meter used on this test is located in the office, as shown in Fig. 10.

A Wonsever CO_2 recorder, placed in the office, registers the performances of the furnaces. Fig. 12 shows a performance worthy of notice, and represents a ten-hour test that was run to determine the CO_2 content of the flue gases. The continuous lines denote the record obtained from the Wonsever recorder and the heavy line on which the circles appear represents the time of taking and the percentage of CO_2 obtained from a hand Orsat recorder. Forty-five samples of gas were taken just inside of the back nipples of the boiler, during the ten-hour test. The average of the CO_2 record of the Wonsever recorder shows 11.73 per cent. and that of the hand Orsat 12.10 per cent.

The accompanying boiler test gives a good average of the boiler performance at the time of the test.

A reproduction of the boiler-room daily report sheet is shown below. These sheets are bound in book form with two bullard sheets, one for filing with the chief engineer, the other a carbon copy to be filed by the operating engineer. The daily report sheet is 13x24½ inches.

It is so ruled and tabulated that scarcely any explanation is necessary for the reader to understand. The spaces devoted to coal under columns I, II, and III enable the engineers to determine the amount of coal on hand at the end of each day's run. Under column I, record is made of the coal consigned from the coal car to the yard; column II is a record of the coal taken from the car and conveyed to the coal bins over the boilers, and column III is a record of the coal taken from the yard to the bunkers. adding the amount of coal taken from the cars and that taken from the yard the total amount consumed during the day is determined, and deducting the amount of coal taken from the yard, the total amount in the yard as indicated from the previous report is ascertained, which is carried on for each day's report to the next and shows the total amount of coal in storage. Therefore, there is no guess work as to the amount of coal in the yard at the end of any day's run.

The weekly report is a condensation of the daily report, and is made on 8½x19-inch sheets. In case any particular item is in question, it is easily checked by referring to the daily report sheets of the same dates given on the weekly report sheets. These report sheets are perforated at one end, making it easy to tear out of the book. They are also punched for placing in a binder so that the sheets may be readily filed.

The foregoing information and illustrations were obtained through the courtesy of Edward P. Butts, chief engineer of the company.

Central Station vs. Factory Plant

By Henry D. Jackson

Two instances in which the conditions were such that although the tentative figures submitted by the central-station management were in their favor, the actual results proved that a greater saving would have been effected by the installation of individual plants.

For the past few years, central-station men have been making a considerable stir regarding the possibilities of economy in the operation of factory plants through purchased power, the argument being that the central station—owing to the character of its load, type of machinery and the location of its plant—could produce and deliver power to the manufacturing plant at a lower price than a manufacturing plant could generate it.

The central-station men take the stand that the use of exhaust steam for heating, or for any other purpose, has no material bearing upon the cost of power. They usually contend that the back pressure necessitated by the heating system is so great that the increased steam consumption by the engine more than neutralizes the gain which might be obtained through the use of this steam for heating purposes; in other words, they claim that it is fully as cheap, and in some cases cheaper, to heat by steam direct from the boiler than by exhaust steam from the engine. Although this may be true under certain conditions, it is by no means true in many cases, particularly in those plants requiring the use of steam in any considerable quantity for heating and other purposes, where low-pressure steam can do the work.

A properly arranged heating system will not put back pressure on the engine, and where a plant is operating condensing, it is sometimes possible to operate a vacuum system of heating, utilizing the exhaust steam from the engine and reducing the vacuum of the condenser to a point which will allow sufficient steam to flow through the heating system. This, however, is available in comparatively few plants, as the gain thereby is not sufficient to warrant it.

An example of central-station engineering recently came to the writer's attention in a plant requiring considerable power for operating its machinery and for lighting. The central station made the claim and apparently substantiated it with figures of its own making, to prove that it would be more economical to operate with electric drive—the power to be furnished by the lighting company—than with the original belt drive. The owners were convinced of the advisability of the change and installed the electrical equipment, apparently under the engineering advice of the central station. To the great astonishment of the owners, after the installation was complete, the cost of operating the factory, instead of decreasing, increased to a very marked extent. It was at first supposed that increased production was the cause of the increased cost, but a comparison of the output soon showed this to be untrue; the production was less but the cost greater.

Numerous attempts were made to locate the trouble but without success until a few carefully made tests throughout the factory and a thorough examination of the conditions existing about the installation, showed that while a large amount of heavy shafting and countershafting had been removed with its attendant friction, the actual friction power was still far in excess of what it should have been in a properly laid out electric drive. The rooms were low studded and the shafting was quite close to the ceiling, so that the permissible diameters of the pulleys were restricted. The motors were of the highest speed obtainable, in most cases, to reduce first cost. The ratio of pulley diameters was far too great for the economical transmission of power, and the exceedingly small motor pulleys and short centers required a very heavy belt tension which deflected the shafting itself; this deflection naturally caused a heavy friction loss throughout the entire line shafting.

It was further found that much of the machinery, which was intermittent in operation, would not operate satisfactorily, owing to the excessive slip on the small motor pulleys when the machines were put into service. In other cases where the shafting was run along the floor, motors were hung on the ceiling underneath, the belts running through the floor to the shafting. The ratio of pulley diameters was about 5 to 1, the motor pulleys being approximately 3 inches in diameter and the distance between centers about 3 feet. The friction loss on these particular shafts was about 98 per cent. of the total power required to operate when the machinery was in service. In many cases throughout the factory, the friction power required to drive motors and shafting was over 75 per cent. of the average power required. A careful study of all the conditions showed that the power required to operate the shafting and motors alone was considerably over 50 per cent. of the total power required to operate the factory under full-load conditions.

Further study showed that had the electric company agreed to furnish power for one-half of its regular charge, the total cost of operating the plant, including heat, would have been practically the same as that which existed with the original belt drive; also, that a change in the methods of drive would result in a marked decrease in the friction loss; and as steam was required for heating purposes practically the year round, the plant could generate its own power for approximately one-half that which the lighting company could furnish it. Hence, under the conditions of decreased friction, the plant could generate its own power and utilize it throughout the factory with a considerable saving over the old belted installation. The figures included all of the fixed charges on the plant, as well as all of the operating charges.

A few instances of waste power were discovered, which could readily be remedied, among them being one place where forced circulation of air was used for drying purposes. A comparatively inexpensive change in the arrangement of the drying outfit would do away entirely with the use of power. It was also found that certain pieces of apparatus which were used all day were connected across the lighting circuits and might readily be put on the power circuits. There was, however, a difference in the charge for light and power of approximately two to one, so that it was to the advantage of the central station to have these pieces of apparatus on the lighting circuit.

Another instance which came to the writer's attention was in a comparatively large establishment, to which power was offered for approximately $40 a horsepower-year of 3080 hours, and an attempt was made to show that power was costing the owners considerably more than this figure. A study of this plant showed, to the contrary, that power was costing them far less than $40 a horsepower-year. This surprised the owners and also the lighting company. The reason for it, however, was plain enough; in the first place, at least double the amount of steam was required for various purposes throughout the plant that was required for power production. The temperatures required were such that exhaust steam or low-pressure steam was effective, so that the engines used did not need to be bought for steam economy and were not, and this heat was required the year round. Furthermore, waste material from the plant which could be sold for practically nothing could, to a large extent, be utilized for fuel; in fact, for many days out of the year little or no coal was used, so that the fuel bill was exceedingly small. The cost of the installation itself was low, the attendance was small compared to the size of the plant, and as a result the total power bill per horsepower-year was considerably under that which could be offered by the electric company.

In their figures, the electric company took the stand that the coal required was approximately four pounds per horsepower-hour, that the steam plant cost in the neighborhood of $100 per horsepower, and that the attendance on the basis of a plant operating twenty-four hours a day, also interest, maintenance and depreciation, were figured at excessive rates.

These are two of the most glaring instances the writer has yet come across, but there are numerous other instances where the management of a central-station plant has made use of figures which were hardly reliable and made claims of being able to furnish power at prices which the owners could, if they but knew how, readily prove to be exorbitant.

There are many plants which can profitably buy power from a central station, but there are also many plants where the central station cannot afford to make a price which the owner should listen to. These are due very largely to local conditions, but they exist in practically every locality where power is sold. No manufacturer can afford to neglect the cost of heating, either for the buildings or for special processes of manufacturing as a part of the operating cost of his plant; and when a central station offers power at what seems to be an exceedingly low rate, he should take into account when making a comparison, what it costs him to purchase power and supply all of the heat required, as compared to what it will cost him to operate his own plant, supplying all the heat required. If he is not capable of making this comparison in a thoroughly accurate manner, he should employ someone who can. It should be noted particularly that in making these comparisons, it is absolutely essential that every item entering into the cost be figured, such as labor, coal, water, oil, taxes, interest, maintenance, depreciation, etc.

Loaded Safety Valve

By M. [illegible]

Michigan has been responsible for a great many interesting engineering combinations, and the one illustrated herewith is another of which she will have to take the responsibility.

Anyone interested can figure out at

Weighted Safety Valve

what pressure the safety valve, shown in the accompanying illustration, will blow, with 123½ pounds weight on the lever that has a length of 3 feet 10 inches, a fulcrum of 2½ inches, and a valve diameter of 2½ inches. In making the calculations it will, of course, be necessary to neglect the possible effect of corrosion resulting from long continued inaction.

John Brown & Co., Ltd., of Clyde Bank, the builders of the "Lusitania," the "Carmania" and the "Caronia," have received an order from the Cunard company for a new Atlantic liner exceeding in power and dimensions the "Olympic" and "Titanic," being built by Harland & Wolff, of the White Star Line. The design has not yet been finally settled but Engineering gives the probable dimensions at about 900 feet over all, about 50,000 tons gross tonnage, and 70,000 to 80,000 shaft horsepower, which is expected to give a sea speed of 25 knots in service. The machinery will be of the turbine type, driving four shafts and screws.

Piping Layout of Closed Heaters

By W. H. Wakeman

The exhaust steam for heating the feed water is led into the main heater and the surplus steam then carried over to an auxiliary heater supplying water for manufacturing purposes.

In Fig. 1 are shown two closed heaters located in a shop where considerable steam is used for heating water for manufacturing purposes, in addition to the boiler supply. It is necessary to use more or less live steam for this purpose, but inasmuch as it takes only about one-sixth of the exhaust steam from an engine to heat the feed water, there is a large surplus which can be used for other purposes. No special advantage is gained by the use of two heaters, as the same results may be secured with one if large enough to do the work. However, it should be fitted with two independent coils so that it will be impossible for employees of the shop to use water which the engineer needs for the boilers.

Where two heaters are in service it is often because of the fact that only one was formerly used, and that the demands for hot water had increased until this was no longer sufficient for the purpose, resulting in its being taken out and a larger one substituted and the old one connected up afterward in order to use all of the exhaust steam. In the present case, exhaust steam passes through the larger heater, and what is left is prevented from going directly to the atmosphere by the back-pressure valve. Therefore, it passes to the right, through a pipe which projects through a brick wall, beyond which there is a tee connecting with a smaller heater; this has no outlet on the bottom except a drip for removing water of condensation. Steam passes readily into a heater piped in this way, because water passing through the coil condenses some of the steam and creates a partial vacuum; more steam rushes in to fill this space and the supply is maintained as long as there is any steam passing through the horizontal pipe. If any is left it passes on to be used for other purposes.

There are at least two ways for connecting the water pipes of such a system, the better of which is here shown. Water from the pump passes to the bottom of the large heater and coming out at the top is conducted through the upper pipe to the boilers. This insures hot water for the boilers as long as the engine sends enough exhaust steam through the first heater. Entering near the bottom of the smaller heater, the water for manufacturing purposes passes upward and out near the top, then enters the right-hand side of the larger heater. A separate coil is provided for this water and the outlet is on the same side near the top, whence it passes to the shop as indicated.

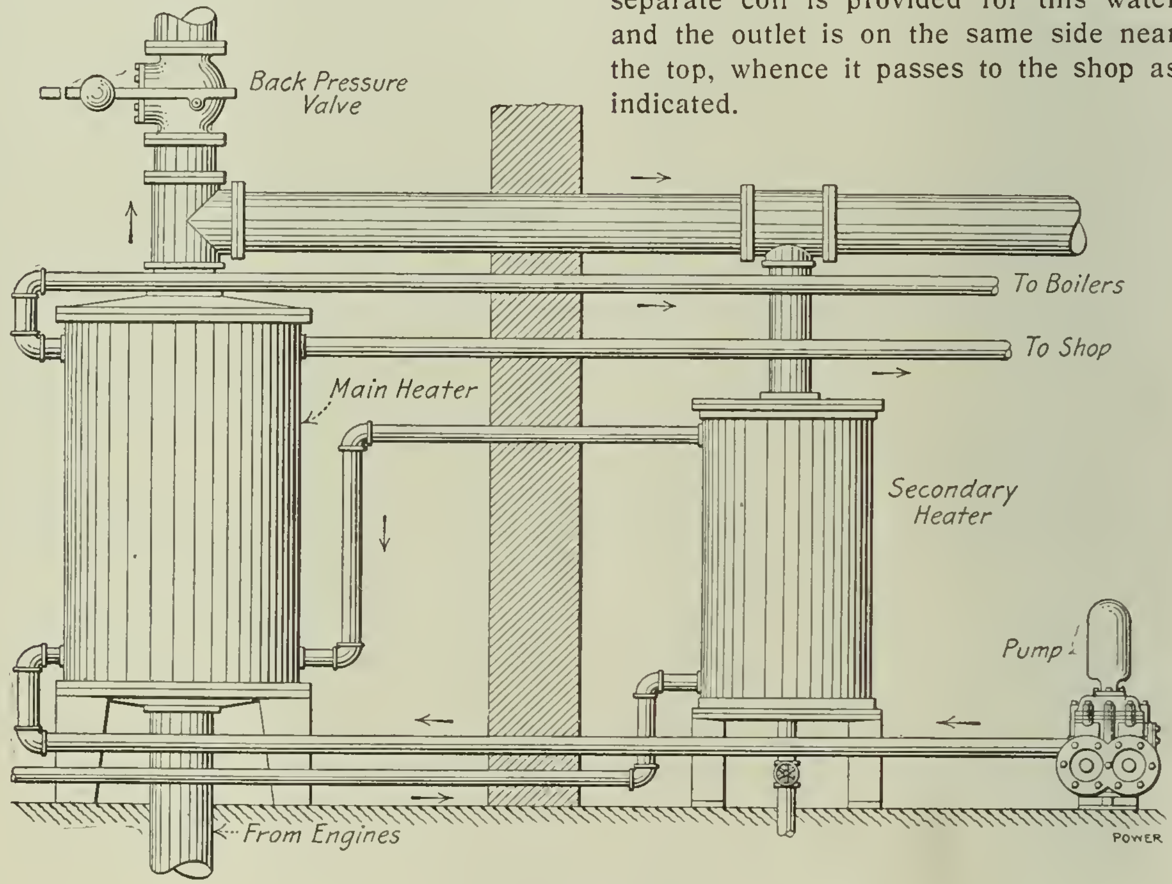

Fig. 1. Main and Secondary Heaters

The engineer of the plant laid out this arrangement of piping, and insisted upon its adoption, although it was not favored by the superintendent; the latter wished to have water for the shop service go into the larger heater before it went into the smaller one. The reason for this difference of opinion is evident. The engineer's plan insures hot water for the boilers, and if there is not sufficient exhaust steam to supply everything, the shop service fails to obtain the required heat. The superintendent's plan would insure hot water for the shop service, and lack of exhaust steam to fill all demands would result in sending comparatively cold water into the boilers. As a rule, it is better to introduce the cold water into a heater near the point at which the exhaust steam escapes, but this is ignored where it would necessitate the use of extra piping and fittings.

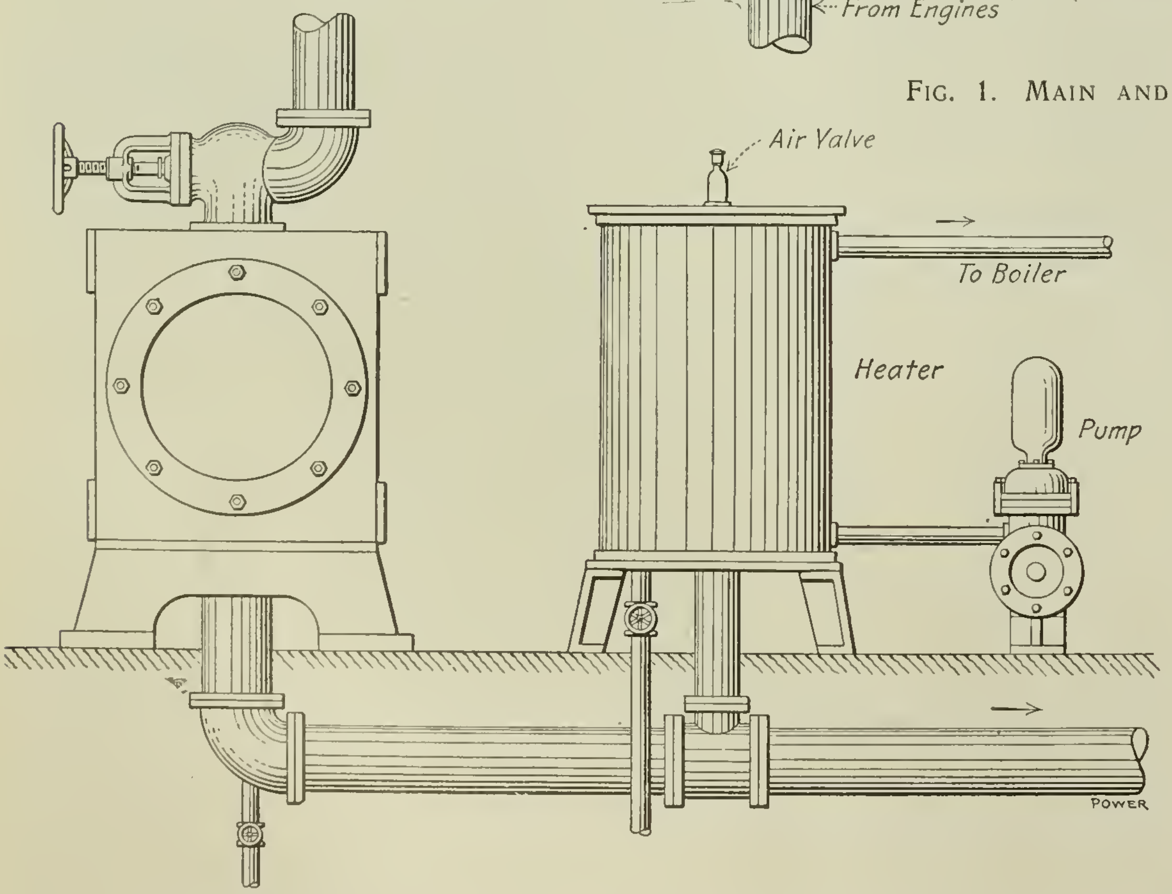

Fig. 2. A Common Arrangement of Piping Heater to Engine

Fig. 2 illustrates a neat arrangement for a heater which is used for the boiler-feed water only. The exhaust pipe is carried under the floor as usual, but it contains a tee the outlet of which projects upward, the pipe from it entering the heater. No outlet is required, but an air valve is provided to release the air which is trapped in the heater when the engine is started. A drip pipe is provided to let out the water of condensation, which, if allowed to flow back through the exhaust pipe, would interfere with the free circulation of the steam.

Exhaust Steam Turbines in England

By James A. Seager

The exhaust steam from the blast-furnace engines is superheated and used at atmospheric pressure in two turbo-generators which supply power to the surrounding districts.

An interesting development in the use of exhaust steam is to be found at the iron works of B. Samuelson & Co., of Middlesborough, England. Here the exhaust steam from the blast-furnace engines is collected and after being superheated is utilized in low-pressure turbo-generators which supply power to consumers as far north as the Tyne. The turbines are of the double-flow Parsons type with water-sealed glands arranged for operating with steam in the event of the water supply failing, and also for use when starting. A view of the turbines and generators is shown in Fig. 1. The governors are of the centrifugal type, driven direct through a worm gear and shaft from the turbine spindle, and control the valve which admits steam to the turbines. Two methods are provided for shutting down the turbines in case the speed should tend to increase above 10 per cent. over normal: one closes the governor valve and the other opens a large air connection to the condenser, thus destroying the vacuum without which the turbine cannot operate.

Fig. 1. General View of Low-pressure Turbines

The surface condensers are placed directly beneath the turbines, Fig. 2 showing one end of a condenser together with the other auxiliaries. A striking feature is that there is no reciprocating apparatus in the whole installation, the dry-air pumps being of the Leblanc type and wet-vacuum pumps of the two-stage centrifugal type. Elaborate arrangements are made to keep the condenser and pumps free from mud or foreign matter which may be deposited from the circulating water drawn from the river.

On regular full-load service the condensers maintain a vacuum of 29 to 29½ inches with the barometer at 30 inches. In order to keep a continuous check on the steam consumption of the turbine the wet-vacuum pump delivers into a special measuring tank in the basement, from which the water is returned to be used over again.

The generators are of the three-phase, two-pole, revolving field type each capable of delivering 1250 kilowatts at a voltage of 6600. The guaranteed steam consumption of the unit was 27 pounds per kilowatt-hour with steam at atmospheric pressure superheated 50 degrees Fahrenheit and exhausting into a vacuum of 28.8 inches, referred to a 30-inch barometric pressure. These figures were easily attained on the recent official tests.

Fig. 2. Condenser and Pumps

According to a note in the *Electrical Review*, the total available horsepower of the rivers of Canada is stated to be 25,982,907 on the basis of minimum flow development. Of this total only about 2 per cent.—516,887 horsepower—is now developed. The distribution of the water powers in the various provinces is as follows, the figures representing horsepower: Yukon, 470,000; British Columbia, 2,065,500; Alberta, 1,144,000; Saskatchewan, 500,000; Manitoba, 504,000; North-West Territories, 600,000; Ontario, 3,129,168; Quebec, 17,075,000; New Brunswick, 150,000; Nova Scotia, 54,300.

Firing Boilers with Pulverized Coal

By W. S. Worth

A 300-horsepower boiler at the Henry Phipps plant in Pittsburg has been fitted with the Blake system of pulverizing coal, and during a period of two hundred days' operation has shown a high degree of economy. With this system the proper mixture of air and fuel is attained in the pulverizer, hence complete combustion takes place in the furnace. By using a set of nozzles the flame does not come in direct contact with the tubes.

About a year ago, a 300-horsepower boiler at the Henry Phipps power plant, Pittsburg, Penn., was fitted with a device for burning pulverized coal. This has been in operation about 200 days and has proved very satisfactory. Several tests and the records of the plant show that it has a high efficiency and that there is a considerable saving of fuel as compared with the other boilers of the same type fitted with mechanical stokers. The system is the invention of J. E. Blake, of New York, who spent 14 years in its development.

Principle of Operation

Referring to Figs. 1 and 2, the coal is crushed by an ordinary commercial crusher into small lumps about the size of cherries, and placed in the feed hopper of the pulverizer and blower, from which it is fed into the machine by an endless screw. The pulverizer is of the rotary type driven by a 12-horsepower motor. From Fig. 2 it will be seen that the coal, upon entering the chamber, is struck by the revolving paddles which break up the lumps into smaller fragments. The centrifugal force produced by the rotary motion given to the larger-sized lumps causes them to revolve near the surface of the cylinder and the baffles prevent them from passing to the second chamber. The air is drawn into the first chamber with the coal through passage *A* and also through the opening *B* around the shaft. After being given a whirling motion by the rotor, it passes to the second chamber and thence through the successive chambers, receiving in each a whirling motion before passing to the next. The smaller and lighter particles of coal in the first chamber are caught in the whirl of air and carried to the second chamber where the pulverization becomes finer, and so on throughout the successive stages until in the fourth chamber it is reduced to a fine powder suitable for burning. After entering the fan chamber, the mixture of coal dust and air receives an additional supply of air which is drawn into the fan chamber through the opening *C* and is discharged in an intimate mixture into two pipes conducting the mixture to the furnace. The air entering through openings *A*, *B* and *C* prevents the escape of coal dust.

Each pipe branches into a distributer, from which cylindrical nozzles discharge the mixture into the furnace, where it burns with a long flame closely resembling that of natural gas, except for the luminous particles heated to incandescence. The flame, which is directed downward at an angle of about 20 degrees to the vertical, impinges upon the bottom of the furnace, forming eddy currents, and the minute particles of coal dust burn completely while in suspension, the gases then passing over the heating surfaces of the boiler.

As the refractory lining of the furnace is heated to a high temperature, it assists in producing complete combustion. The furnace is of the reverberatory type, its action being the reverse of the ordinary industrial type.

Crusher

The crusher is of the ordinary vertical "coffee-mill" type and is belted to a one-horsepower motor. Low-grade slack coal is fed into the crusher by hand and is crushed into small lumps suitable for feeding into the pulverizer. The crushed coal is transported and charged into the pulverizer by hand. As the capacity of the crusher is greater than that of the pulverizer, it is not run continuously, the supply being crushed at suitable intervals.

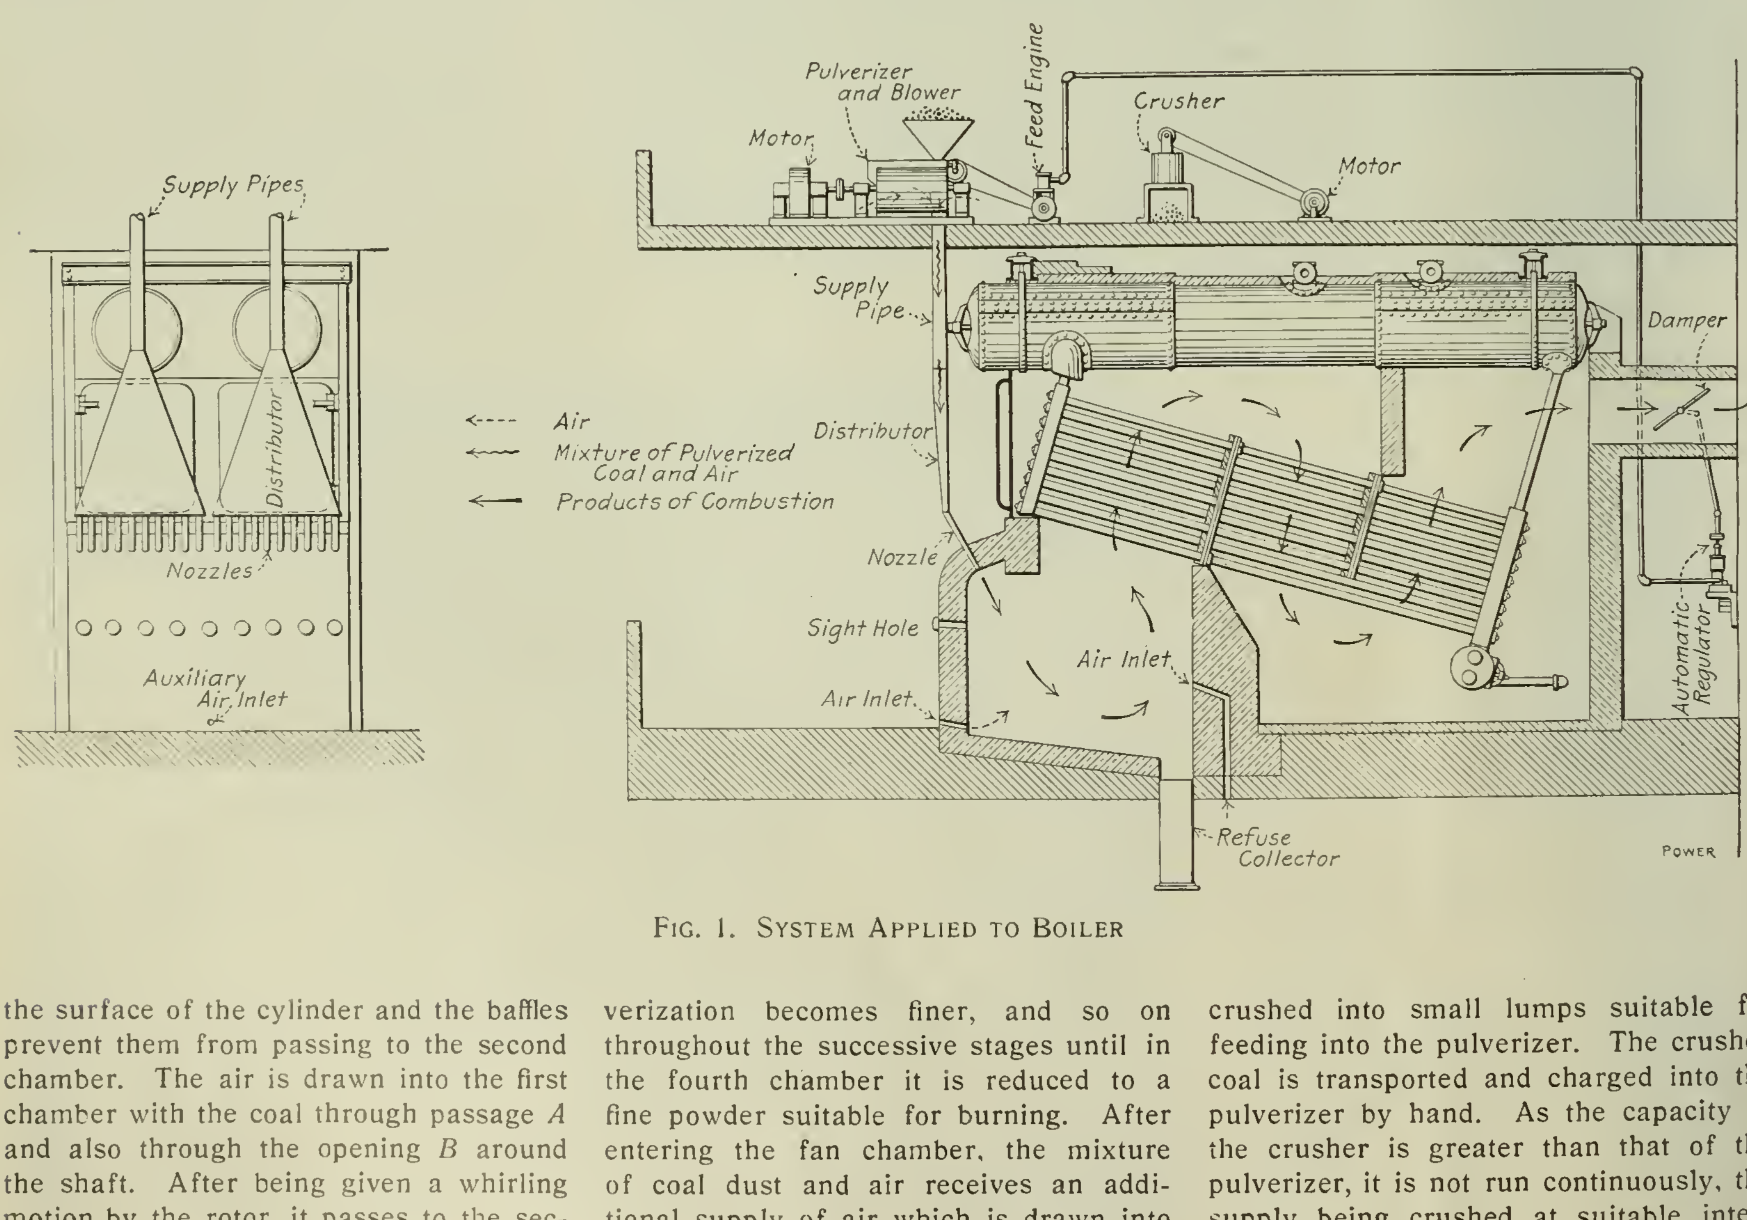

Fig. 1. System Applied to Boiler

Pulverizer and Blower

The pulverizer and blower are driven at a speed of 1200 revolutions per minute by a 12-horsepower motor direct connected to the rotor of the pulverizer. A small simple engine is belted to the feeding screw of the pulverizer. The casing of the present pulverizer and blower is made of boiler plate, but it is intended in the future to make this of cast iron divided horizontally on the center line as shown. The rotor consists of a steel shaft, carried in ring-lubricated bearings, to which are keyed the forged-steel rotors. To the arms of the rotor are bolted the paddles, which consist of hard tempered-steel plates.

The fineness to which the coal is pulverized depends upon the character of the coal and the required length of flame—the powder usually being from 80 to 120 mesh fine—and is regulated by the velocity of the air passing through with the coal; if the velocity is high, the powder will be coarse, and *vice versa*. The areas of the openings *B* and *C* can be adjusted to give the desired flow of air. The discharge pressure of the mixture is from $\frac{1}{2}$ to $\frac{3}{4}$ inch of water.

It is planned to improve future machines of this kind by mounting the crusher on the pulverizer and operating it from the driving motor. A small model, about the size of a derby hat, in which these improvements were incorporated, was used successfully in firing a 12-horsepower boiler. In future designs, provision will also be made for varying the speed to suit the conditions.

Supply Pipes, Distributors and Nozzles

As shown in Fig. 1, the pulverizer discharges into a header from which the coal passes to the supply pipes, distributors and nozzles, all of which are made of No. 24-gage sheet iron. As no valves or cutouts are fitted, all nozzles are used regardless of the rate of combustion, there being eleven 2-inch cylindrical nozzles leading from each distributor: twenty-two in all.

Furnace

The furnace is lined with ordinary firebrick and has a refuse collector in the back, as shown in Fig. 1. It is about 5 feet long, 7 feet high (from the bottom to the boiler tubes) and 6 feet wide. The interior can be observed through peep holes in the front and one in a door at the side. A small supply of air, about 5 per cent. of the total supply, may be admitted to suit conditions through one opening in front and another in the back. The refuse collector extends through the floor and has an opening through which the refuse is run into a car on the floor below.

Automatic Regulator

The amount of coal fed, which is regulated by the speed of the engine driving the feed screw, is automatically controlled by a regulator in such a way that a decrease in boiler pressure increases the amount of coal fed, and vice versa. This regulator, which is located behind the boiler, controls the opening of the uptake damper and the amount of steam admitted to the engine which operates the feed. Referring to Fig. 3, the apparatus works as follows: Steam from the boiler is admitted through pipe *A* into the chamber below cylinder *B*, containing a diaphragm upon which the steam pressure acts. Lever *E* pivoted at *D* and carrying weight *F* acts on the diaphragm at *C*, resisting the steam pressure beneath it. The movement of lever *E*, caused by the rise or fall in boiler pressure, opens or closes an electric circuit at contact *G*. When the pressure rises and the contact is made, the current energizes the solenoid *I* and causes its armature to rise, thereby raising the lever *J* which, in turn, reverses the stem *K* and the valve which it carries. This opening of the valve in cylinder *L* permits water under pressure to flow from pipe *M*, which is connected to the fire system, through the valve and pipe *N* into cylinder *O*. This cylinder contains a piston attached to the rod *P*, which rises when the pressure of the water is sufficient to overcome the weight on the piston. The rise of the piston rod, which is connected at *R* by levers to the uptake damper, causes the latter to close an amount corresponding to this movement. Should the piston rise sufficiently, the collar *S* will strike the arm *T*, lifting it together with rod *U* and rack *V*. The movement of rack *V* rotates the spur wheel *W*, which, in turn, moves the valve contained in *X*. The movement of this valve reduces the amount of steam flowing from the boiler through *Y*, *X* and *Z* to the engine operating the pulverizer feed, decreasing its speed, the quantity of coal fed and consequently the rate of combustion.

A fall in pressure permits lever *E* to drop; this breaks the circuit at *G* and shuts off the current from solenoid *I*, the armature of which descends and turns the valve in cylinder *L*. This shuts off the water entering through *M* and connects the cylinder, through pipe *N*, to the waste pipe *Q*, thus permitting water to flow out of the cylinder and allowing the piston and rod *P* to descend. The movement of *P* opens the uptake damper to which it is connected, and, if the movement be sufficient, collar *S* will strike the arm *T* and cause a downward movement of rack *V* which rotates the valve in *X* and admits more steam to the engine, in this way increasing the feed.

The boiler pressure can be adjusted as required by increasing or decreasing the weight *F*. The amplitude of the movement of lever *E* can be regulated by set screws *G'* and *E'*. The stroke of the piston and rod *P* can be adjusted by collar *S*, and the speed of the engine is adjusted with collars *S* and *P* as it should.

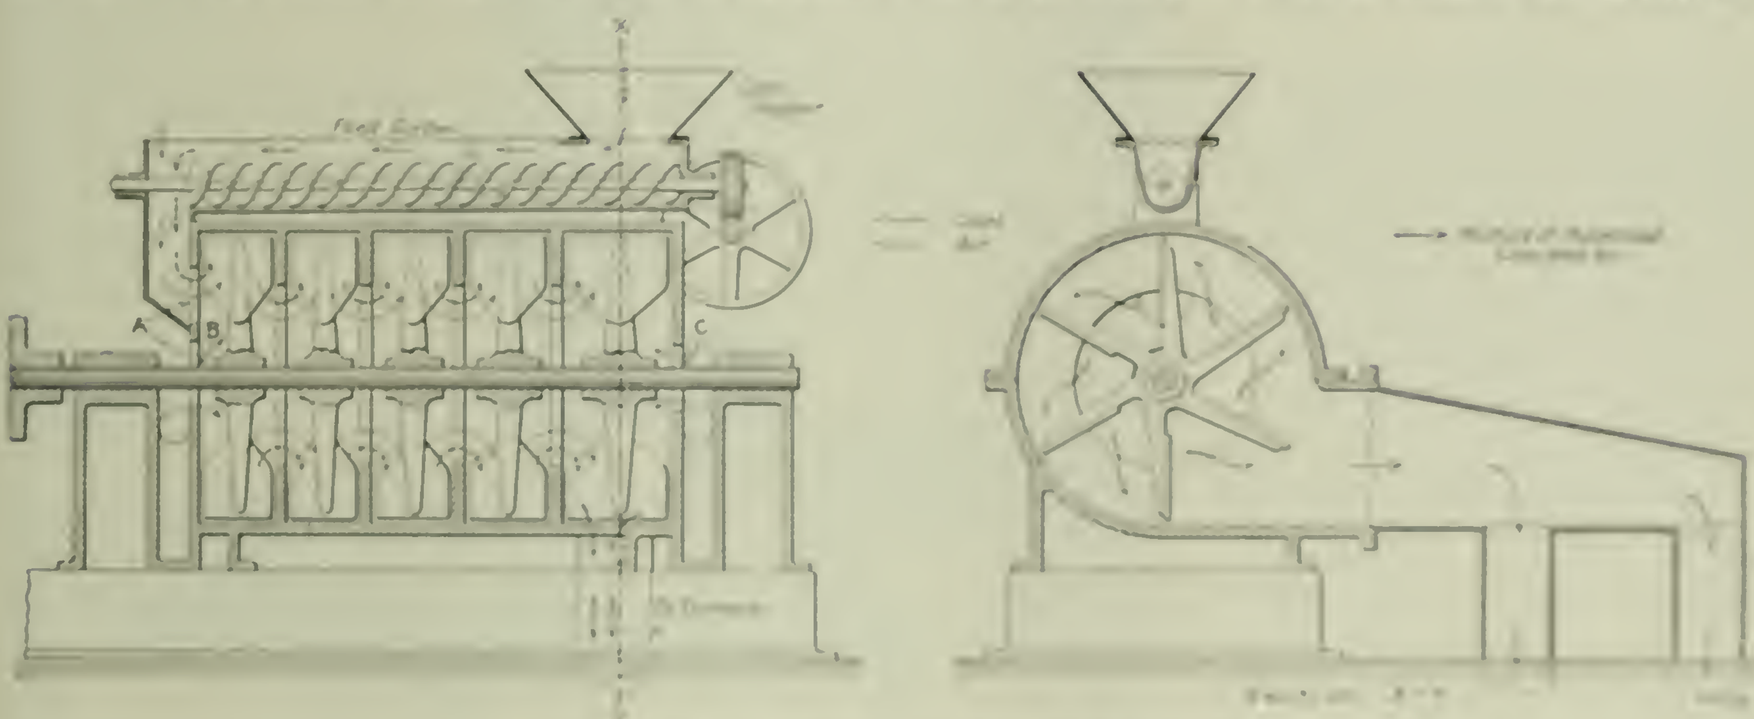

Fig. 2. Section through Pulverizer and Blower

arm T may be clamped to the rod by set screw F'.

The operation of the regulator is very satisfactory and there is no difficulty in regulating the pressure to give a variation of less than five pounds. Although it is used here to regulate only one boiler, it can be used for several.

TEST WITH PULVERIZED COAL AT THE HENRY PHIPPS POWER PLANT.

Duration of test, hours..........	6
Total weight of coal, fired, pounds	5,160
Total weight of water, pounds...	56,160
Average temperature feed water, degrees Fahrenheit............	186
Average steam pressure, pounds per square inch................	162.3
Factor of evaporation...........	1.084
Water evaporated per pound of coal (actual, pounds)..........	10.88
Water evaporated per pound from and at 212 degrees, pounds....	11.725
Boiler efficiency (coal containing 14,350 B.t.u.), per cent........	78.93
Horsepower of boiler............	294.6
Builder's rating.................	300
Temperature of escaping gases, degrees Fahrenheit.............	386
Cost of coal, 2.58 tons @ $1.315 per ton........................	$3.392
Cost of coal per pound..........	0.0006575
Pounds of coal per boiler horsepower per hour...............	2.92
Cost of coal per boiler horsepower, cents........................	0.19199

Economy

The foregoing table shows the results of a test made by the superintending engineer of the plant. This test agrees very closely with other tests which have been made, none of which show a boiler efficiency less than 77 per cent. In making these tests, the evaporation was determined by measuring the amount of water fed to the boiler.

It should be noted that the temperature of the escaping gases is very low. Under the usual working conditions it does not exceed 400 degrees Fahrenheit, and after uniform conditions have been attained it does not vary over 25 degrees. The power-house records show that this boiler is much more economical in coal consumption than the other boilers and it is claimed that the saving in fuel exceeds 11 per cent. In addition to the saving in the quantity of fuel, a considerable saving in the cost of operation is effected because of the following factors: Cheaper coal is used—the coal for the boiler using pulverized coal costs 4 cents per bushel, whereas the coal for the other boilers costs 5 cents; fewer repairs are required; and, in addition to these, may be added for future plants, less cost for attendance and less wear and tear on the boiler, due to the uniform temperature.

Operation and Performance

To get up steam, a wood fire is first built in the furnace and the pulverizer is started supplying air and fuel, moderately at first and finally working up to the normal rate of combustion. There is no difficulty in starting as the mixture ignites readily and burns with a steady flame. The combustion is more perfect, however, when the flame is not cooled by impinging upon the cold surfaces of the furnace. It requires about three hours to heat the furnace to its normal running heat, after which the high temperature of the furnace assists in producing complete combustion. The time required to raise steam depends upon the rate of combustion. Ordinarily steam is raised in about an hour, but this time could be reduced to half an hour if desired.

When normal running conditions have been established, the combustion is completed before the gases pass to the tubes. All parts of the furnace are clearly visible as there is no smoke and the flame is unusually transparent. Moreover, there is practically no noise from the furnace.

The refuse is a fine light powder, resembling fine sand, and containing no unconsumed carbon. It is neither corrosive nor adhesive and can be easily handled with compressed air. This dust collects on the tops of the horizontal tubes but does not adhere to the remainder of the tube surfaces. When the apex of the pile of dust on a tube reaches a certain hight, the powder begins to slide off, and, when once started, nearly all runs off. In view of this it is not considered worth while to clean the tops of the tubes; hence tube cleaning is eliminated from the routine.

In many cases where pulverized fuel is used a large percentage of the refuse passes through the boiler and passes up the stack. With this system, however, apparently none of the refuse passes out through the stack as no traces of it have been found on the roof of the power house nor on those of adjacent buildings. As previously mentioned, the refuse from the furnace is deposited in a collector. There is a comparatively small quantity of refuse and ordinarily the collector is emptied every three or four days. After eight days of operation, when using 750 pounds of low-grade Pittsburg slack per hour, only about three-quarters of a ton of refuse was removed from the collector.

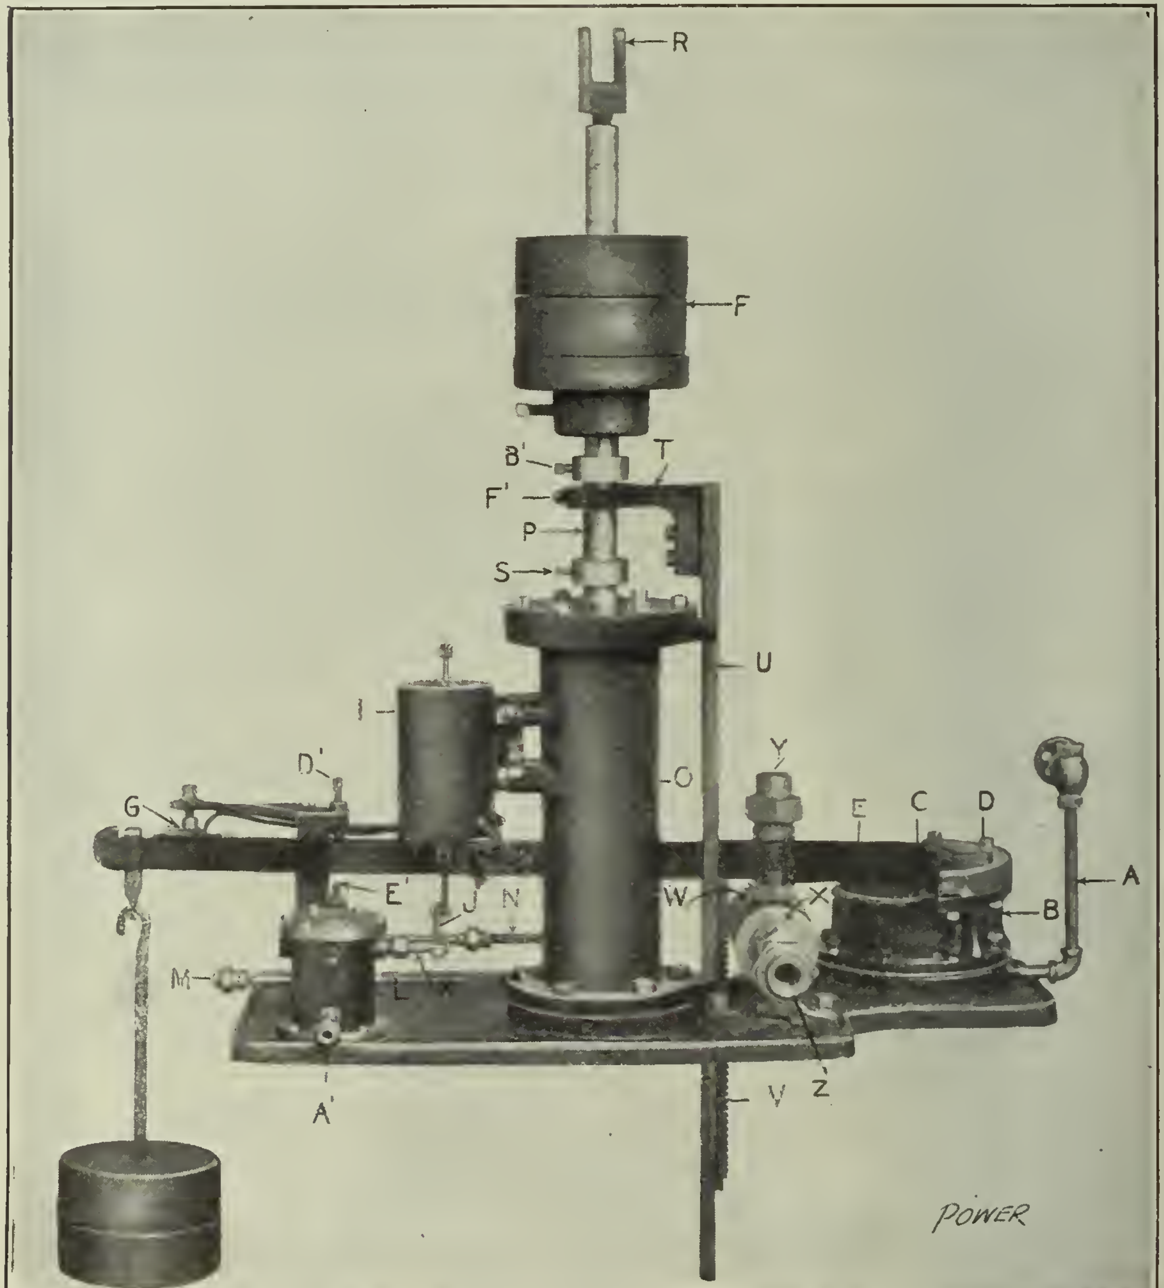

Fig. 3. Automatic Regulator

The tubes immediately above the furnace become coated with a sulphurous deposit which does not appear on the other tubes. This deposit does not exceed ⅛ inch thick and it soon cracks and falls off. The refuse cakes on the firebrick lining of the furnace to a thickness of less than an inch; but this can be easily scraped off. In fact, it is an advantage in that it protects the firebrick and prolongs the life of the furnace.

No difficulties have been experienced by the tubes becoming burned, which is undoubtedly due to the fact that the flame does not impinge on the tubes, and also that combustion is completed before the gases come in contact with the tubes.

Experience has demonstrated that even a large percentage of moisture in the coal has no appreciable effect on the pulverization and burning. The moisture is dried out by the mechanical action of the air during pulverization so that the dust is quite dry and the particles do not adhere. Only two kinds of low-grade coal have been used, but there is little doubt that high-grade coals can be used successfully.

The fineness of pulverization depends upon the quality of the coal, a coal which burns with a long flame being pulverized finer than one having a short flame. Hence, the length of flame can be regulated by adjusting the pulverizer. The rate of combustion can be regulated through a wide range and can be reduced until the heat is just sufficient to keep the furnace hot. The proportion of air to coal is kept constant for all rates of combustion, the quantity of mixture being regulated.

With this apparatus, one man is required to operate the crusher and the pulverizer, and on the boiler floor another attends several boilers. With the apparatus as improved, the supply of fuel will be handled entirely by machinery and the regulation will be automatic, thus considerably reducing the attendance. The cost for repairs has been less than five dollars for 200 days' operation, and it is estimated that the paddles will last at least a year with almost continuous operation. The cost of pulverizing a ton of the coal used in the test herein cited, was 9.2 cents; and it is estimated that the power required for driving the improved pulverizer will be less than 0.04 horsepower per boiler horsepower.

The chief thermal gain in the use of pulverized coal is due to the high degree of perfection in combustion, coal in the powdered state being the best form in which to obtain perfect chemical combination with the oxygen of the air. The rapid combination of the air and coal, however, produces a high temperature, which, in many cases, has been so excessive as to cause failure. The chief difficulties that have been encountered from this source are the fusing of the firebrick lining of the furnace and the fusing of the refuse, forming a slag. To remedy the former, a special firebrick, made from carborundum dust, has been used successfully, but it cannot be said that this disposes entirely and satisfactorily of the difficulties from high temperatures. In the system under discussion, this problem has been solved in a satisfactory way, by regulating the intensity of combustion and in consequence the temperature of the furnace.

Analyses of the flue gases from boilers using pulverized coal show exceptionally good results, there usually being not more than 10 to 15 per cent. excess of air, and no CO, and in most cases the CO_2 is from 13 to 15 per cent.

Pulverized coal is particularly suited to automatic regulation and it is unusually sensitive to control, so that the demands of fluctuating power are easily met. Perhaps the best method is to regulate the mixture automatically so that the correct proportions of air and coal required for complete combustion will be maintained regardless of the quantity supplied. It is obvious that provision should be made for adjusting the air and coal independently to obtain the correct proportions for the particular fuel being used. As the pulverizer described herein was designed for working under practically constant conditions, no provision was made for the automatic regulation of the air in conjunction with that of the coal, but, for future work, provision will be made for the automatic regulation of the air and coal together so that the correct proportions will be maintained under variable conditions.

Either hard or soft coal can be burned satisfactorily in the pulverized state. Coal with a fair percentage of volatile matter seems to be better suited for this purpose as it is more easily pulverized and burns better. Moisture up to 15 per cent. does not interfere with the pulverizing and burning, and in this system the air that is present during the pulverizing and mixing dries the coal sufficiently to prevent the particles from adhering. One of the principal advantages of pulverizing is that coal with a high percentage of ash can be burned efficiently, poor grades of coal having been burned with about the same thermal efficiency as that obtained from high-grade coal. Slack coal requires less power for pulverizing, and is therefore the more desirable.

Pulverized coal is safe providing it is used correctly, but it is hard to convince some that it is not extremely dangerous. Many accidents in the use of pulverized coal have been recorded, but it is safe to say that they were caused by not observing the proper precautions, both in design and operation. A number of accidents have been caused by spontaneous combustion and others by the ignition of a mixture of air and coal dust. Although it is claimed that pulverized coal can be stored with safety, it is obviously better to entirely eliminate this source of danger by not storing it at all. With properly designed machinery, having a short and direct discharge to the furnace, there is no difficulty in preventing the escape of the dust.

Boilers using pulverized coal are not subjected to sudden changes of temperature, such as are hand-fired boilers, hence the uniformity of temperature is a particular advantage.

In marine work mechanical stokers have not been successful, and in this field pulverized coal has the greatest advantages. On account of the limited space on a ship, it may not be possible to prevent the escape of the refuse in the form of dust, but, it is doubtful if this will be very objectionable.

For naval work in particular and marine work in general, its advantages are as follows: Greater economy in fuel can be attained. Maximum power can be maintained as long as the coal can be supplied. There are no fires to be cleaned and the fire-room force can be reduced. There is no smoke and the pulverizers and pneumatic ejectors would take the place of blowers and ash-handling machinery, and it would not be necessary to carry large supplies of spare grate bars, firebrick, etc. The refuse does not cause corrosion and the fire-room bilges would remain in good condition, which also applies to the heating surfaces of the boilers. On account of the uniform temperature, there would be less wear and tear on the boilers. The fire rooms would not be under pressure and could be left open. Low-grade coals could be used.

It cannot be said that firing boilers with pulverized coal has been an unqualified success. In fact, nearly all attempts have failed in one respect or another, and it is the general opinion among engineers that, although it is possible to burn pulverized coal, its use for firing boilers is neither practical nor commercial. This doubt may be dispelled to some extent by the fact that this plant is running practically and is a success commercially. It is expected that further tests will be made in the near future and if these substantiate those already made, there will be no question as to the success of this system of firing boilers in both land and marine practice.

When cutting pipe threads in a lathe it is sometimes difficult to get the exact diameter necessary. When a mistake is made and the threads on a 6-inch pipe are cut a trifle too small, so that it screws right up to the shoulder, then it remains for the workman to get out of the trouble the best way he can. A very good way is to use wire cloth of the brass variety, about 60 or 80 meshes to the inch, similar to that used by the farmer for straining his milk. Wrap a bit of wire cloth around the pipe, daub it with litharge or red lead and screw the pipe home with the wire cloth in the joint. This joint will never leak or come loose.

A plan is on foot to use the power at Great Falls on the Potomac river for a hydroelectric plant to generate current for consumption in the District of Columbia. At present 4450 horsepower is developed, but the power available at Great Falls, even at low water, is considerably over 8000 horsepower, and by using a storage reservoir above the falls it could be increased to about [illegible] horsepower.

Jones; Trouble Killer

First Talk about Power Factor

"Well, well," exclaimed Harvey, "if that ain't Jones cuttin' corners through the back lot I'll eat hay till hell free—"

"You'd oughter eat it, anyhow," broke in the engineer; "I would, if I'd made such a jackass o' myself as you did last time Jones was here."

Further compliments were prevented by the unceremonious entrance, through the spur-track door, of a rotund person wearing a Fedora hat tilted on the left side of his head, a wide opening in his face just below his nose and a nondescript suit of clothes. Nobody ever knew or cared what kind of clothes Jones wore; his hat and his grin caught your attention first and your eyes never got below the grin.

A Rotund Person Wearing a Fedora Hat and a Large Opening Under His Nose

"Hello, boys," sang out Jones cheerily; "what do you know about this for winter weather?"

"Nothin' the matter with the weather," replied the engineer, "except its power factor 's a little low."

"Joke," said Harvey. "No wonder Jones is in a sweat. Say, old man, if you don't hurry and wipe your face, you'll drown."

"Surest thing you know," agreed Jones, taking off his coat and mopping his face and neck with a two-foot bandanna. "But, talking about power factor reminds me that I promised to reel out a yard or so of dope on that subject the next time I got around. How about it, Jim?"

"You sure did," said the engineer, "and the primary class is ready and willin' to take his medicine."

"Well," said Jones, shedding his vest, collar and necktie and turning up his sleeves, "let's see where we'd better begin."

"Hadn't I better run over to the house and get you a suit o' pajamas?" asked Harvey, with mock courtesy.

"S'pose," began Jones, paying no attention to Harvey's effort at bantering, "s'pose your voltmeter showed 115 and your ammeter 30 and your indicating wattmeter 120 kilowatts. You know what the power factor would be, don't you?"

"Yes; because you told me how to figure it," said the engineer, "but I don't understand why."

"Never mind that for the present," said Jones. "Just to get a good start at the beginning, figure that power factor."

"Cinch," broke in Harvey; "lemme do it," and he jotted down these figures on a scratch pad:

115 volts
30 amperes
3450

"A hundred and fifteen multiplied by thirty is thirty-four hundred and fifty—thirty-four hun— oh, you're stringin' us."

"No he ain't," exclaimed the engineer excitedly, "you've forgot that when the voltmeter reads a hundred and fifteen the voltage in the primary line where the ammeter is connected is twenty-three hundred. Here—" and he hastily scrawled Fig. 1. "The voltmeter takes current through a transformer and shows the secondary voltage but the ammeter shows the primary current."

"Right you are," said Jones, beaming like a polished tomato. "The primary class is making headway. Finish the job."

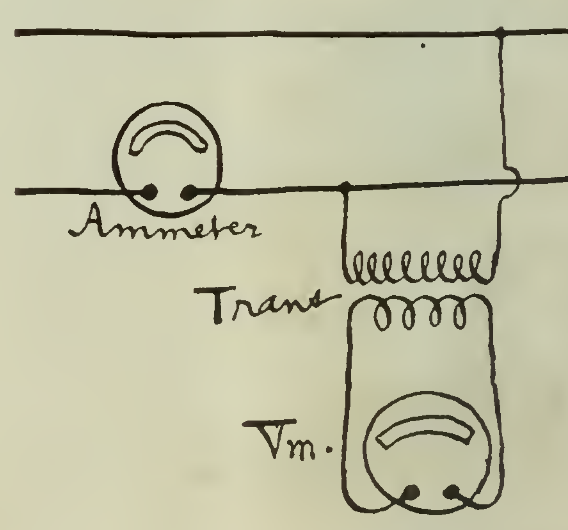

Fig. 1. The Engineer's Sketch

"When the voltmeter voltage is a hundred and fifteen the line voltage is twenty-three hundred because the transformer ratio is twenty. "Let's see—" and he began figuring as follows:

2300 volts
30 amperes
69000 app. watts

69000)120000(

"Thirty times twenty-three hundred is sixty-nine thousand and sixty-nine thousand goes into a hundred and twenty thousand—hold on; that would make the power factor nearly two," he exclaimed.

"Come to," advised Jones, relaxing his grin a couple of points. "You know better than that."

"Thirty times twenty-three—"

"Cut it out," said Jones. "Your arithmetic's all right; no use to keep on repeating that like the man who went crazy saying 'twice two is four, twice three is five.' It's your horse sense that's off—not your figures."

The engineer scratched his head and Harvey stared at the figures with a bewildered expression.

"Oh, stuff!" ejaculated Jones. "You ain't thinking; you're just rattled. Where is your ammeter connected in regularly?"

"In the A phase of the line," replied the engineer.

"Where is your wattmeter connected in?"

"In both pha— oh, damn! The ammeter measures the current in one phase and the wattmeter measures the power in both phases, of course."

"Quite so," agreed Jones; "proceed."

Harvey softly whistled "Every little movement has a meaning all its own," and the engineer chased him into the producer room.

"But you didn't say anything about the current in the other phase," protested the engineer, returning to his seat on a transformer case.

"And you didn't use your brains, so you fell for it," rejoined Jones, increasing his grin to 3½ inches. "Now, start all over again and do it right."

"Or quit," amended Harvey, from a safe distance.

"Better paste that editorial in the middle o' your lookin' glass," suggested the engineer, taking a dig at Harvey's only serious weakness—personal vanity.

"Well," he resumed, "if the two phases are balanced, each one'll carry half the power, so that if the total power is a hundred and twenty kilowatts the power in each phase'll be sixty kilowatts or sixty thousand watts."

"Right," said Jones.

"Then, if the apparent watts in each phase are sixty-nine thousand and the actual watts are sixty thousand, the power factor'll be—" and he made the following division:

```
69000) 60000 (.8695
       552
       ---
        480
        414
        ---
         660
         621
         ---
          390
          345
```

"point eight six, nine, five—practically point eighty-seven."

"All right," said Jones, "but what does point eighty-seven mean?"

"Eighty-seven hundredths."

"Yes; but is that what you'd call the power factor?"

"Oh; eighty-seven per cent."

"Correct. Now you said thirty times twenty-three hundred was sixty-nine thousand, but you didn't say sixty-nine thousand what. It isn't watts, is it?"

"No; apparent watts."

"Yes; that's true enough, but there's a better name for it."

The engineer shook his head.

"Search me."

"Volts multiplied by amperes make what?"

"Appar—"

"You said that before; try something else. Wits gone wool-gathering again?" as the engineer sat staring at him.

"N-o-o, but—"

"Oh, come now; wake up. Volts multiplied by amperes—volts times amperes—volts, amperes—"

"Volt-amperes," said the engineer meekly; "please kick me."

"I'll leave that to your conscience," said Jones. "You see, apparent watts is a good enough name because volts multiplied by amperes would be watts if there weren't any power factor to bother with. But volt-amperes is more descriptive, because it is common custom in engineering to hitch two things together with a hyphen when you are talking about their product and there isn't any name for it. There's feet multiplied by pounds—foot-pounds; kilowatts multiplied by hours—kilowatt-hours, and so on."

"But why do volts multiplied by amperes make volt-amperes in alternating-current work and not with direct current?"

"I never said any such thing," replied Jones; "you've got it twisted. Volts times amperes are volt-amperes every time and in any system, but volt-amperes are the same as watts in a direct-current system, while they are not the same with alternating current unless the circuit is entirely free from inductance, which is not usually the case."

"Then, what's the difference between watts and alternating volt-amperes?" asked the engineer.

Jones manifested signs of impatience.

"How do you figure the power factor of a circuit or a system?" he asked.

"Divide the watts by the appar— by the volt-amperes," said the engineer.

"Then, for heaven's sake why can't you see the relation between watts and volt-amperes?" asked Jones. "Suppose you knew the power factor and the volt-amperes, how would you figure out the real watts?"

The engineer figured on his pad awhile.

"Multiply the volt-amperes by the power factor?" he suggested, doubtingly.

"Of course. Then, why do you ask me what the difference is between watts and volt-amperes?"

"Well, I didn't mean it exactly that way," said the engineer, a little abashed. "I know how watts and volt-amperes and power factor are tied together in arithmetic, but—"

"Let's make sure of that much," advised Jones. "You persisted in saying 'apparent watts' awhile ago when I wanted you to say 'volt-amperes.' Now go back to your apparent watts. Apparent watts are apparent power, and you just said that multiplying volt-amperes or apparent watts by the power factor gave you the real watts, didn't you?"

"Yes; but—"

"Don't butt in. If your apparent power were fifty thousand volt-amperes and your power factor eighty per cent., what would the real power be?"

"Forty thousand watts," said the engineer, after a moment of hasty scribbling.

"Right. Now, don't you see that the power factor is simply the number by which the apparent power is multiplied to get at the real power?"

"Ye-es."

"No you don't, but listen. With fifty thousand volt-amperes and eighty per cent. power factor, the real watts would be forty thousand, you said."

"Yes."

"Then eighty per cent. of your apparent power is *real* power, isn't it?"

"Oh, I see what you are driving at. Sure; I understand that if the power factor is eighty per cent. then eighty per cent. of the apparent power is real power, and if the power factor is sixty per cent., then sixty per cent. of the volt-amperes are real power. But I don't understand why *all* of the volt-amperes ain't real power, like direct current. Why is there any power factor?"

"That's what I'm coming to," said Jones, "but we've wasted so much time on the arithmetic it's time to eat. I'll tell you the balance after we feed." And he made a dive for the wash sink just in time to beat Harvey to it.

Old man Dodder doubled the size of his dry kiln at the planing mill and found that the fan was too small and would not deliver enough hot air. His nephew Bill was back from college and tackled the job. He figured all over the side of the shed and told his uncle that to deliver twice the amount of air he would need a 120-horsepower engine to run the fan, as the rules showed one must cube the horsepower required to run the fan with the old kiln. The old man scratched his head and sent for Jim, the engineer, to help him out. Jim grinned and said that all they would need was another 5-horsepower fan, as the two would deliver double the amount of air.

Dodder [illegible] Bill had [illegible] and help Jim a while.

The Melville-Macalpine Gear for Direct-current Turbine Generators

By Geo. W. Malcolm

In a paper read some time ago before the Engineers' Society of Pennsylvania, J. A. MacMurchie advocated the use of the now widely known Melville-Macalpine turbine gear to drive direct-current generators, instead of coupling them directly to the turbine. Mr. MacMurchie cited, as warranting this practice, the fact that it would permit the use of a generator running at its most economical speed instead of one driven at such a high rate as to entail excessive losses by windage and friction.

A chart was presented with the paper which indicated the following comparisons, based on steam at 150 pounds pressure and a condenser vacuum of 28 inches:

	Pounds of Steam per Kilowatt-Hour.	
Size of unit	1000 kw.	2000 kw.
Direct-driven, direct-current generator	20.6	20.2
Direct-driven alternator and rotary converter	20	19.5
Gear-driven direct-current generator	19.3	19

The combination of turbine-driven alternator and rotary converter was included in the comparison in order to cover all practical methods of obtaining direct-current distribution from a turbine-driven generating plant. It is exemplified by railway practice throughout this country, rotary converter substations being used to change the high-tension alternating current sent out from the generating station into direct current of the proper voltage for the railway. Such a system, however, can scarcely be compared with the turbine-driven direct-current dynamo because the conditions to which the two are rationally applicable are widely dissimilar.

The logical comparison is between the direct-driven and the gear-driven direct-current generators.

According to Mr. MacMurchie's chart, the gear-drive outfit would require 19,300 pounds of steam per hour and the direct-coupled outfit 20,600 pounds, in the 1000-kilowatt size. The heat energy theoretically available by expanding a pound of steam under the conditions stated is 339 B.t.u., if the steam be superheated 100 degrees initially. On this basis the overall heat efficiency of the direct-coupled unit would be 48.8 per cent. and that of the geared unit 52.2 per cent. The following tabulation gives a comparison of the two generators for four values of turbine efficiency and on the assumption that the Macalpine gear has 97 per cent. efficiency:

Turbine Efficiency.	Corresponding Generator Efficiency.		
	Direct driven Generator.	Gear and Generator.	Geared Generator.
54%	90.4	96.7	99.7
56%	87.2	93.2	96.1
58%	84.2	90.0	92.8
60%	81.4	87.0	89.7

Obviously, the combination indicated in the first line is impossible because the generator could not have 99.7 per cent. efficiency. The most plausible combination would seem to be the one in the second line, although 96 per cent. is a little high for the geared generator and 87.2 is unnecessarily low for the direct-driven generator.

It is difficult to imagine such an increase in generator efficiency as the 9 per cent. shown practically throughout the range here considered, due merely to the difference between the speeds of the coupled and geared generators. The windage, iron losses and friction would be increased by the higher speed, but this would be neutralized to a very great extent by the decrease in purely electrical losses. Moreover, the increased fixed charges on the cost of the geared outfit would require a very healthy decrease in fuel consumption to offset it.

Steam Heated Flume Racks for Hydraulic Plants

Operators of power plants in which the generators are driven by waterwheels do not need to be told anything about the difficulties in keeping head-gate racks clear of frazil ice in latitudes where ice forms. An interesting method of eliminating such ice troubles was proposed recently by John Murphy. In a paper read before the Ottawa branch of the Canadian Society of Civil Engineers. Mr. Murphy's plan is to equip the head-gate racks with pipe manifolds and to pass steam through the manifolds. The warm pipes, it is stated, prevent the accumulation of frazil ice at the racks by melting the ice, which is formed in very small particles. Mr. Murphy said that a ton of coal per day of twenty-four hours would make sufficient steam to keep the gates of a 3000-horsepower station free from ice. This, obviously, would be much cheaper than allowing the gate racks to freeze up and driving the generators by auxiliary steam equipment.

When cutting bar steel or rails by the usual method of nicking with a cold chisel, if the nicked part of the material is cooled by laying on a piece of ice, it will be rendered temporarily brittle and fracture easily when struck a blow with a sledge.

LETTERS

Erratic Belt Behavior

A 12-inch belt driving a dynamo persistently runs over one or the other edge of the dynamo pulley when shutting down and starting up, but when pulling the load it runs true with the center line of the pulley. The dynamo pulley is 23 inches in diameter and 16 inches wide; the engine pulley is 7 feet in diameter and 16 inches wide, and the pulleys are 30 feet apart, center to center. Can any reader of Power explain why the belt will not stay in place when starting up and shutting down?

W. S. Hull.

Sheldon, Ill.

A Cranky Induction Motor

Some time ago I was called upon to repair an induction motor that would not carry the load. It was a 220-volt, two-phase machine with a squirrel-cage rotor, rated at 15 horsepower. It had been running a rock crusher about two years and had probably averaged four months' continuous running for each year. It had been out of use about a month when I saw it.

Examination showed that the airgap was not uniform all the way around. The insulation of the stator winding appeared to be in perfect condition and everything else seemed to be all right except the airgap. I equalized this by shimming under the bearings with paper, tested each phase with two 110-volt lamps in series at the motor terminals and also tested them with a magneto; tested for grounds, and finally rewired the autotransformer, thinking perhaps the trouble might be in that, but it is still undiscovered.

The motor will not start until the lever on the autotransformer is in the running notch, but immediately starts on full-line voltage, if started in one direction; if the direction of rotation is reversed, it starts nicely on the second starting point. It apparently takes an excessive current while starting and running in either direction, as it visibly dims the two 110-volt lamps in series on the line.

The motor is supplied from two transformers which do not supply anything else, and each one is of ample capacity to carry one-half the full load. The owner said it had carried the load continuously on a certain Friday and on the following morning had started all right but refused to take any load.

Any suggestions as to what might be the matter with it will be greatly appreciated by me.

H. Blue.

Kirksville, Mo.

Gas Power Department

Everything worth while in the gas engine and producer industry will be treated here in a way that can be of use to practical men

Long Stroke and Short Stroke Engines

By Paul C. Percy

It is a matter of common observation in engineering circles that the daily papers usually make themselves ridiculous when they discuss technical matters. This is natural, though amusing. When a professedly engineering journal makes foolish statements, however, it is neither excusable nor amusing.

The immediate provocation for these remarks is an article on the long-stroke gasolene engine, which appeared in a recent issue of a gas-power periodical. The following are the worst specimens of misinformation contained in the article:

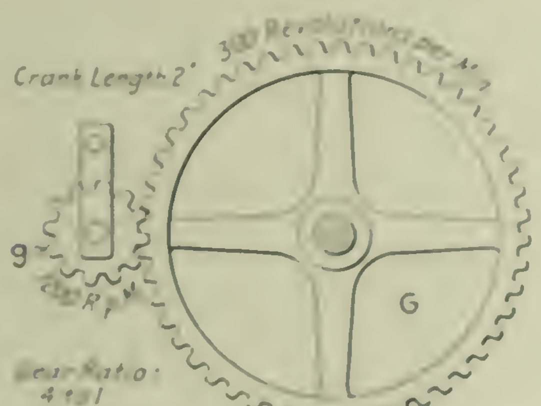

Fig. 1. Gearing of the Short-stroke Engine

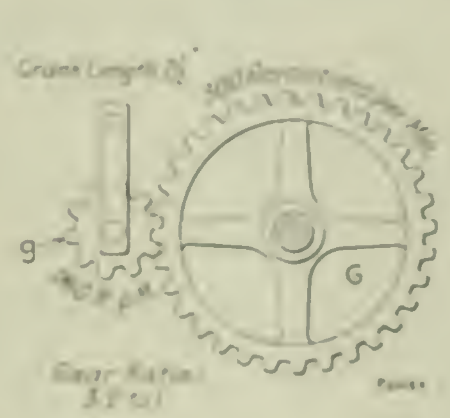

Fig. 2. Gearing of the Long-stroke Engine

1. The long-stroke engine does its work more easily than the short-stroke one for the same reason that a big man walks at four or five miles an hour with an easy swinging stride, while a small man has to "exert himself tremendously" to keep up with the other.

2. In a long-stroke motor the question of leverage enters. The long-stroke motor can turn its crank shaft with less effort than the short-stroke engine because of the longer crank throw, giving greater leverage over the load.

3. The gases in a long-stroke motor, "starting at a higher initial pressure on account of the increased compression possible with the longer stroke, are worked down to a much lower final pressure before they are exhausted into the atmosphere."

4. The gases in a long-stroke engine are expanded to a greater number of clearance volumes than in a short-stroke engine, and the long-stroke engine allows a much greater compression; hence the long-stroke engine is more economical.

5. The exhaust gases of the long-stroke engine are much cooler than those of the short-stroke engine because of the greater expansion.

All of the foregoing statements are absolutely untrue. The long-stroke engine is more desirable than the short-stroke engine in the following respects only:

The short-stroke engine must make a greater number of revolutions per minute than the long-stroke engine to run at the same piston speed. Therefore, the wear and tear on the reciprocating parts, crank pin and crank-shaft bearings is greater, for equal piston speeds.

The piston speed of the long-stroke engine can be made higher than in the short-stroke engine and the number of revolutions per minute kept the same or even be made less; if the latter is done, a smaller piston diameter is required, and this gives a correspondingly smaller total pressure on the connecting-rod boxes and main bearings.

These points are presented clearly and concisely by the numerical comparison in Table 1. These figures are, of course, appropriate for automobile and motor-boat practice. For the ordinary stationary engine the comparison in Table 2 is more suitable.

Both of these tables show clearly that for equal horsepower a long-stroke engine can be made to run at fewer revolutions per minute with the same total piston pressure and piston speed, or with less piston pressure and higher piston speed.

Now, let us see about the question of

TABLE 1

Engine	Short-Stroke, A	Long-Stroke, B	Long-Stroke, C
Piston diameter, inches	4	4	[illegible]
Piston area, sq. in.	12.57	12.57	[illegible]
M.E.P. per square inch	70	70	70
Total mean pressure	[illegible]	[illegible]	[illegible]
Stroke, inches	4	[illegible]	[illegible]
Revolutions per minute	1200	960	[illegible]
Piston speed	800	800	[illegible]
Estimated horsepower	24	24	24

TABLE 2

Engine	Short-Stroke, D	Long-Stroke, E
Piston diameter, inches	[illegible]	[illegible]
Piston area, sq. in.	[illegible]	[illegible]
M.E.P. per sq. in.	[illegible]	[illegible]
Total mean pressure	[illegible]	[illegible]
Stroke, inches	[illegible]	[illegible]
Revolutions per minute	[illegible]	[illegible]
Piston speed	[illegible]	[illegible]
Estimated horsepower	[illegible]	[illegible]

"leverage." In the examples cited in the article I am criticizing, the piston speed was the same for both short-stroke and long-stroke engines, as in the cases A and B, of the first table. Figs. 1 and 2 illustrate this case diagrammatically. In the one case a 2-inch crank (4-inch stroke) revolves 1200 times a minute and is geared to the load shaft at 4 to 1; that is, the gear g on the crank shaft is one-fourth as large as the gear G on the load shaft and therefore turns four times as fast; consequently, the load shaft runs at 300 revolutions per minute. Putting it the other way, while the load shaft is making one revolution the crank makes four.

The diameter of the circle followed by the crank pin is 4 inches; in four revolutions, therefore, the crank pin travels

$$3.1416 \times 4 \times 4 = 50.266$$

inches.

In the other case, Fig. 2, with the same horsepower and the same piston speed the 4x5-inch engine runs at 960 revolutions per minute, and in order to keep the speed of the load shaft at 300 revolutions per minute the gear ratio must be 3.2 to 1 instead of 4 to 1 because the crank-shaft speed is only [illegible] of what it was before. Therefore, when the load shaft makes one revolution the crank makes only 3.2 revolutions. The crank being $2\frac{1}{2}$ inches long, the crank circle is 5 inches in diameter and the crank pin travels

$$3.1416 \times 5 = 15.708$$

inches per revolution. In making 3.2 revolutions, therefore (while the load shaft makes one), the pin will travel

$$15.708 \times 3.2 = 50.266$$

inches, or exactly the same distance the 2-inch crank pin travels during one revolution of the load shaft. Where is the increased leverage over the load?

"But," probably says the author of the criticized article, "I meant the case where the piston speed is increased."

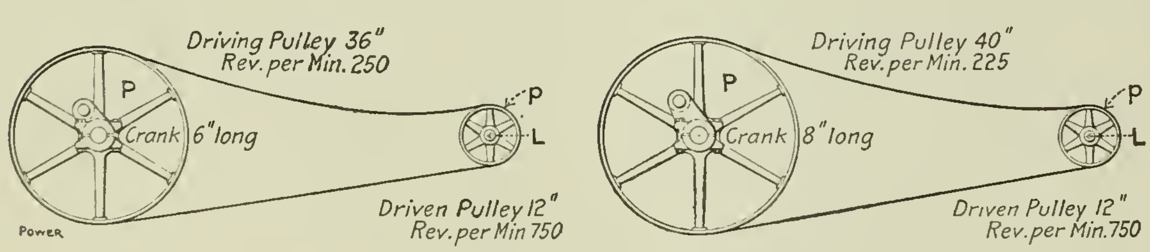
All right; let's see how that pans out, using the figures for engines *D* and *E*, in the second table. Figs. 3 and 4 illustrate the comparison. Suppose the load shaft *L* must run at 750 revolutions per minute, no matter what the speed of the engine may be. That is a practical condition where the machinery driven by the engine runs at constant speed. Also suppose, in order to keep the belt velocity the same, that the pulley *p* is 12 inches in diameter in both cases and that the diameter of the gas-engine pulley is chosen so as to get the desired speed at the load shaft *L*.

In Fig. 3 the short-stroke engine *D* (see data in Table 2) is represented as driving the load. As its speed is 250 revolutions per minute, its pulley must be 36 inches in diameter because the speed ratio is

$$\frac{750}{250} = 3$$

and the pulley ratio must be the same. The orbit of the crank pin is 12 inches in diameter, so that the pin travels

$$3.1416 \times 12 = 37.7$$



FIGS. 3 AND 4. COMPARISON WITH DIFFERENT PISTON SPEEDS

inches when the crank shaft makes one revolution. During this time the load shaft *L* makes three revolutions; consequently, the crank pin travels

$$\frac{37.7}{3} = 12.5667$$

inches for each revolution of the *load* shaft.

Now refer to Fig. 4, where the long-stroke engine *E* is represented as driving the same load. On account of the lower speed of the engine its pulley must be larger; the speed ratio is

$$\frac{750}{225} = 3\frac{1}{3}$$

and the engine pulley is therefore

$$3\frac{1}{3} \times 12 = 40$$

inches in diameter.

The crank-pin circle is 16 inches in diameter; therefore, in one revolution the crank pin travels

$$3.1416 \times 16 = 50.266$$

inches, and for each revolution of the *load* shaft it travels

$$50.266 \div 3\frac{1}{3} = 15.08$$

inches, as compared with 12.57 inches for the 6-inch crank.

"Aha," says the other man, "didn't I say the long-stroke engine had more leverage over the load?"

You did, you did; but hold up a moment. What good is the extra leverage if the force applied to it is less? Refer to the data in Table 2 and you will see that the total piston pressure of the engine *D* is 6283.2 pounds, whereas the engine *E* can exert only 5236 pounds. Of course, these are not the average pressures on the crank pins, but the proportionate pressures are in the same ratio. That is, if the average pressure on the crank pin, throughout one revolution, were 2400 pounds for the short-stroke engine *D*, it would be only 2000 pounds for the long-stroke engine *E*, both developing the same horsepower.

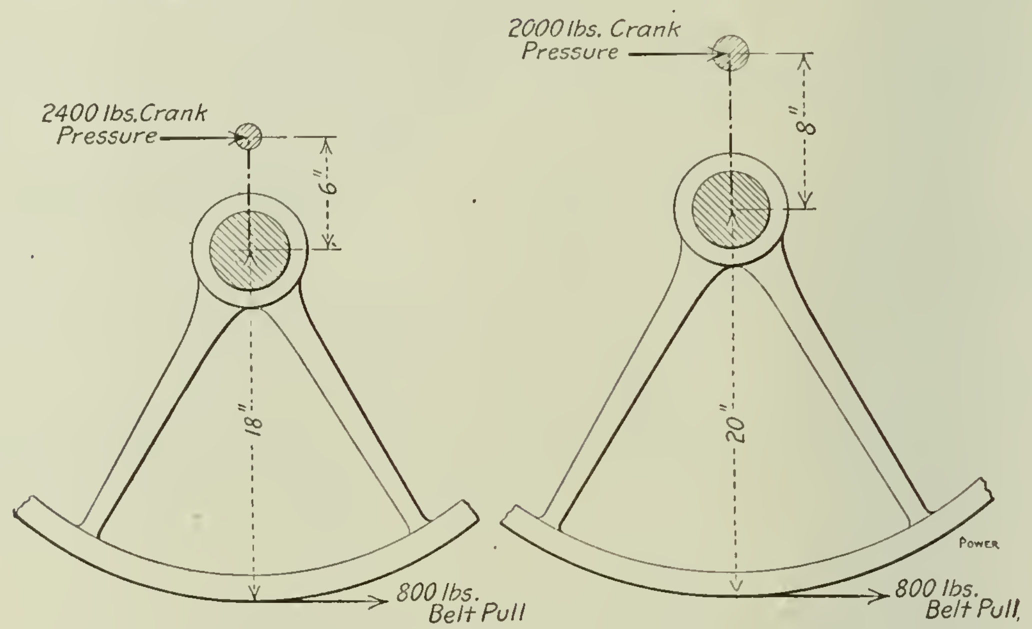
Now, the previous calculations showed that the pin of the 6-inch crank travels 12.5667 inches in the same length of time that the pin of the 8-inch crank travels 15.08 inches. Suppose the average pressure on the short crank is 2400 pounds and that on the long crank 2000 pounds; evidently, it is not any harder for the pressure of 2400 pounds to push the load 12.5667 inches than for the pressure of 2000 pounds to push it 15.08 inches in the same length of time, because

$$2400 \times 12.5667 = 30{,}160$$

and

$$2000 \times 15.08 = 30{,}160.$$

Look at it in another way. As the load pulley *p* is of the same diameter in both cases, the belt velocity is the same and the belt pull the same in both cases. Suppose the belt pull to be 800 pounds



FIGS. 5 AND 6. BALANCE BETWEEN CRANK PRESSURE AND BELT PULL

and the engine to be frictionless. Then 2400 pounds pressure at the pin of the 6-inch crank will balance the 800 pounds belt pull at the rim of the engine pulley, because the radius of the pulley is three times the length of the crank; see Fig. 5.

Now, consider the long-stroke engine *E*. The crank-pin pressure is 2000 pounds; crank length, 8 inches; pulley radius, 20 inches, and belt pull, 800 pounds, as represented in Fig. 6. The pressure of 2000 pounds at 8 inches distance from the center will exactly balance the pull of 800 pounds 20 inches from the center, because

$$2000 \times 8 = 800 \times 20.$$

Since the forward pressure on the crank pin is equal to the backward pull of the load × the leverage, in both cases, where does the long crank get any advantage in "leverage"?

Suppose a big man could lift exactly 300 pounds and no more, and a little man could lift exactly 100 pounds and no more. Could the big man lift his 300 pounds any easier than the little man could lift his 100 pounds? Not so you could notice it. The case of the long-stroke and short-stroke engines is precisely the same, so far as "leverage" and pulling the load "easier" are concerned.

COMPRESSION AND EXPANSION

The statements were made that a higher compression could be obtained with a long-stroke engine and that therefore the initial pressure will be higher, the expansion greater and the exhaust gases cooler.

Of course, if the clearance volume is the same in a 4x5-inch engine as in a 4x4-inch engine the compression would be higher, but no one who had the most elementary knowledge of gas engines would make the clearances the same. The compression pressure is limited by pre-ignition or safe maximum pressure on the moving parts, according to which limit is reached first. In gasolene engines pre-ignition always limits the compression pressure; in producer-gas engines the maximum pressures usually set the limit for compression.

When the builder decides what compression pressure to use, he makes the clearance space of the right volume to get it, no matter what the relation of stroke to bore may be. If a 4x4 engine will not stand more than a certain compression pressure without danger of pre-ignition, neither will a 4x5 engine. On the other hand, if it is safe to make the compression pressure of a 4x5 engine higher than that of a 4x4 engine, then the latter is too low and should be increased by reducing the clearance volume.

To get a numerical comparison of the various points brought up in paragraphs 3, 4 and 5, let us suppose that a small gasolene engine, say of 4 inches bore, cannot be operated reliably with more than 82 pounds compression pressure (absolute). The explosion pressure of such an engine will be about three times the compression pressure and the pressure when the exhaust valve opens will be a trifle over one-sixth of the explosion pressure or one-half the compression pressure. These proportions give the figures in Table 3.

Evidently there is no difference here in anything relating to cylinder pressures except the piston displacement and clearance volume. Now, supposing for the sake of argument, that the same clearance volume could be used in both engines, what would be the comparison? The figures in Table 4 give it clearly. Where is the expansion to lower exhaust pressure and the corresponding lower exhaust temperature? The truth is that statement 2 is absurd. The fact that the initial or explosion pressure is higher does not necessarily make the exhaust pressure lower. The expansion ratio is higher, of course, with a higher compression ratio, and this tends to increased efficiency.

But there is no ground for assuming that the compression pressure can be carried higher in a long-stroke engine than in a short-stroke engine of the same horsepower and using the same fuel. Therefore the comparison in Table 3 is the correct one.

There are true features of comparison which the writer of the article under discussion did not even consider. For example, the short-stroke engine has less wall surface in the cylinder and the heat loss can therefore be made less than in a long-stroke engine of equal power. On the other hand, combustion of the fuel at constant volume can be more nearly realized in the long-stroke engine because the piston is practically stationary at the end of the stroke for a slightly longer time.

TABLE 3.

Engine	A	B
Cylinder	4x4	4x5
Piston area	12.57	12.57
Piston displacement	50.27	62.83
Clearance volume	16.76	20.94
Compression ratio	4	4
Compression pressure	82	82
Explosion pressure	246	246
Expansion ratio	[illegible]	[illegible]
Exhaust pressure	42	42

TABLE 4.

Engine	A	B
Cylinder	4x4	4x5
Piston displacement	50.27	62.83
Clearance volume	16.76	16.76
Compression ratio	4	4.74
Compression pressure	82	[illegible]
Explosion pressure	246	[illegible]
Expansion ratio	[illegible]	[illegible]
Exhaust pressure	[illegible]	[illegible]

These are points of minor importance, however; the main points are the greater wear and tear of the short-stroke engine and, on the other hand, the greater weight and cost of the long-stroke engine. The choice of stroke-to-bore ratio is a compromise between these opposing disadvantages.

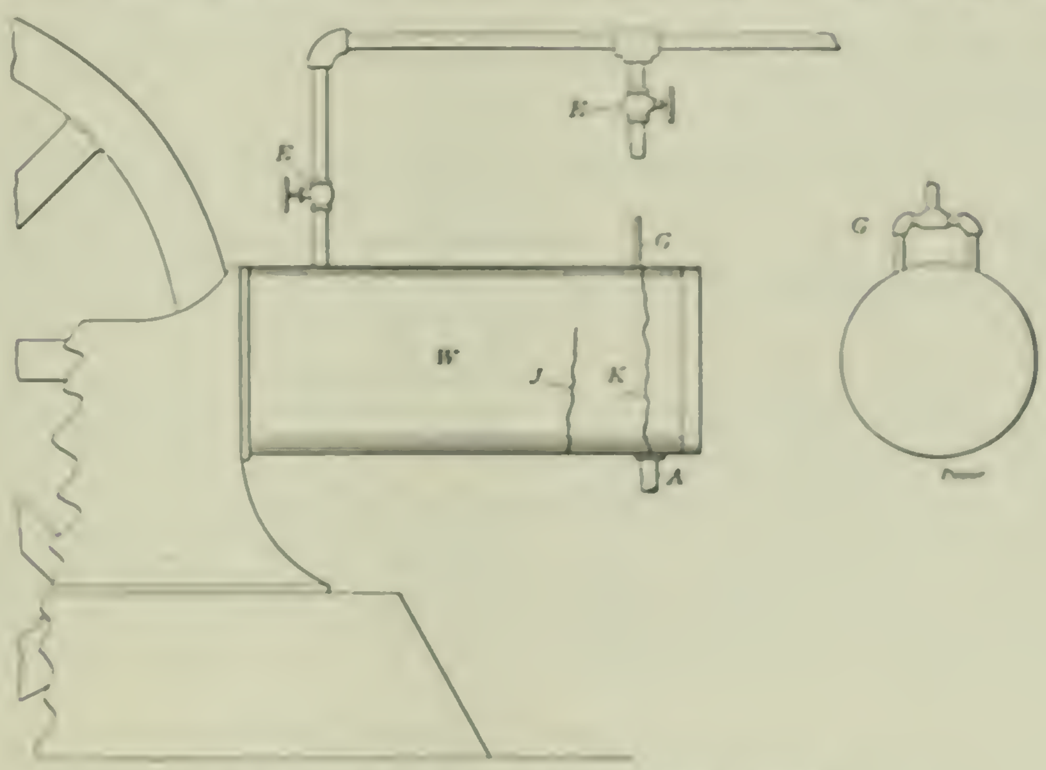
After you have studied a machine for weeks and understand the cause of the trouble, do not expect the boss to take your word for it, or expect him to understand all you try to tell him about it with one explanation.

CORRESPONDENCE

Mr. Booth's Gasket and Mr. Sanders' Cracked Jacket

In the issue of December 6, Frank E. Booth recommends the use of graphite on the gasket between the cylinder and head. I think that would be condemned by most engineers because the gasket would be more apt to blow out. In my experience with gas engines I have used a wire-inserted asbestos cloth in making that joint, and did not put anything on it. On removing the head I used a case knife to cut the gasket loose.

Referring to F. W. Sanders' article on the same page, I cannot see how reversing the flow of the water would change the pressure. I should say that the cool water entering at that point and coming in contact with the hot plate would set up strains that caused the leak. On reversing the flow the water would merely be warmed considerably before reaching this point.



Working with a Cracked Water Jacket

Mohave City, Ariz.

Lignite mining and the manufacture of patent fuel are of growing importance in Germany, according to the British consul in Berlin, the constant increase in consumption being due to the fact that both materials are used for many more purposes in the present day than was possible formerly. New plants are now fitted up with steam boilers that have been specially constructed for the use of lignite and patent fuel. The existing lignite syndicates have established far-reaching organizations for selling lignite, and have forwarded their aims to no small extent by the introduction of stoves specially adapted for heating by briquets.

Practical information from the man on the job. A letter good enough to print here will be paid for. Ideas, not mere words wanted

Making Pipe Covering

When tearing out or changing old pipe work, it is difficult to preserve the pipe covering, especially the cheaper grades, as it cracks and drops to pieces.

Many engineers throw away this old covering, and, in some instances, it is replaced with a new covering at a considerable expense.

The accompanying illustrations show how this old covering may be used to good advantage, and save the expense of purchasing new covering. *A* is a piece

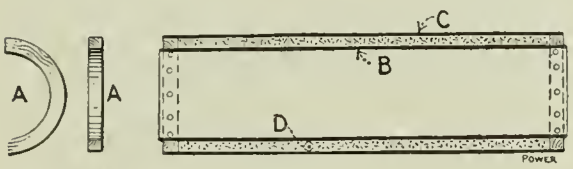

Fig. 1.

of wood about $\frac{3}{4}$ inch thick, cut in a circular form, the inner diameter being equal to the diameter of the pipe to be covered, and *D* being equal to the desired thickness of the covering.

One of these pieces is used at each end of the form, and a piece of sheet iron, bent to fit the outside of the pipe, is put on the inside of the circular pieces of wood.

Another piece of sheet iron is then bent to fit the outside of the blocks, and both are fastened by small bolts, running through the blocks, as shown at *C*.

The old pipe covering is then crushed or broken up, and mixed with enough water to make it work well. The form is laid in a horizontal position, and the plaster poured into the space between the two pieces of sheet iron *B* and *C*.

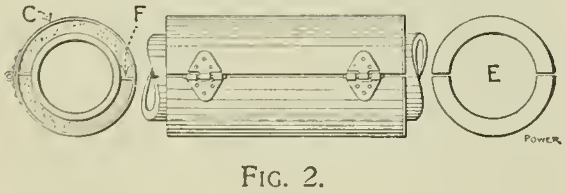

Fig. 2.

Care should be taken to push the plaster down well into the form, so that there will be no holes in the bottom.

If a little portland cement is mixed with the covering before the water is added, it will dry quicker and be more substantial. After it has dried for a few hours, it may be taken out of the form and put on the pipe.

Fig. 2 shows another form which is more convenient for small pipe and may be made for larger pipe, if desired.

Instead of using blocks, the two sides are made as shown and are hinged on one side. A piece of pipe the size to be covered is used for the inside of the form.

A ring *E* is cut, as shown, and one piece is soldered to the lower end of each side to hold the pipe in the center of the form. The covering is then poured in from the top. When it is dry, the form may be opened and the covering taken out.

The projections *F*, on the sides of the form, cause the covering to be cast in two pieces.

The covering will come out easier if the inside of the form is greased a little before putting in the plaster. This will prevent the covering from sticking to the form.

R. L. Rayburn.

Kansas City, Mo.

Don't Neglect the Safety Stop

Our engine has a 12-foot flywheel and runs at a speed of 80 revolutions per minute. A 70-kilowatt generator is belt driven from a jack shaft. The generator was fitted with a 16-inch cast-iron pulley and ran at a speed of 600 revolutions per minute.

One evening this pulley burst, breaking the belt which flew under the rope drive, knocking the ropes from the flywheel and knocked off the governor belt. This would have resulted in a serious wreck if the safety cams had not been properly adjusted, because I was left in absolute darkness until I could get to the switchboard and throw the house-lighting switch on the other engine, which was in service at the time.

I am always very cautious about removing the pin or lever from the governor, and always instruct my assistants to be likewise.

A governor with the pin left in is as useless and dangerous as if it were not a safety-stop governor.

Walter Carr.

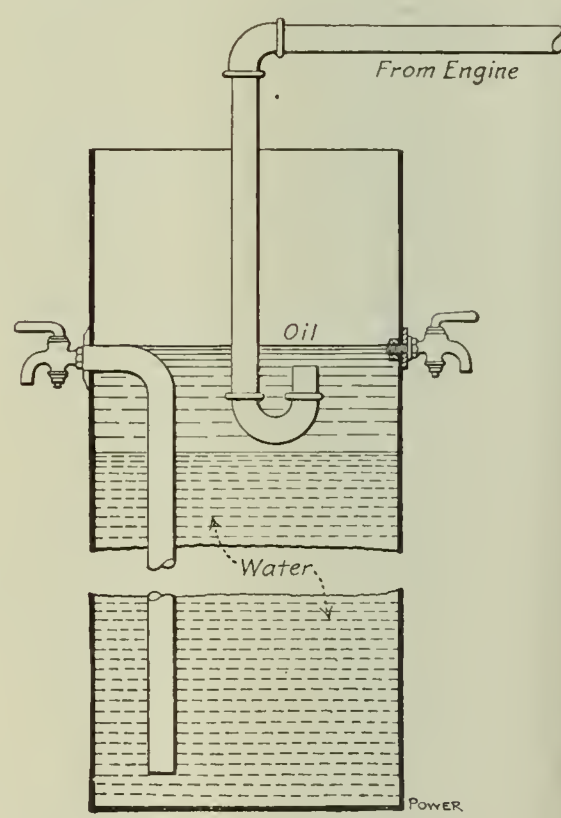
Harrisburg, Ill.

An Oil Trap

A couple of years ago I was running a 500-horsepower tandem-compound engine on which 50 gallons of oil was used per month.

Of course, this was out of all reason, but it was some time before I took a tumble to the fact that the oil was splashing back from the crosshead and guides into the stuffing-box drip and through a pipe into the sewer. Then I devised a separator, which may not be new to the "old heads," but I have never seen one like it, and it may help someone.

I took a can 24 inches deep and 5 inches in diameter, and soldered in a $\frac{1}{4}$-inch cock, $3\frac{7}{8}$ inches from the top, for an oil drip.



Details of Oil Trap and Piping

Then I soldered a piece of lead pipe, 20 inches long, to another $\frac{1}{4}$-inch cock and soldered in this cock at a point 4 inches from the top of the can, allowing the pipe to extend nearly to the bottom of the can. Next, I ran a $\frac{3}{8}$-inch pipe from the engine cesspool, allowing it to dip some 6 inches into the can and ending in a return bend.

The can would fill with water and oil, the oil staying on top of the water of course, and the excess water passing out through the pipe. When four or five inches of oil accumulated, it would rise to the level of the oil drip and flow to the filter, while the water would flow to the sewer from the other cock.

After installing this device the oil bill dropped from $12 to $2 per month.

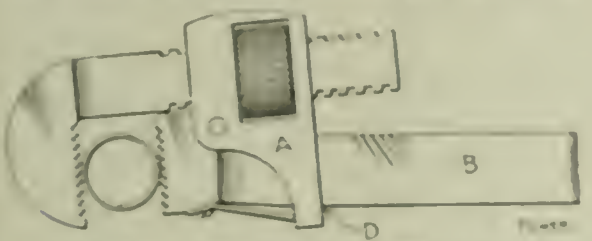
How to Use a Pipe Wrench

Every engineer knows that a pipe can be easily jammed by a pipe wrench, but if my instructions are carried out, one can be used on even thin pipes without jamming them.

Place the wrench on the pipe and get it to bite; then slack off on the nut until the frame *A* comes in contact with the



APPLICATION OF PIPE WRENCH

handle *B*, at *D* (see illustration), thus preventing the jaws from closing; the wrench then has power to turn, but not to jam the pipe.

H. A. GREENE.

Boston, Mass.

Exhaust Head Too Small

On taking charge of my present position, I found that an exhaust head had been installed on the exhaust pipe of the main engine. The exhaust pipe ran from the main engine to the feed-water heater, and from the heater to the atmosphere, and a drip pipe ran from the exhaust head to the heater. With a light load on the engine the exhaust head did its work very satisfactory, but with a heavy load it was not of sufficient size to handle the exhaust steam, and the moaning of the steam through the head could be distinctly heard for some distance. The head was removed and the superintendent did not miss it for nearly a week, when down he came to the engine room to know why I had removed it.

I told him I did not like the sound of the tune it was playing, for one thing, and for another it was difficult to convince the feed-water heater that it was right and proper for it to stop on the job while the exhaust head was in place.

He started for the office, but I got there first and told the manager I understood when I took charge of the steam plant that I was expected to use my best judgement and handle the plant as economically as possible, but that it would be impossible for me to do so if the superintendent was allowed to interfere. I never knew what the manager said to the superintendent, but on his next visit he said, "I believe you are trying to do the right thing around this plant, and I will try and help you all I can"; and he did.

Similar conditions prevail in a good many factory plants where the superintendent and foreman try to run the whole show, and block the engineer when they think he is showing too much ability, for fear that he may get on the inside with the management.

Who should be the best judge of what is right or what is wrong in the care and management of the steam-plant equipment, and who is the best judge of a fireman or assistant if it is not the chief engineer who has had years of experience and made a special study of the work?

W. G. WALTERS.

Stratford, Can.

Governor Arm Broke

About a year ago I was employed in a lighting plant that ran nights only. A 150-kilowatt alternator, direct connected to an automatic engine, was usually started up in the evening and ran until about 11 o'clock, when it was shut down and the load carried on a smaller unit until morning.

One night after the load had been put on the smaller unit and the big engine was being shut down, one end of the flywheel-governor bar carrying one weight broke off close up to the eccentric. I was called, but after looking over the governor I decided nothing could be done until morning, when the shops opened and tools could be obtained that I did not have at the plant.

At 8 o'clock all hands were ready to take off the flywheel and governor bar and try to put an iron strap around it and along the sides to hold it together until a new one could come from the factory. After working until noon and not even getting the flywheel key started, it was seen there would be no lights that night unless something else could be done.

The superintendent suggested that we block the governor wide open, which was done, and the remaining arm of the governor was clamped to a spoke in the flywheel. A pair of wires were run to a voltmeter near the throttle and a man was stationed at the throttle and regulated the speed of the engine by hand for three weeks, until the new governor came.

It was found that there was a bad flaw in the arm of the old governor and the bumping in shutting down finally found the weak spot.

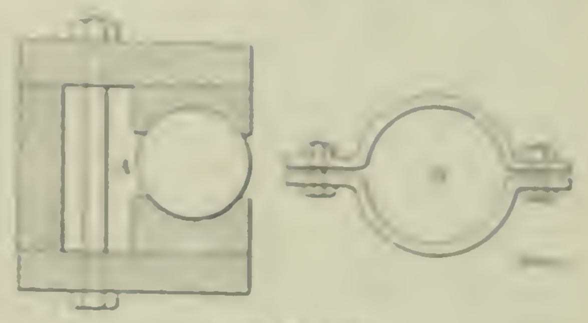
Delta, Colo.

Pipe Clamps

A water or steam pipe may develop a bad leak while the plant is in operation and it is not convenient to cut out the particular pipe line for repairs.

If the leak is not too close to a fitting, a temporary repair may be made with a piece of sheet packing and a couple of



PIPE CLAMP

blocks of wood bolted together as shown at *A*, or a heavy sheet-iron clamp may be made as shown at *B* in the accompanying illustration.

CHARLES H. TAYLOR.

Bridgeport, Conn.

Homemade Tube Cleaner

Some concerns will not invest in the necessary apparatus for the power department, and then it is up to the engineer to do the best he can. The accompanying drawing shows how a tube blower can be made out of a few fittings.

This blower consists of a piece of ½-inch pipe 18 inches long and tapered at

HOMEMADE TUBE BLOWER

the end, that is, screwed into a tee, the end coming to a point beyond the [illegible]. On the other end of the tee is screwed a piece of 1-inch pipe. It is screwed in so that the end reaches to the tapered end piece of the ½-inch pipe.

On the end of the 1-inch pipe is screwed a 1-inch perforated cap which serves to [illegible] the steam into a number of currents which pass into the tube and cleans it of soot.

A piece of ½-inch pipe is screwed into the side outlet of the tee and when steam is turned on the device acts as a syphon and draws a current of air through the handle and prevents it from heating so that the handle is always cool.

[illegible]

[illegible], O.

Getting the Position "Higher Up"

Much has been published in regard to becoming a more efficient engineer in order to assume greater responsibilities. Very little has been published, however, about how to secure the job higher up. It is more of a task to secure the job after one is fitted for it than some seem to think.

To illustrate, a certain uptodate engineer I know is young and progressive and has never let a chance slip whereby he could better himself. He holds a diploma from a correspondence school, is well versed in electricity, combustion and the multitude of things that a first-class engineer should know, and without a doubt is an A No. 1 engineer in every way. His present employer has told me that he is the best engineer he ever employed (and he has employed a good many). Now, in view of the fact that we read good men are always in demand, this man has been trying to get a better position for over two years without success.

Probably one reason why an engineer does not "get next" to better jobs is because he is tied down so close and does not have the opportunity to hear of the openings and is greatly handicapped in that way.

I would suggest that the boys give us their ideas on the following: If an engineer is desirious of securing a larger position, how should he proceed to get it? It is assumed that he is capable of holding it in every way.

Bridgeport, Conn.

Federal Laws

In reading Mr. Blanchard's letter, published in the January 10 issue of POWER, I noticed that he mentions a bill that is to be considered by Congress, relating to the Federal inspection of all locomotive boilers in the United States. I saw a copy, or rather, it was supposed to be a copy of this bill some time ago, and, if I remember right, the Boilermakers' Union is "fathering" it. I noticed one paragraph in particular which reads about as follows: "No applicant will be examined for the position of boiler inspector unless he has had at least five years' practical experience as a journeyman boilermaker." It seems to me that by inserting this clause in the bill the Boilermakers' Union is trying to form a sort of monopoly of all the inspectors' jobs that will be created if the bill becomes a law. We have quite a few good boiler inspectors in the State of Massachusetts and I venture to say that a large percentage of them have not had five years' practical experience as journeymen boilermakers.

I fully agree with Mr. Blanchard in regard to a Federal boiler-inspection and stationary engineers' license law. This would most assuredly be a step in the right direction. In my opinion it is up to the National Association of Stationary Engineers to start the ball rolling.

FRANCIS CLEGG.

Taunton, Mass.

Removing Oil from the Eye

Oil in the eye causes a burning, itchy feeling, but relief can be obtained by filling a wash basin with luke-warm water, in which a teaspoonful of table salt has been dissolved. Then put the eye in the salt water and open and close it slowly a few times.

Next fill the basin with cold water and, after opening and closing the eyes under water, dry them on a clean towel, but do not rub them.

Salt water cuts the oil, and the cold, clear water rinses the eyes and invigorates them.

WILLIAM E. DIXON.

Malden, Mass.

Fitting Piston Rings

Two rings of the snap type were turned ¼ inch larger than the cylinder and had to be cut slantwise before it would fit the cylinder. About ¾ inch had to be cut off and when a ring so treated is sprung together and forced into a cylinder, the sharp points will keep a considerable part of the ring from bearing against the cylinder walls. I therefore filed these points down and rubbed the rings in a bore provided for the purpose and spotted them to an all-round bearing.

Some engineers might expect the rings to wear to a fit. Suppose they will do so without scoring the cylinder, there would be a waste of steam during the wearing process and the result would be an unnecessarily large opening at the joint.

I fitted the rings to the grooves just tight enough to hold the joints together but so they could easily be moved by tapping them with a hammer handle. I have been told that this is much too tight, as the rings should be loose enough to slide in the grooves, or otherwise they would not expand against the cylinder walls.

If piston rings are fitted so that the spring is just compensated by the friction in the grooves, they will expand as soon as the piston begins its reciprocating movement.

If the rings are loose enough to slide they certainly have a side movement, which will increase, and cause them to rattle in a short time. I do not advocate the indiscriminate use of a coarse file, nor do I believe in jamming rings into the grooves, but in carefully fitting them both ways.

H. WIEGAND.

Chicago, Ill.

Water in the Turbine

One morning I dropped into the power house of our electric-light company and the operating engineer was running a high-pressure turbine of 1500 kilowatts capacity. All at once the lights began to grow dim, as the machine began to slow down. The turbine did not sound as though overloaded.

Engineer and switchboard operators were looking for a short-circuit and, being satisfied there was none, the engineer ran to the turbine and was about to make adjustments to speed it up, at the same time giving orders to the oiler to get an exciter and engine ready to cut in, when the lights came on and it seemed that everything was all right; but in about 30 seconds down went the lights again.

Finally the trouble was located in the boiler room; one of the firemen had let his boiler fill up with water and, of course, the machine did not make a very good water and steam turbine. The water did not cause any damage, as when it was lowered everything went along as usual.

Steam was carried at 140 pounds and, the water being high, slugs of it passed over into the turbine.

By being present at that time I got a little education in the variation of sound between a short-circuit or overload and water going into a turbine.

L. O. HUSTED.

Curtis, Colo.

Homemade Babbitt and Belt Dressing

If mining machinery in the mountains, or the drilling outfit of the prospector, miles from civilization, suddenly breaks down, it taxes the resources of the attendant to make repairs and keep things moving.

I recall an experience in the "Rockies" where it was absolutely necessary to have a quantity of good bearing metal at once, and the outfit was 160 miles from the base of supplies. The problem was solved by making a sacrifice of a copper wash boiler from the cook house, and by melting the solder from a collection of tin cans. These, combined at the ratio of one pound copper to ten of the solder, gave us splendid results. Subsequent experiments have shown that an alloy of twenty parts zinc, one of copper and three of tin give an all-round metal very hard to improve upon.

An excellent emergency belt dressing can be made as follows: Take 25 parts of linseed oil and 12 parts of turpentine; heat in a water bath and add 12 parts of pulverized rosin. Stir the mixture thoroughly and allow it to cool. Should the oil, turpentine and rosin not be available, castor oil with 10 per cent. of tallow added makes a very good dressing.

EDWARD VAN ANTWERP.

Brownsville, Tex.

Questions Before the House

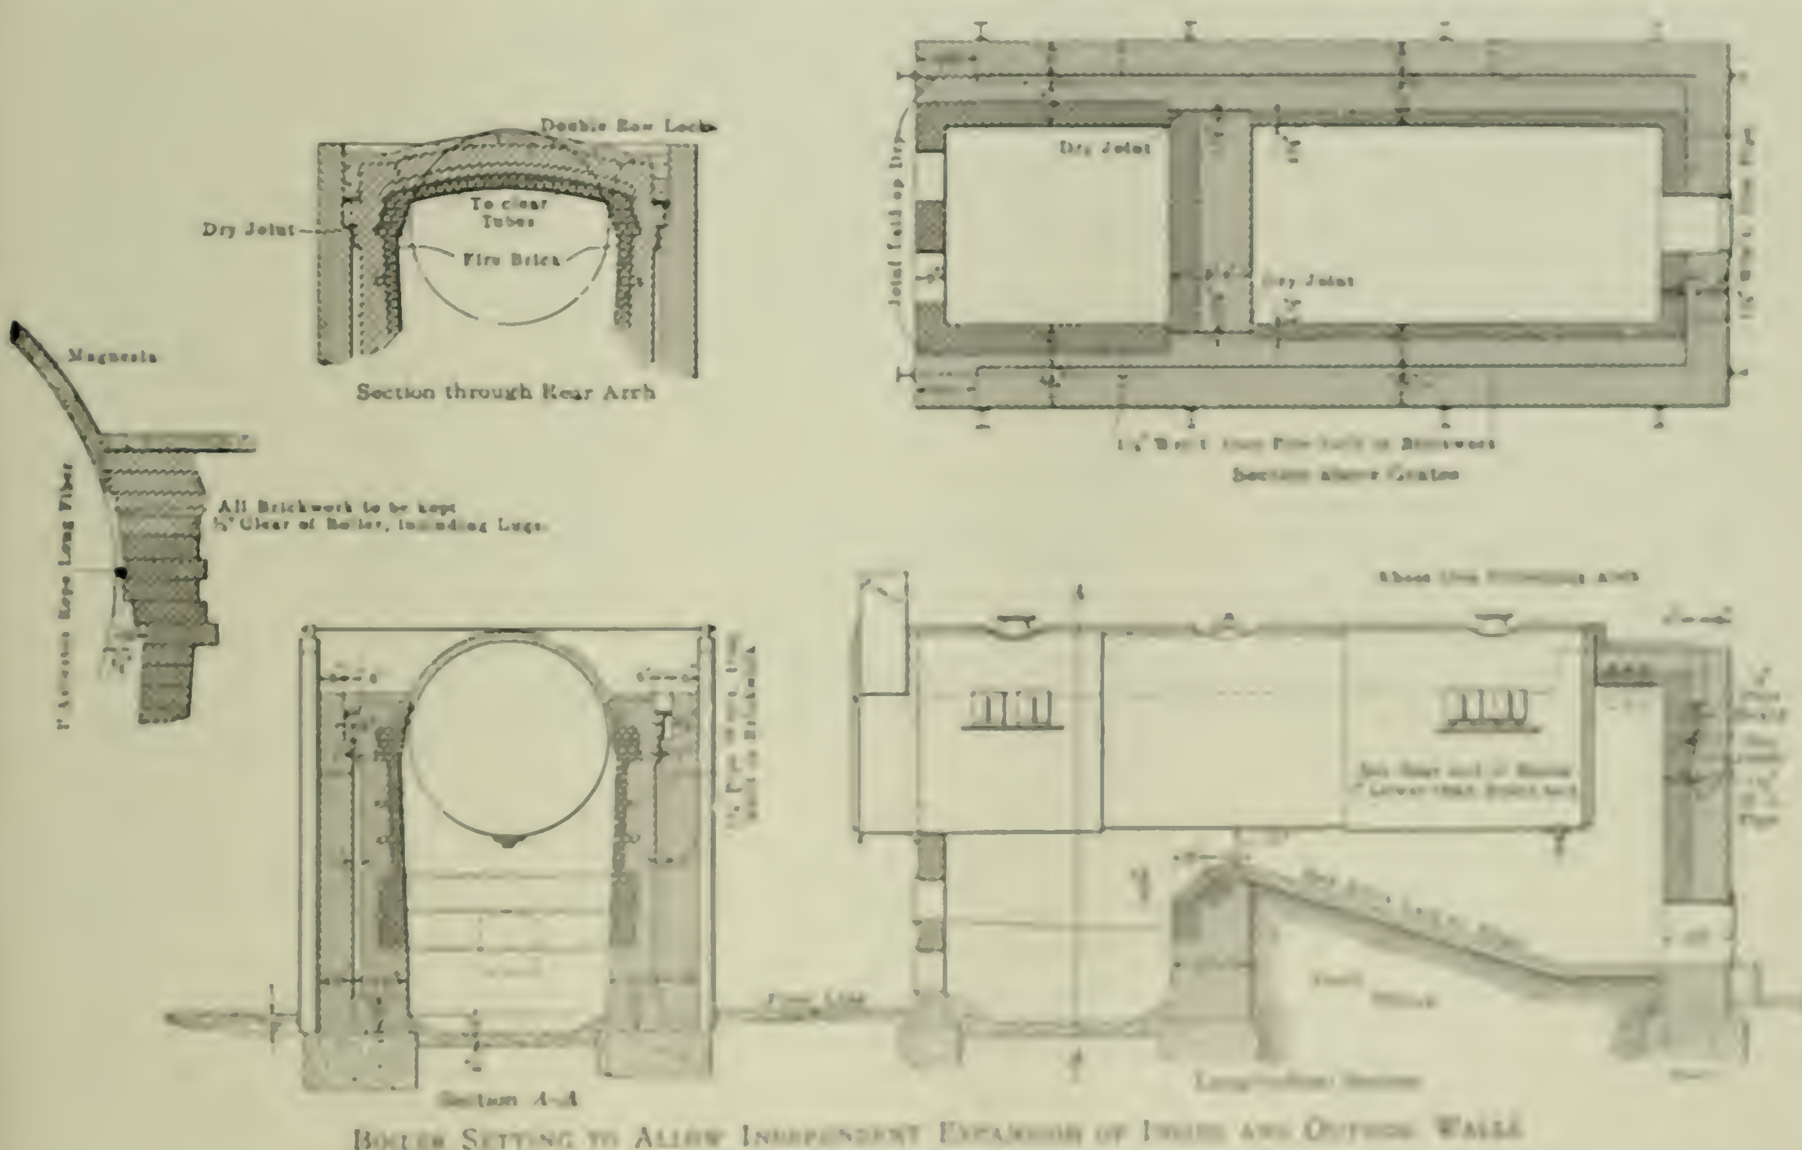
Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

Setting Horizontal Tubular Boilers

I read with considerable interest S. F. Jeter's excellent and instructive article on "Setting Horizontal Tubular Boilers" in POWER for January 3. Supplementary to this article I would say that it is the aim of an engineer to so design the brickwork of a horizontal return-tubular boiler setting that it will be as free from cracks due to expansion as possible.

Figs. 2 and 5 of Mr. Jeter's article show the sections of settings as commonly designed and built, in which the inside and outside walls are bonded together at the top of the air space above the horizontal center line of the boiler. When a boiler is in operation the inside walls of a setting are necessarily much hotter than the outside walls and the expansion of the inside walls will of course be the greater. To avoid cracks from this cause I consider that the inside walls should be free to move from this cause independently so far as possible.

The accompanying figure shows a setting which I designed a few years ago with this point in view. This design is used as a standard for boiler setting in the office of Charles T. Main, engineer, Boston, Mass., and a number of boilers with settings so built have proved very satisfactory. The figure is clear enough to be self-explanatory.



BOILER SETTING TO ALLOW INDEPENDENT EXPANSION OF INSIDE AND OUTSIDE WALLS

I presume that some may question the object of the 1½-inch pipes built into the outside walls near the top of the air space. This is to allow a free escape of the vapor arising in the air space as the walls dry out after the boiler is started up. This is not original and is the practice of not a few in boiler-setting design. I do not know whether there is any virtue in it or not, but I do not see that it can cause any harm and it may do some good, and the pipe can be plugged with cement after the brickwork has dried out.

F. B. COLE.

Boston, Mass.

Troubles of a Refrigerating Engineer

In the December 27 issue, Mr. Walters writes about trouble with his refrigerating system. Mr. Walters does not state what kind of a machine he is running. According to his explanations he has what refrigerating engineers call a "dry system"; that is, no outfit without an oiling system (oil cooler, etc.), such as furnished by the Pennsylvania Iron Works, Frick, York, Vilter, etc. With all of these machines, except the Vilter, the ammonia compressors are built vertical. As I do not know what kind of a machine Mr. Walters has, I will take the Vilter machine as an example. This machine has a horizontal compressor. A small pump, driven from the engine shaft by a belt is used to supply with oil the sleeve through which the piston rod works. The oil in the sleeve serves to keep the piston rod from getting hot. Sometimes oil is taken with the piston rod into the compressor. There is also a connection on the suction of the machine to supply the cylinder and valves with oil (ammonia liquid base) now and then.

The stuffing box of Mr. Walters' machine must be in a bad condition, possibly too much clearance exists between the piston rod and the back of the stuffing box. This will permit, after the packing gets worn some, too much oil to get into the compressor, and finally the packing goes the same way. I cannot understand, however, how Mr. Walters could find bits of packing, etc., in pockets in the high-pressure side of the system unless the system was flooded with such matter.

The machine discharges the ammonia and some oil into the discharge tank; the oil falls to the bottom of the tank, while the ammonia gas passes into the condenser to be liquefied and from there as a liquid into the liquid or pressure tank. The discharge tank is provided with a glass gage to indicate the hight of the oil in the tank. Of course, when the passages of the gage cocks are clogged, it is impossible to see the oil. The liquid or pressure tank has also a gage so that one can tell by opening the cock how much liquid is in the tank. In case some oil does get into this tank it will not do any harm; but, if so desired, it may be removed. From the discharge ports of the machine to the liquid tank, including the condenser and storage tank, is the "high-pressure side" of the system. The ammonia liquid is forced through the regulating valves (or expansion valves, as they are often called) to the expansion coils. If the ammonia is free from oil or other substances and not turned on too full, it freezes the coils connected to the suction of the machine. The part of the system from the regulating valves to the compressor is called the "low-pressure side" of the system.

If Mr. Walters will put a metal ring at the bottom of his stuffing box, use a good grade of packing, clean out the discharge tank and, if necessary, the liquid tank, he will find a great difference in the operation of the system. Should he still find the regulating valve to be operating badly, if he will replace it with a new one the trouble will stop. He should shut off the main liquid cock or valve first. All of the regulating valves in the different rooms ought to be marked so that they may be set at the same point again after the new regulating valve is in place. Sometimes one or more of these valves leak; this causes considerable trouble when pumping out one room separately, therefore, he should open them all. Pump the system down to zero, stop the machine and after a while start up again and pump down to zero once more or even a little lower. Not until the low-pressure gage hand remains where it was when the machine was stopped the last time is the system empty. Rap the gage slightly as the hand may hang a little. The suction and discharge valves on the machine may be closed if they are suspected of leaking. If the hand on the low-pressure gage remains at zero, it is safe to break a flange on the valve to be taken out and let the oil, if any, mixed with some ammonia out. Perhaps in Mr. Walters' case the main liquid valve was leaking, or perhaps he did not pump out properly.

In the case of a leaking main liquid valve, the effect will be noticed on the low-pressure gage, the hand will still rise after the system has been pumped back several times in succession.

To replace a valve, get all tools ready that may be needed. Have all of the nuts working easily. Start the machine, pump down to zero or a little below and keep the machine turning just fast enough to keep the pressure below zero. Then, have a good helper ready with a stopper; take out the old valve and have him close up the pipe. After everything is ready, remove the stopper and put in the new valve. If each one knows what to do, it will not be long before the new valve is in place; the quicker this is done the better. Whatever little air that is pulled into the system should not do any harm.

William L. Keil.

Philadelphia, Penn.

Hotel Power Costs

O. L. Sherman asks in the January 3 issue for data on hotel and office-building power plants. My letter in the December 20 issue will give him some figures as to power costs.

The statement for the month of October, 1910, in the above mentioned letter did not contain the total output of the generators for that month, which was 51,750 kilowatt-hours, which makes the cost per kilowatt-hour 2.36 cents. This was brought about by the large sale of current for that month.

As to the cost of the installation per kilowatt, this would depend upon the size of the units, the larger the units the lower the cost per kilowatt.

I take it that Mr. Sherman is in charge of a hotel plant where current is bought from the central station, and the remainder of the power is generated at the hotel. High-pressure steam for the laundry and kitchens is required, also for the pumping equipment and perhaps for the refrigerating machine, and, unless he has electric elevators, these also require high-pressure steam.

He probably has a boiler plant and equipment capable of carrying 100 pounds pressure. As it takes but very little more steam-generating capacity for a generating plant when the exhaust steam is used for heating purposes than when live steam is used to heat the building, he probably would not have to add to his boiler equipment in order to operate electric generators.

The size of the units will depend on the size of the hotel, that is, on the number of rooms used for guests.

Considering all from the above standpoint, and assuming that he has a "250-room house," he would get a night lighting load of about 100 kilowatts, taking in the outside lights and the roof sign, if he were using carbon lamps throughout. If he were using tungsten lamps, it would bring the load down considerably. If he has electric elevators, these would necessitate large units.

Under the requirements for lighting he would require one 100-kilowatt unit for the night load and one 50-kilowatt unit for the day load. This would leave him no spare unit for the night load in an emergency. He might have a "breakdown" connection with the central station; otherwise he would require one extra 100-kilowatt unit.

As to the cost of installation, if he did not have to enlarge the boiler plant, but just installed the steam and exhaust piping and the generating set, the cost would be approximately $45 per kilowatt, complete, including foundations, erecting, piping and pipe covering.

If an extra boiler had to be installed, it would cost from $10 to $15 per horsepower, depending on the size of the boiler. This would cover the cost of a complete boiler installed.

As to which would be the more economical, turbines or reciprocating engines, I could not say; but it seems to me that for small units, reciprocating engines would be better. One thing is certain, whatever type of machine is decided upon, it must be a quiet running one, as vibration or a singing noise would not, or cannot, be tolerated in a first-class hotel.

Mr. Sherman will do well to have all foundations built heavy and substantial, and, if possible, have all steam mains supported from the floor instead of hung from the iron work of the building.

Another point that might be of use to Mr. Sherman is that if he is considering the installing of a generating plant, and if his building is located in a business section where there are office buildings and stores near by, he could derive (by installing larger units) a good income from his plant by selling current outside for light and power purposes, and surplus exhaust for heating, also hot water for domestic use.

He could charge for the current at just a little under the rate of the central station and get plenty of customers. The steam he could charge for at the rate of from 40 to 60 cents per 1000 pounds, depending on the cost of coal; or, if he did not want to install a water weigher, he could charge a flat rate of from $4 to $5 per 1000 cubic feet of space to be heated.

From my plant I take in from $250 to $575 per month for light, heat and ice, depending on the season of the year. I have a very good customer, a theater, to which I furnish both heat and light.

WILLIAM J. BEDARD.

Rochester, N. Y.

Placing the Responsibility

If the authorities to whom is intrusted the duty of investigating and placing the responsibility for boiler explosions would conduct them more after the manner of common police-court investigations, there is reason to believe that a marked decrease in the number of failures would be the result.

Every boiler-explosion investigation that I have ever heard of or read about has apparently been conducted with the object in view of placing before the public a report that contained far more material for the scientific mind to consider than to place before the criminal prosecutor evidence that would show if there had been a probable guilt of criminal carelessness.

What has been the result? So far as I can ascertain no one in this country has ever been criminally prosecuted in connection with any of the thousands of boiler explosions that have occurred since steam boilers became at once a menace and a necessity to the public welfare.

If it were not for the appalling testimony of death and destruction intermixed with the reports of these investigations the reading of some of them would be amusing.

In the early days a report was sure to state that "the engineer admitted cold water into an overheated empty boiler"—especially was this the verdict if the engineer had disappeared with the explosion, as was often the case. This form of report eventually became unsatisfactory, for if the engineer lived he would sometimes contradict and possibly prove that such conditions did not exist.

Overpressure has always been a good explanation to hand to the public when it was bowed down with grief over the premature departure via the boiler-explosion route, of fellow townspeople, it being understood that "overpressure" was merely incidental to the operation of a boiler.

The ironmaker should be held more strictly to account for failure to use the best material and the best process for the manufacture of the iron and steel for the particular use it is intended for.

The boilermaker should be required to follow more stringent rules and should be held to account whenever investigation showed that a boiler had been improperly or carelessly constructed.

The owner should be held accountable for having in his possession a boiler that could in any manner become an unnecessary menace to public safety. He should also be held responsible for the selection of the operatives to whom is intrusted the care of the boiler.

The operatives should be held responsible for the condition and management of the boiler and the condition of appliances that pertain to the safety of its operation.

The inspectors and boiler-insurance companies should be held to a far more strict accounting than can be estimated in dollars and cents for the unfaithful performance of the duties which the words suggest.

Statistics show that comparatively few boilers explode up to a certain age. Then, why should not that age be made the limit for the term of use?

In nearly every instance when a boiler explodes, some circumstance will be brought out that will indicate that dollars were weighed against human life and the dollars weighed the most.

Air Pressure for Lifting Water

The answer given to the inquiry of A. L. W., in the January 3 issue, in my opinion is not correct.

The air pressure necessary to operate an air lift is governed entirely by the submersion and the friction of the air line, and would be the same whether the lift were 50 feet or 200 feet, although the volume of air required would vary with the lift. The formula would be

Submersion × 0.434 + friction of air line = pressure.

The air pressure required to operate an air lift with 200 feet submersion with an air line of proper size should not exceed 90 pounds. The quantity of water lifted has no effect on the air pressure. The work performed in an air lift is entirely due to the buoyancy of the air and the compressor has no effect on the air after it is liberated at the bottom of the well.

In reference to the statement that the air pressure is "never less than is required to support a column of water of a height equal to the lift," this would be true if we were lifting a solid column of water, but the weight of the column is greatly reduced by being mixed with air bubbles.

In regard to this I wish to call attention to the article on the Harris pump in the March, 1905, issue of POWER, which actually lifted water 300 feet with 40 pounds air pressure and on which the patent office at first refused to grant a patent on the ground that the pump would not work. A number of these pumps have been in successful operation on the Pacific coast for a number of years.

G. A. RICHARD.

Los Angeles, Cal.

Graft

An editorial in the January 10 issue does me the honor of criticizing the communication that appeared over my name in the December 20 issue, entitled "An Engineer's View of Graft." As the editorial so controverts the facts and shows that the opinions I expressed have been misunderstood, I will endeavor to make clearer my ideas as set forth in those parts of the article that the editorial criticizes.

Ability to write so as to be understood is comparatively easy, but to write so that you cannot be misunderstood is an art; this possibly explains why more engineers do not write, a question recently propounded in these columns.

The editorial states that the opinion expressed "is not calculated to accelerate the movement for the abolition of graft." I wish emphatically to state that no such acceleration was intended if, as my article states, the accepting of the usual tokens given in return for honest patronage is to be considered as "graft."

I regret that the editorial did not define the meaning of the word, as one object of my writing was a curiosity to ascertain the scope of the word when applied to engineering.

A great deal of the sentiment expressed in the picture of the "Employer conspiring with his engineer to get more out of the seller of supplies than the face of the bills calls for" depends on the point of view. Considered from an office chair and biased by the assurance of a large salary the subject is apt to present a very different aspect than the view of a man sitting on the edge of a coal bunker, ruminating on the dismal foreboding that the grocery bill will have to go over another week in order that the "kiddie" may have a new pair of shoes.

The idea expressed by the term "conspiracy" has been considerably perverted from what was intended. Instead of "conspiring" to get more out of the seller of supplies than the face of the bill called for, the employer merely sanctions the acceptance of part of the commission that, if not received by the engineer, would remain in the bulging pocket of the salesman.

The simile of "master and menial" in some cases is very good as the engineer works for from 12 to 14 hours a day, six days a week, and receives something like $14 each week for his services. After working a short time under these conditions you can call a man most anything without injury to his feelings.

I cannot answer the conundrum, "Where are the high ideals of the professional engineer?" as I do not believe he has any, my conception of the term "professional engineer" being—One who can receive as *fees* and *commissions* what to the ordinary work-a-day engineer would be considered just plain "graft."

As I particularly desire to be considered among the "immunes," will my criticizer kindly answer the following: Does the acceptance of the premiums offered for the securing of subscribers to POWER, or the premiums offered by advertizers for the purchase of their goods, or the acceptance of a consideration for writing this article, consign me to the "black list"?

AMOS SKEG.

Saugus, Mass.

Experience of an Indicator Man

We are all big children, and like children, like to have the last word.

I would like to reply to Mr. Wheat's comment in the January 10 number on my letter in the December 6 issue. My remarks referred to an article in the issue of November 15, which described a case where an engine could not carry the load, and, upon applying the indicator, it was found that there was 68 pounds mean effective pressure in one end, and only 15 pounds in the other. Now, I think that anyone will agree with me that no such state of affairs could exist, unless the cutoff was so badly out of adjustment that one might say that it was not adjusted at all, and the engine was very little better than a single-acting engine having one power stroke per revolution. I, therefore, maintain that it should be apparent to the novice.

It is customary for erecting men to block up the regulator on Corliss engines about ½ inch and then, while the engine is running slowly, to set the cam rods so that both cams will just unhook the valves. They know all about the effect of the connecting rod on the piston travel, but they leave that refinement to be corrected by means of the indicator. There is no trouble in getting the engine to deliver its full power and with economy. The same might be said about setting the rods from the wristplate to the valve cranks, and locating the eccentric on the shaft. These adjustments are all made by marks on the ends of the valves and the ends of the valve ports, when the cylinder is cold. Heating up the cylinder distorts these adjustments to some extent Also, the shop men are sometimes careless in marking the valves and cylinder, and to get these adjustments right, the indicator must be used; but, speaking in a general way, setting the valves and cutoff in this manner is correct, and adjustments by the indicator afterward are in the nature of refinements.

W. E. HOPKINS.

Torrington, Conn.

I think that Mr. Wheat is too severe with Mr. Hopkins in his letter in the January 10 issue under the above title. I do not believe that Mr. Hopkins meant that an absolutely even cutoff could be obtained by adjusting the dashpots by the eye, and it would seem as though the difference in the rise would have been noticeable and if adjusted so that the rise looked about even, or even if the rise were equalized by the use of a rule, the engine under discussion would have had a much nearer equal cutoff than when found by the indicator man. Of course, this could be improved by giving the crank end more rise; according to one's general experience or knowledge of that particular engine. I know of one in which the difference in rise necessary to equalize the work is ¼ inch.

With engines on which the cutoff can be adjusted while running and which are direct connected to electric generators, the indicatorless man can even up the work done in each end of the cylinder by watching the vibration of the voltmeter pointer and noticing which stroke allows the finger to drop back, giving that end a longer or the other end a shorter cutoff until the finger is steady. Diagrams taken from each end after this adjustment alone might not be of the same shape, but if care were taken in setting the valves, knowing that there was no indicator available with which to check the operation, and then, if after the load on the cutoff was adjusted by the voltmeter, it would seem as though a fair job of valve setting would result.

A. N. BOGART.

Effects of Cold Air

In answer to H. C. Fiske, relative to cold air admitted over the fire, I will say that as engineer engaged by the smoke department of one of the Middle West cities I frequently resorted to this practice for one or two reasons. First, the coals in use at that place are very high in volatile contents and there is a great volume of gas distilled during the first three to five minutes after each firing. These gases require a vast amount of air to supply the required amount of oxygen necessary for complete combustion. This air cannot be supplied through the grates as the green fuel just added has temporarily cut off this source of supply. The second reason is that when the rate of combustion is high, the temperature in the furnace is so great as to distil the above mentioned gases in such volume as to be beyond the control of the furnace operator, but, by admitting cold air through the furnace doors, the temperature can be controlled and much better results realized.

I have experienced a good deal of trouble from practical and experienced engineers and firemen who object to this practice for fear of the resultant effect on the boiler; but, after extended experience, I feel confident that no ill effects are caused by a judicious supply of air over the grates in horizontal return-tubular and water-tube boilers, although judgment should be used when this practice is applied to locomotive, Scotch or economic boilers.

H. M. PURNELL.

Erie, Penn.

Pittsfield Boiler Explosion

From information about the Pittsfield boiler explosion gathered from the daily press, as brought out by the coroner's inquest, it would appear that the boiler was fired up previous to the morning of the explosion, and that the safety valve blew freely when the gage registered only about 20 pounds. It was supposed that the gage was out of order and it was removed and brought to the city to be tested. The test seemed to indicate that the gage was correct and it was put in place again. When the boiler was again fired up the safety valve blew at the same pressure. Thinking that the steam gage was correct, it was natural to suppose that the safety valve was out of order, and to alter the tension spring.

It is possible that the engineer first gave the adjusting nut one full turn and waited to see how high the pressure would rise. Probably the valve blew again when the gage showed only a slight increase in pressure. The conditions at the ice plant on this morning possibly were something like this: fine ice-harvesting weather; 100 or more men under pay waiting for the engineer to start up; the owners fussing around, and the engineer a little rattled. What would be more natural than for the engineer to think to himself, if one turn on the nut only increased the pressure two or three pounds, I'll turn the thing down far enough at once and run according to the steam gage, which he proceeded to do.

The expert from the valve makers, the man who set the valve in the shop, says that the nut was screwed down twelve threads lower than when the valve left the factory. In my opinion it was down so far that the spring became practically a solid bushing, and I do not think the valve would have blown off at any pressure.

The results of this accident are deplorable, and the friends of the victims deserve much sympathy; it seems too bad that a little more gray matter was not used in the operation of this plant.

GERALD GRIFFIN.

Hartford, Conn.

Cause of Boiler Explosions

The numerous recent boiler explosions tend to confirm the theory which I have long entertained. Investigations seem to show that the length of time that a boiler has been in service has a strong influence on its safety. This is due to the change in the texture of the metal more than to the wearing away of any particular part of the boiler shell. A new piece of boiler steel can be bent double without showing any fracture; but, a piece cut from a boiler which has been long in service will not stand this test. This is especially true of the thicker plates. The farther the water is removed from the fire, due to the thickness of the plate, the more rapidly does crystallization of the shell seem to take place.

The editorial in a recent issue of POWER in which it is urged that the life of lap-seam boilers be limited, is eminently to the point. There should be an age limit for all boilers of lap-seam construction. The date of construction should be stamped in a conspicuous place on each boiler so that the length of time it has been in use may easily be ascertained.

Another point is that inspections should be more numerous and more carefully and thoroughly made. If it costs more to make such inspections raise the price of the insurance. Often, inspectors do not have sufficient time to make good examinations. There seems to have been too many points that were overlooked by the inspector recently which have led to disastrous results.

C. R. McGAHEY.

Baltimore, Md.

In the discussion of boiler explosions, some express the opinion that the opening of a stop valve too quickly might cause a boiler explosion in accordance with the theory that a sudden relief of pressure causes an upheavel of the water against the shell with explosive force. Others maintain that if this were possible, boilers might explode by the mere popping of the safety valve.

Tests made upon different makes of pop-safety valves, as recorded in a paper read before the American Society of Mechanical Engineers in 1909 by Phillips E. Darling, showed an average lift of 0.07 of an inch at opening for the 4-inch valves and 0.061 inch lift at opening for the 3½-inch valves. So, the discharge area of the 4-inch valve was

$$0.07 \times 3.1416 \times 4 = 0.879 \text{ square inch.}$$

Opening a stop valve quickly would give many times this area and a correspondingly greater discharge. As a safety valve often sucks up water, a stop valve would be much more likely to do so if opened suddenly, and perhaps cause destructive water hammer in the piping.

B. N. EVERITT.

Jamestown, N. Y.

"Something Just as Good"

Upon reading the ad. editor's page in the January 10 issue, I was reminded of an experience I had with a sample of "just as good" hydraulic packing.

I was induced to try a sample, so I packed both plungers of a duplex boiler-feed pump, using three rings in each plunger. This pump was used at night and kept in reserve in the day time. The packing was recommended for hot water and the pump took its supply from a large tank which received the return and pumped through a closed heater to the boilers.

On the third morning after the pump had been packed the night fireman reported that the pump would not throw any water. I at once opened the water end and found the trouble. Of the six rings that I had put in, all were gone but two and these certainly would never be recognized as rings; they looked like bunches of cotton waste.

I repacked the plunger with the packing that I had always used and thought that the trouble was over. But it had only commenced. At noon we had to take the caps off the check valves on the feed-water pipes of three boilers and take some of that packing from under the clappers. That night we had to clean out the check valve on the closed heater; two days later we had to shut down the No. 1 boiler on account of the lower connection to the water column being clogged up. A few days later we had to take off the blowoff cock of the No. 3 boiler as that boiler did not blow down freely. In this boiler we found enough of that packing to fill a quart measure; some of it was in shreds and some was in small lumps like pulp. I have often wondered how they ever got it into ring form.

It certainly did *look* just as good as any other packing, but I found that looks were deceiving and the trial of that "just as good" cost me a few dollars, plenty of worry and a good amount of hard work.

I am now waiting for another visit from that drummer. I am very anxious to have a good confidential chat with him about "just as good" goods.

M. T. MARKHAM.

Burlington, Vt.

Selection and Use of Packing

While Charles H. Taylor, in the January 3 number of POWER, has given a good lesson on the above subject, he has made one statement that upsets a theory of long standing. It is an accepted theory that one surface in moving over another produces a friction which is proportional to the total pressure between the surfaces regardless of the area of contact.

As an illustration of this it will be found that a common building brick will require the same amount of force to drag it across the floor when it stands on edge as when it stands on its side.

Mr. Taylor's statement that a packing with a flat side in contact with the rod produces the least friction because the pressure is more evenly distributed, is not in accord with the theory of friction.

T. E. HAMLET.

Means, Ky.

The Engineer's Education

W. C. Walters has something to say in the January 10 issue about chemistry for engineers. I find that in a great many cases engineers are sacrificing their chances of securing a first-class practical education to fill up during every hour of spare time on chemistry, and the theory of hydraulics, pneumatics, electricity and a dozen other things. These are all good to know, but any man who gets a good working knowledge of mathematics, steam boilers, gas and oil engines, electricity, steam engines, refrigeration and the hundreds of other things essential in a modern average steam plant, cannot possibly get time to become expert in a dozen different professions.

Every engineer must learn a little about chemistry and other things. Some engineers who write for POWER try to convince the readers that they are well up in all of the subjects just mentioned. I have spent several years studying the theory of steam engineering and it has proved of vast assistance to me. But I got my practical education first.

I would advise young engineers to visit as many different steam plants as possible, and when a thing is seen and not understood to ask questions. As Mr. Walters suggests, try to get an idea of the chemistry of the things most important in the plant, as water, coal, etc., but for your own sake do not attempt to wade through the hundreds of things in chemistry and the like that can never possibly be of any use in the engine and boiler rooms. If you must neglect one branch of engineering do not let it be the practical side, and remember, no engineer ever will rise to the top if he has no technical knowledge. But remember also that the technical expert with no practical experience is not a safe man to have charge of any plant, no matter how small. When I say "the top" I mean chief in a steam plant, that is about as high as any engineer with a little knowledge of a dozen different trades and professions can get. This is the day of the specialist, for it has been proved beyond controversy that it takes a lifetime for even a smart, brainy man to make himself a first-class expert in any one of the many different trades or professions into which every engineer must dabble more or less.

JAMES E. NOBLE.

Toronto, Ont.

Inquiries of General Interest

Questions are not answered unless accompanied by the name and address of the inquirer. This page is for you when stuck—use it

Governor Pulley and Engine Speed

If an engine having an 8-inch shaft runs 200 revolutions per minute, what diameter of pulley will be required on the governor to drive it 256 revolutions per minute?

T. E. H.

The circumference of a circle is 3.1416 times its diameter.

The 8-inch shaft at 200 revolutions will pass

$8 \times 3.1416 \times 200$ *ft. of belt per min.*

The pulley will at 256 revolutions pass

Diam. $\times 3.1416 \times 256$ *ft. of belt per min.*

and these, of course, must be equal to each other for the same length of belt passes over both pulleys in the same unit of time. Then,

$$Diam. \times 3.1416 \times 256 = 8 \times 3.1416 \times 200$$

$$Diam. = \frac{8 \times 3.1416 \times 200}{3.1416 \times 250} = 6.25\ in.$$

Since the rim speed of the pulley is inversely proportional to the diameter and directly proportional to the rotative speed, the 3.1416 need not be considered and the case may be stated as one of inverse proportion.

Sp. of Gov.		*Sp. of Eng.*		*Dia. of Shaft.*		*Dia. of Pulley.*
256	:	200	::	8	:	6.25

Size of Pump for Given Boiler

How is the diameter of the water cylinder of a pump suitable for feeding a boiler calculated?

J. F. M.

First find the number of gallons of water that will be evaporated per minute, then decide the number of strokes to be made per minute by the pump. Multiply the number of gallons by 231; divide this by the piston stroke in inches; divide this by the number of strokes per minute; divide this by 0.7854. The square root of the result will be the diameter of the water piston required. It is good practice to operate a feed pump slowly, and running at its normal speed it should be capable of supplying double the average requirements.

Clearance and Mean Effective Pressure

What effect has clearance on the mean effective pressure?

C. M. P.

For a cutoff at any fraction of the stroke, the greater the clearance the higher the mean effective pressure will be.

Heat Required to Convert Ice into Steam

A block of ice weighs 10 pounds, and has a temperature of 18 degrees Fahrenheit. Compute the amount of heat required to convert it into steam having an absolute pressure of 30 pounds.

S. C. S.

To raise the temperature of one pound of ice from 18 to 32 degrees requires 7 heat units; to convert it from ice at 32 degrees into water at 32 degrees requires 142 heat units and to convert it into steam at a pressure of 30 pounds absolute requires 1158 heat units. Adding

$7 + 142 + 1158 = 1307$ *heat units.*

Ten pounds will require 10 times this.

Utility of Expansion Tank

Of what use is an expansion tank in a hot-water heating system?

U. E. T.

Like all other substances, water varies in volume with changes of temperature and the expansion tank placed at the highest point in the system furnishes room for the increase of volume of water in the boiler, piping and radiators as it is heated.

Size of Steam Pipe

How can I determine the proper size of steam pipe to supply a given size of cylinder?

S. S. P.

Multiply the cross-sectional area of the cylinder by the speed of piston travel in feet per minute and divide the product by 6000.

$$\frac{Piston\ area \times piston\ speed}{6000} = Pipe\ area$$

Ratio of Expansion by Volume

In a 12x18-inch engine the clearance is 5 per cent. Cutoff takes place when the piston is 6 inches from the end of the stroke. What is the real cutoff and what is the ratio of expansion by volume?

S. S. C.

The distance swept through by the piston is 18 inches, 5 per cent. of which is 0.9 inch; this makes a total cylinder length of 18.9 inches. If the cutoff takes place at 12 inches of the piston stroke the real cutoff will be $\frac{12.9}{18.9}$ of the cylinder volume, and as the ratio of expansion by volume is the final volume divided by the volume at cutoff. The volume at cutoff in this case is proportional to 12.9 and the final volume to 18.9. Hence the ratio of expansion is

$$18.9 \div 12.9 = 1.46.$$

Power Required to Drive Vessel

If 4000 horsepower will drive a vessel at a speed of 14 knots, how fast will 2000 horsepower drive the same vessel?

P. R. D.

The power required to drive a vessel is proportional to the cube of the speed, and inversely the speed will be proportional to the cube root of the power expended; hence,

$$\sqrt[3]{4000} : \sqrt[3]{2000} :: 14 : S$$

$$\sqrt[3]{4000} = 15.8\ .\ \sqrt[3]{2000} = 12.6$$

then

$$15.8 : 12.6 :: 14 : S.$$

$$S = (12.6 \times 14) \div 15.8 = 11.$$

If 4000 horsepower will drive the vessel 14 knots, 2000 horsepower will drive the same vessel 11 knots.

Diameter of Pipe for Given Flow

What will be the diameter of a pipe 150 feet long which will deliver 600 pounds of steam per hour with a pressure drop of 5 pounds, the boiler pressure being 75 pounds?

P. G. F.

A much used formula for the flow of steam in pipes is,

$$W = 56.68 \sqrt{\frac{w\,(p_1 - p_2)\,d^5}{L}}$$

in which

W = Weight of steam flowing per minute;

w = Weight of 1 cubic foot of steam at higher pressure;

$p_1 - p_2$ = Drop in pressure;

d = Diameter of pipe in inches;

L = Length of pipe in feet.

Substituting the known values,

$$10 = 56.68 \sqrt{\frac{0.2044 \times 5 \times d^5}{150}}$$

$$100 = \frac{3220 \times 0.2044 \times 5 \times d^5}{150}$$

$$d^5 = \frac{100 \times 150}{3220 \times 0.2044 \times 5} = 4.55$$

$$d = 1.35\ inches$$

As there is no pipe made in this size, 1½-inch pipe will be required.

POWER

The Engineer and the Machine

Through many channels the field of the operating engineer is being invaded and with a success that depends entirely upon the alertness of the particular engineer whose plant is selected by the outsider as a possible source of revenue. The lubricating engineer, the supervising engineer and the emissary from the central station are all looking for business and the isolated plant is the land of promise they seek to exploit.

So great has been the improvement in machinery designed to displace or render needless the skill of the human hand and brain that whole trades have disappeared and armies of skilled hand workers have been reduced to the ranks of common laborers, tenders of machines, etc.

In the supervising engineer one form of the machine idea manifests itself, for in one individual is all the skill considered necessary for the economical operation of several plants, the routine work being done by rote by the commonest labor, which costs so much less than skilled labor that the payroll shows quite a decrease after deducting the fees of the peripatetic supervisor.

In the lubricating engineer the machine idea takes another form. Claiming to have saved a large percentage of the fuel used in this or that plant by intelligent lubrication. The fuel buyer's ear is readily gained and the skill of the engineer as a user of oil is rendered useless if the professional oiler gets a foothold and makes good. A cheaper man will do the oiling in the future.

But the greatest menace the engineer faces is the central station, which with its lines reaches to the limits of human habitation and industries. It stands ready to displace the engine with a motor that will run for months or years without either oil or supervision and may be started or stopped by pushing a button in any convenient location.

It is the engineer's problem to prove that it is cheaper for the power user to buy his skill than the partially or wholly machine substitute. Power generation and transmission is the field in which the special skill of the engineer is required and it depends upon his alertness or inertia whether he holds the field to himself, shares it with another at a reduced wage or is forced out altogether with no wage at all. The man in charge of a power plant, whether large or small, is directly the determining factor in the economy of its operation, and he should know more about every detail of this operation than is possible for any outsider, however well equipped he may be.

Successful steam engineering requires special training and special knowledge along several lines. Special knowledge comes only from special application. The engineer has in his own plant, small and unimportant though it may be, better facilities for special study of his own conditions than any other man in the world and he must use them to the limit of his ability or be displaced by some one of the many forms of skill-supplanting machines, human or mechanical, and take his place with the workless workers of other excluded trades.

Milwaukee Garbage Destructor

In the December 7 issue of the *Municipal Journal and Engineer*, there appears a statement attributed to H. E. Briggs, commissioner of public works, of Milwaukee, which, if true, would constitute a severe arraignment of Milwaukee's new garbage destructor, some test figures from which were given in our issue for November 29. The statement is to the effect that it is costing the city of Milwaukee two dollars and eighty-five cents per ton to dispose of garbage at the new plant, when, as a matter of fact, this figure includes not only the cost of incineration but also of collecting the garbage. Of the total cost of two dollars and eighty-five cents, therefore, not more than approximately eighty-five cents can be charged to incineration, the remainder of the charge being for hauling and labor incidental to the delivery of garbage at the plant. When the conditions of the test as reported in Power are understood it is easy to see how the cost is divided. The specifications called for a test run to include only the actual operation of the fire, stoking, etc., and keeping the grates clear of ash and clinker. The test was not to include the costs of supervision, hauling, weighing, unloading, dumping of ash and clinker, or repairs, as it was assumed that these items would be the same for any system of disposal and could therefore be eliminated. The percentage of garbage in the present [illegible] tor in the cost of operation and the test figures were obtained when using forty-one per cent. of this constituent. At the present time the everyday cost of operation is somewhat higher than the figures given in the test, by reason of the fact that the condition of the garbage and refuse as delivered to the plant varies with the season of the year, and from fifty-five to sixty per cent. of garbage is now being incinerated. Also the pay of a fireman has increased from two dollars to two dollars and fifty cents per eight-hour day.

In the *Journal* of Associated Engineering Societies, for December, S. A. Greeley, superintendent of the plant, gives the cost figures for the first five months of its operation, the cost ranging from eighty-two cents to one dollar and seven cents per ton. According to these figures the average amount of material disposed of per day was one hundred and ninety-four tons; the average percentage of garbage was sixty-six; the percentage of ash was twenty; of rubbish, eleven, and manure, three; while the average cost of disposal during this period is given as ninety-five cents per ton. For the month of November, 1910, the cost was seventy-eight cents per ton.

There is one interesting feature of this installation which has not been touched on and which will throw considerable light on the management of municipally operated institutions. Some months ago, in the effort to economize in op[illegible]ion, the labor expense for the pl[illegible] [illegible]duced to such an extent as t[illegible] the expense for disposal of refuse per ton from eighty-eight cents to seventy-eight cents. This was unsatisfactory to the labor organizations and the city administration ruled that the men should be reinstated. Whenever a municipally operated project is proposed the cry goes up that on account of the high wages and short hours commonly associated with such institutions the project cannot compete with a privately operated plant. Here we have an example of a municipally operated property run by a Socialist administration which is extremely friendly to union labor and where the difference in labor cost between satisfied and dissatisfied union workers represents roughly only twelve per cent. of the total cost of operation.

Smoke and Health

At a meeting of the Engineers' Club of Philadelphia, a short time ago, at which the subject of smoke prevention was discussed, an eminent physician made the following statement:

"Is it any wonder that respiratory diseases and diseases of the mucous membranes are so common and habitual in our big cities, where railway and factories daily pour forth volumes of black smoke? Sore eyes and catarrh of the nose, throat and bronchial passages may be produced directly by the mechanical irritation of smoke particles. Smoke does not produce tuberculosis. The infective agent of this disease is carried in dust. However, the smoke evil, if not a direct producer, is indirectly an important and serious predisposer to the disease. This happens in two ways: First, by a local irritation of the membrane of the air passages it sets up a catarrhal susceptibility to infection; secondly, by the habitual catarrhs and insufficient quantity of fresh air so contaminated by smoke the general systematic resistance to disease is diminished, and when the recuperative and reparative powers of the body are thus debilitated and weakened, the bacillus soon finds favorable soil and lodgment, and ready access to the vulnerable tissues."

So much for the injurious effect of smoke, but how about the sulphurous gases with which the air of large cities is contaminated due to the burning of coals high in volatile sulphur?

President Taft's Water Power Policy

On February 1, President Taft approved a plan for the leasing by the Government of water-power sites on public lands. The essential features are that the Federal Government shall continue to own and control the water powers on the public domain. Legislative authority must be sought for issuing term leases for periods not to exceed fifty years. Those leasing from the Government must pay for what they get and must promptly and fully develop the powers so that there shall be no unnecessary limitation of output. Rates to consumers declared exorbitant by the Supreme Court shall be ground for the cancelation of the lease. At the expiration of the lease, it is proposed to give the lessee a preference right to renewal unless the Government desires to use the property for public purposes; and, provided the lessee fails to secure a renewal either because the Government desires the land or because another applicant offers better terms, the previous lessee shall receive compensation for the actual value of improvements on the ground or be allowed to remove such equipment.

As president of the National Conservation Association, Gifford Pinchot highly commends President Taft's water-power policy. It is in full accord with the principles for which the association stands, and the policy as outlined has been enforced by the United States Forest Service so far as the existing law would permit.

The rigid enforcement of this policy will mean a great deal to the country. It will prevent a monopoly in water power, tend to keep the rates for power at a reasonable figure, and above all keep the water powers in the hands of the people. It should be enacted by legislators, rigidly enforced by employees of the Government and supported by the people.

The Isolated Plant Association

The motto "In union there is strength," seems to be the keynote of the present movement to resist the encroachment of the central station on the field of the isolated plant. It is not alone the engineer who feels the ground slipping from under him; the manufacturer, the salesman and everyone even remotely concerned with them, feel the pinch that is to come when but one public-service corporation shall furnish all the power required in a community. Accordingly these various interests have united in an organization known as the National Isolated Plant Association.

As is the case with all such organizations its success or failure will depend largely upon its policy at the start. It must gain the confidence and coöperation of all parties concerned, and in order to do this it must be manifest, both in words and action, that the common interest alone is to be served.

Little will be gained by adopting a hostile attitude toward the central station, but much progress can be made by proceeding along competitive lines, based upon actual knowledge of the facts. It must be conceded that there are a few classes of service wherein the central station can legitimately furnish power cheaper than the isolated plant, and it should be the policy of this organization to show the consumer just where the line should be drawn. In short, its duty will be to seek the truth, even though the shoe may pinch in certain instances.

In his annual report, Pres. Henry M. Whitney, of the Rhode Island Coal Company, made the following statement: "The coal is of excellent quality, and the so called 'treatment' has been found to be unnecessary, since the coal burns as well without as with it." Over a year ago Power gave some little attention to Rhode Island coal and we are glad to see that Mr. Whitney's present opinion concerning the value of the treatment verifies our prediction.

According to reports of the United States Geological Survey, California contains approximately one-tenth of the total oil-producing territory in the United States. Yet it is estimated that she furnishes one-half the probable minimum and one-third the probable maximum oil production of this country.

Some engineers imagine that because they have kept a small power plant running, they can handle a large central station.

Falling Stack Kills Engineer

During a high wind that swept over New Jersey, Saturday, January 25, a 90-foot brick stack at the Caledonian mill of the United Box Board Company, Whippany, N. J., was blown down, instantly killing the engineer, George Lockwood, and severely injuring Superintendent William Purcell.

Fig. 1. Tilted Iron Stack

The stack stood at one end of the boiler house and served one of three return-tubular boilers. The other two boilers were each served by a separate 60-foot iron stack. When the brick stack collapsed, it parted the guy wires of one of the iron stacks, causing it to tilt over as shown in Fig. 1.

In falling, the brick stack crashed diagonally through the engine-room roof and that of the stock room of the main building. It was in this latter room that Lockwood was killed. Fig. 3 shows the crumbled condition of the base of the chimney and the wreck of the buildings. Most of the chimney fell into the engine and stock rooms, partially wrecking the engine and other apparatus. Fig. 2 shows a partial view of these rooms after much of the débris had been removed.

Lockwood was found pinned under an 8x12-inch timber which had supported the roof and it was this same timber that partly protected the superintendent, who is expected to recover.

This stack was erected about fifty years ago. It was recently repaired, but according to the consensus of opinion the stack was unstable at the corner next to the mill, where the brick had weakened with age. This and the high wind were sufficient to cause the disaster. From the appearance of the brick débris, the base of the stack collapsed, allowing the upper part to settle, and, then losing its equilibrium, to topple over onto the roof of the building.

Men were set to work cleaning away the wreckage and a good deal of the stack had been removed before a Power representative could get to the scene of the accident.

A report that seems to be borne out by the evidence is to the effect that the chimney had been considered unsafe for some time, and that the engineer, becoming anxious about it in the high wind, looked up the superintendent and that both men were on their way to the boiler room when the crash occurred.

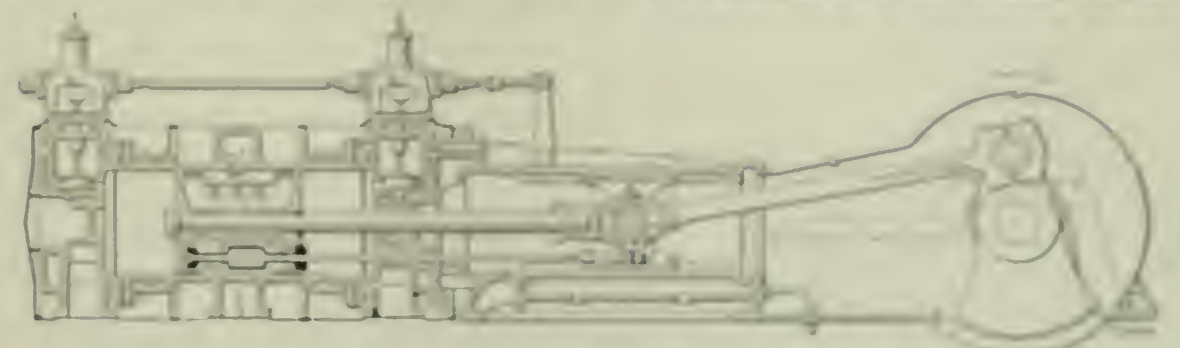
Fig. 2. Engine and Stock Rooms

Fig. 3. Crumbled Stack Base and Wrecked Wall

They're buildin' Lock 26 on the Ohio river near Gallipolis, an' the other day I got a picture postal from there showing the "Coffee Dam" an' the battery of bilers fer makin' er. Now I wonder what brand of coffee'd be strong enough to dam the Ohio?

Latest Design of Straight Flow Engine

In the article by Rudolf Klein on the straight-flow engine, which appeared in the January 31 issue of Power, reference was made to Fig. 5 as the latest design of noncondensing straight-flow engine. A cross-section of a condensing engine designed for connection to a jet condenser was inadvertently substituted for the accompanying illustration. Mr. Klein's description was as follows:



Longitudinal Section through Straight-flow Engine

The latest design of noncondensing straight-flow steam engine, which bears witness of the resourcefulness of the inventor, is shown in Fig. 5. A piston valve is placed inside the piston directly below the rod. It is operated by a little rocker arm, which is attached to the crosshead end of the connecting rod, and rocks about the crosshead pin as center. The valve alternately opens one side of the piston or the other to the respective cylinder ends, providing passage for the exhaust steam from these ends through its seat and the holes in the side of the piston to the exhaust slots. These valves close a trifle after the exhaust slots are closed by the second set of piston edges passing them. Pressure inside the piston is kept atmospheric throughout the stroke.

The third paragraph from the end of the article should have contained the word balancing, as this is the feature referred to.

Oldest High Pressure Steam Engine

By B. M. Baxter

This engine, which was without doubt the first of the high-pressure early cutoff type, was built by Oliver Evans at Philadelphia in 1801. It is still in good condition and at present is the property of the University of Pennsylvania.

A steam engine, which bears the date of 1801, and probably antedates any other of its kind built on this side of the Atlantic, is to be found at the mechanical-engineering laboratories of the University of Pennsylvania. It is complete in every respect with the exception of the flywheel and could be put into running order with very little trouble.

The engine, as shown in Fig. 1, is of the vertical-beam type, sometimes called the "grasshopper" type, and has a 12-inch cylinder and a 20-inch stroke. The slide valve is driven from an eccentric on the main shaft, through a rocker arm and shaft and vertical side rods attached to a yoke which, in turn, is connected to a vertical valve stem. In Fig. 2 this valve gear is clearly shown.

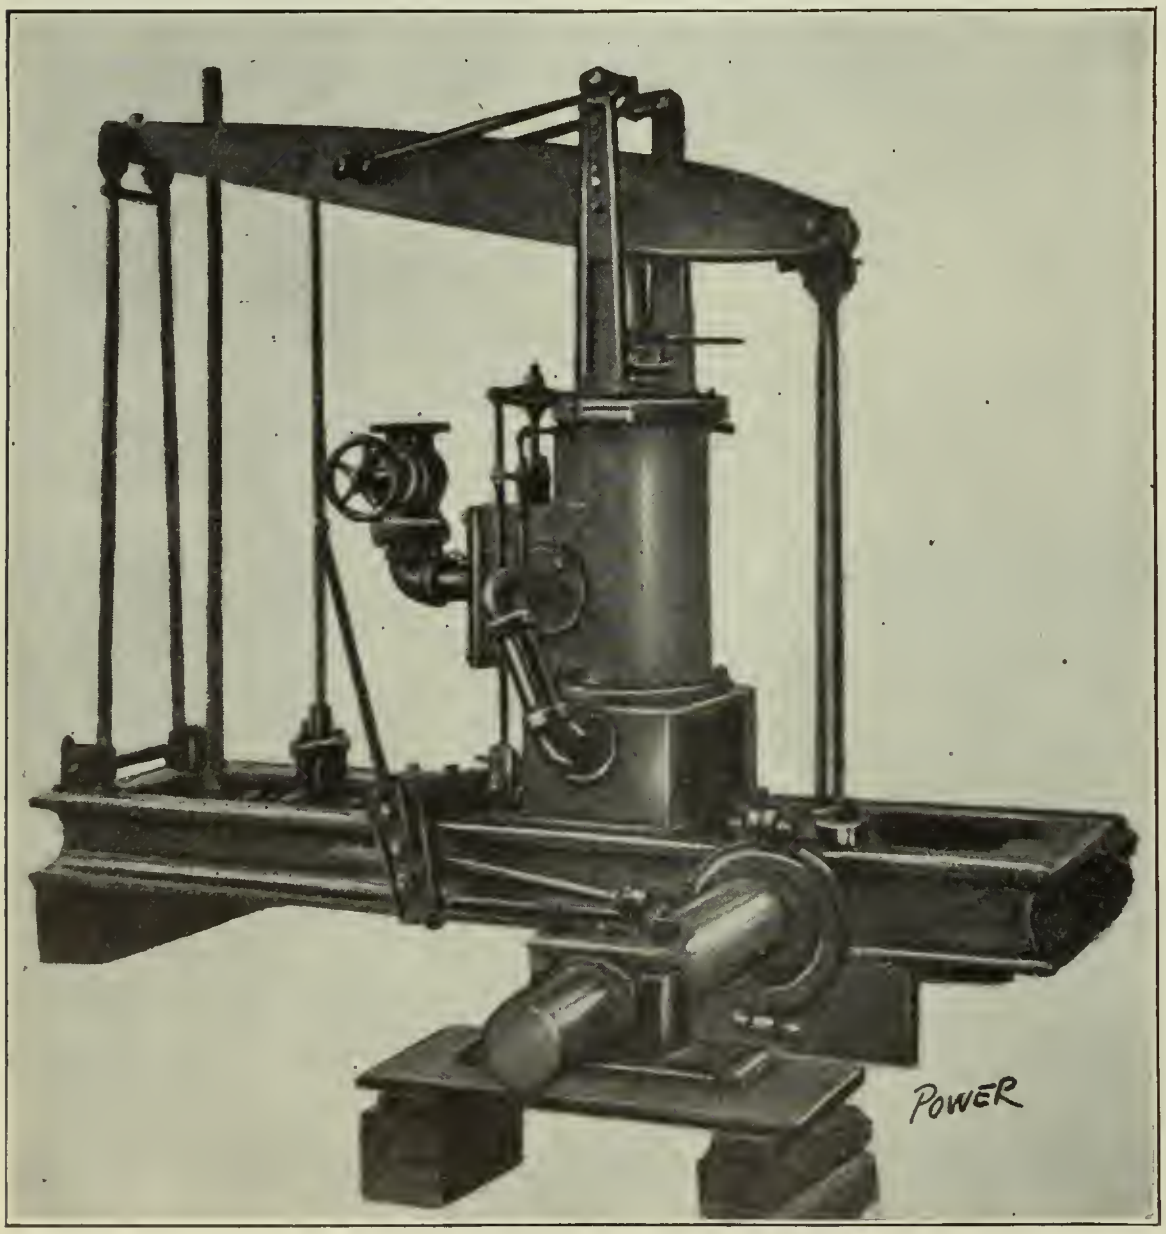


Fig. 1. General View of Engine

The crank is of the overhung type, and all the rod ends are strap ended with gib and key adjustment, similar to that used on many engines of modern design. The vertical rod attached to the beam, to the left of the cylinder, operates a plunger pump, which was probably used for the boiler feed. The discharge pipe from the pump projects vertically upward near the end of the frame.

There are two brass plates attached to the beam, which bear the following inscription:

OLIVER EVANS
1801

The inscription on a third plate, apparently of great age, is not legible, and another one of more recent date reads:

PRESENTED BY THE WILLIAM CRAMP & SONS SHIP AND ENGINE BUILDING COMPANY TO THE UNIVERSITY OF PENNSYLVANIA.

This engine is of the high-pressure, cutoff type, in contrast to the Newcomen or Watt engines which used steam merely as a means of producing a vacuum, the atmospheric pressure doing the work.

Oliver Evans has a good claim to being the inventor of the cutoff engine, the principles of which are outlined in his book entitled, "The Abortion of the Young Steam Engineers' Guide," which was published in Philadelphia in 1805. Quoting from this work, regarding this type of engine, he says, "Although the inventor had obtained a patent in the State of Maryland, he was so engaged with the introduction of his mill improvements that he could not prosecute his inventions on steam engines, further than filing drawings and specifications of the principles in the patent office in 1792, and trying some experiments which confirmed him in the principles. In the year 1801 he commenced the execution of an engine and in the winter of 1802 had it in full operation." This extract relates to the use of high-pressure steam with early cutoff, pressures of 120 pounds per square inch being mentioned elsewhere in the book.

The Use of Crude Petroleum as Fuel

At a recent meeting of the San Francisco branch of the American Society of Mechanical Engineers, a number of papers were presented upon the subject of oil fuel. In a paper entitled the "Relative Heat Value of Light Oil as Compared with Heavy Oil," Professor Le Conte stated that crude petroleum consists principally of hydrogen and carbon together with small amounts of nitrogen, oxygen and sulphur. The nitrogen and oxygen and any incombustible residue or ash may be classed as inert impurities, while the sulphur, although a combustible, has a low heat value and is otherwise injurious.

The oils rich in hydrogen are of light specific gravity as compared with those rich in carbon; also, the former contain more heat units per pound than the latter. Water in emulsion in crude oil acts as an inert impurity and as it must be converted into steam it reduces the heat value. From the tests of a number of samples of the heavier fuel oils, it was shown that the heat value increases inversely as the specific gravity, but does not increase so rapidly as the weight per unit of volume decreases. Therefore, the heat value per barrel of the heavier oils is greater than that of the lighter ones.

Mr. Weymouth, in a paper upon "The Arrangement of Furnace for Using Oil Fuel," described the Peabody furnace. In this the bridgewall is set back from the boiler front 8 to 10 feet, with the burner of the back-shot type, inserted from the boiler front under the furnace floor and turning up at the bridgewall, without there being any direct impingement of flame. With this design of furnace a boiler efficiency of 83 per cent. has been attained. The paper further stated that when admitting a large excess of air and an average amount of oil, the flame length is a minimum and the temperature of incandescence is reached at the surface of the envelope separating the vaporized oil and air. This bright flame is sought by the untrained fireman, but it results in a loss of heat, as the subsequent mixture of the products of combustion with the excess of air, not in contact with the flame, means a lower mean furnace temperature. With economical firing the flame lengthens before coming in contact with sufficient air for complete combustion, and with the highest furnace efficiency this temperature varies from 2500 to 2800 degrees Fahrenheit.

Due to the high furnace temperature with oil fuel the location of the heat-absorbing surfaces becomes of utmost importance; consequently the first pass should be located directly over the furnace, thus providing for the most direct transmission of heat, both by convection and the absorption of radiant heat.

A paper on "The Size of Stacks with Oil Fuel," by Mr. Dunn, called attention to the fact that in burning coal a large part of the total draft (from 35 to 70 per cent.) is required to overcome the friction through the fuel bed. This is done away with in burning oil fuel, consequently a shorter stack may be used, a stack of 80 to 100 feet in hight usually being sufficient.

An interesting paper upon the "Atomization of Oil Fuel" was read by Mr. Hunt. This was in part as follows:

General practice is to deliver the oil to the burner under pressure, and inject and atomize it, using either steam or air as the atomizing medium. The oil injected into the furnace should be entirely gasified or burned while in suspension in the air; otherwise, if particles of unconsumed oil fall to the bottom of the furnace, coke will accumulate. If the oil is injected into a cold furnace not inclosed by brick walls which become highly heated, it must be in the form of a fine spray. But if the walls are highly heated, the radiation from them will aid greatly in vaporizing the particles of oil and the larger particles will be consumed before they drop.

Most of the oils used for fuel are of a heavy and viscous character and their viscosity is reduced by a rise in temperature. Therefore, it is desirable that the oil be preheated before being fed to the burners. The form of burner is of small importance compared with the furnace construction, proper air supply, etc.

Some work has been done toward atomizing the oil without the use of air or steam. The oil, having been preheated to 220 to 260 degrees Fahrenheit, is injected into the furnace through a needle nozzle having a small orifice. The portion of the needle stem inside the cylindrical part of the nozzle has a screw thread cut on it, which imparts a rotary motion to the oil. The sudden release of pressure and the rotary motion cause the heated oil to issue in the form of a spray sufficiently fine to burn successfully.

From a number of tests, using steam as an atomizing agent, the amount of steam varied from 2.5 to 5.7 per cent. of the total evaporation. It may be said, however, that in designing a plant it is safe to assume 5 per cent. of the evaporation of the boilers as the steam necessary to operate the burners; but, if this exceeds 5 per cent. in actual operation, it may be concluded that conditions may be bettered.

Except in special cases, the use of compressed air as the atomizing agent may be said to offer no opportunity for a saving in fuel over the use of steam.

Capacity of Absorption Machines

By F. E. Matthews

The capacity of an absorption, like that of a compression, ice machine can be estimated by two different methods, either by determining the amount of anhydrous ammonia made in a given length of time or by finding the amount of cooling effect actually produced on brine.

Since the so called "anhydrous" ammonia entering the receiver of an absorption machine is often far from free of water, the latter method is to be preferred.

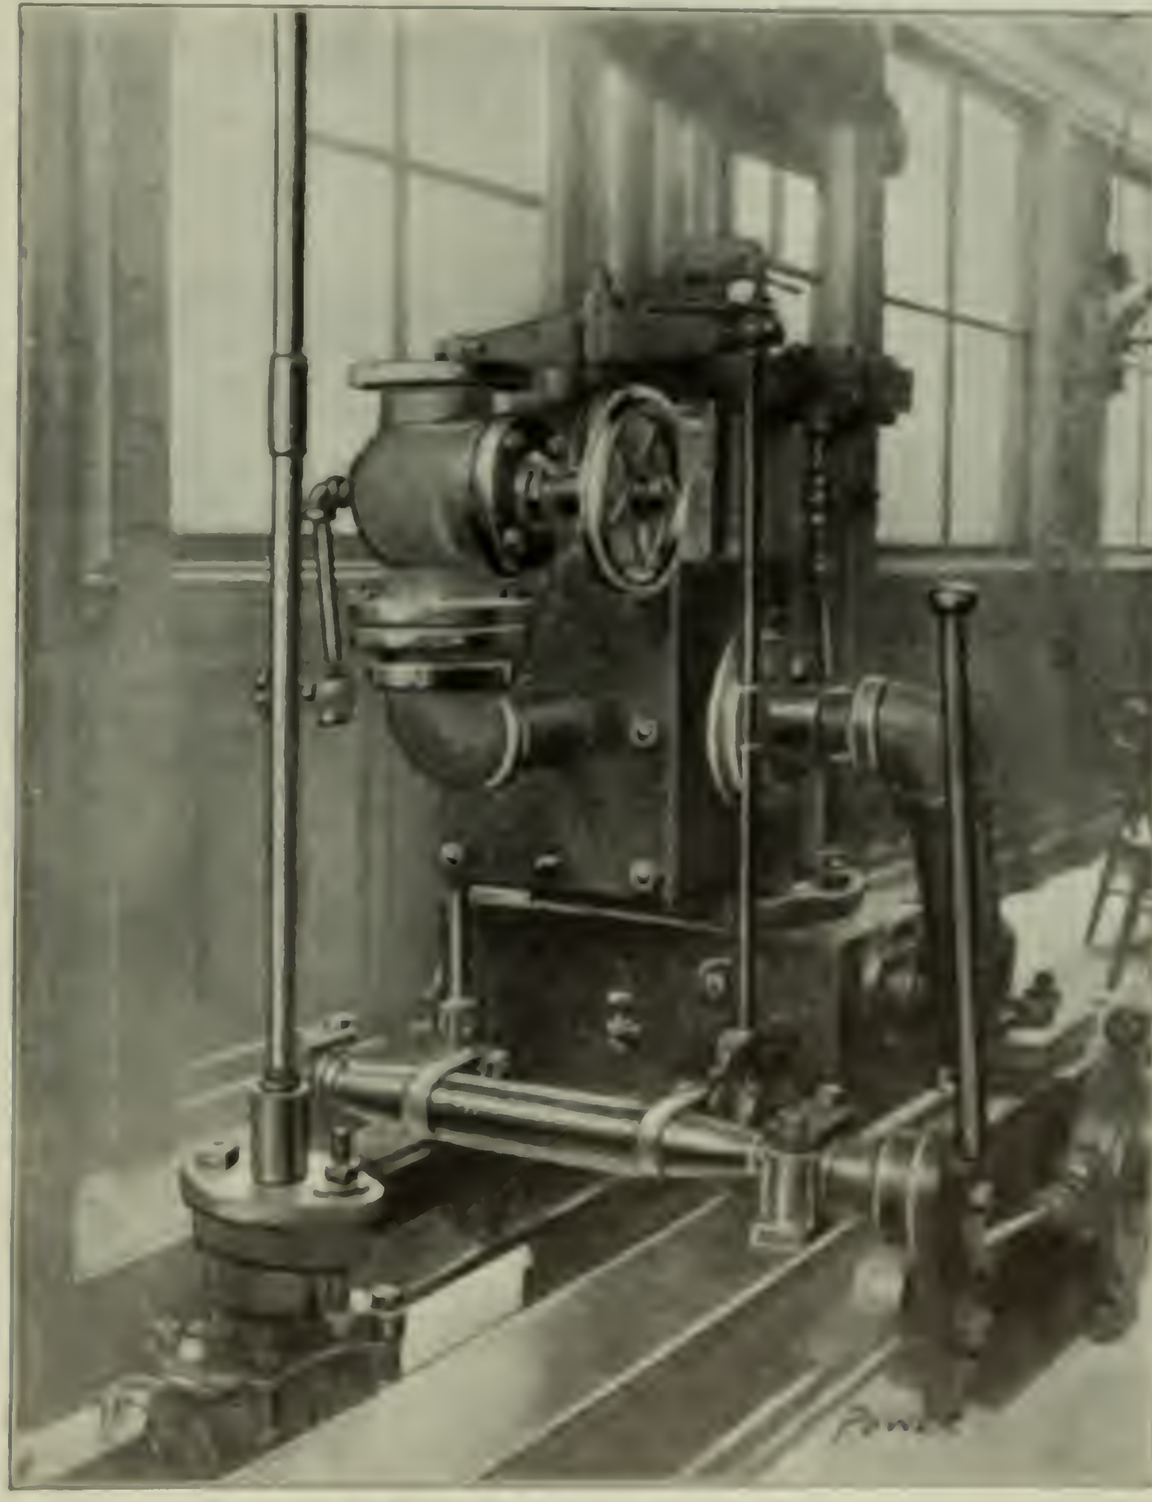

Fig. 2. View Showing Valve Gear

For very rough estimates of the capacity of a machine a cooling effect equivalent to that of five gallons of brine cooled through five degrees Fahrenheit per minute, or what is sometimes known as 25 "heat gallons," is considered a ton.

Since the amount of refrigeration required to cool brine, or in fact, any other substance, depends on the specific heat of the substance as well as on the amount chilled in a given time and the range of temperature chilled through, it is obvious that careful determinations of the specific heat of the brine should be made where accurate results are expected.

Specific heats taken from tables of properties of the kind of brine being used and corresponding to the density of the brine in use as determined by a hydrometer—due correction being made for temperatures—should give fairly accurate results.

If an absorption machine is operating on zero brine, calcium would ordinarily be used. In order to just escape freezing at this temperature, its density would have to be 22 degrees Baumé, corresponding to a specific gravity of 1.179. The specific heat of brine of this strength is 0.834. As a matter of fact, for safety against freezing, a somewhat stronger brine should be used, common practice being to use about 24 degrees Baumé, the specific heat of which is 0.817.

For every pound of brine of this quality cooled, one degree 0.817 B.t.u. of cooling effect is required.

To determine the refrigerating effect being produced, determine the amount of brine, in pounds, being chilled in a given length of time; determine also the range in temperature chilled through. Multiply the number of pounds by the range in temperature giving "pound degrees" and then by the specific heat giving B.t.u.

A ton of refrigeration is the equivalent of the heat absorbed in the melting of 2000 pounds of ice having a latent heat of fusion of 144 B.t.u.; that is, 288,000 B.t.u. The expenditure of cooling effect equivalent to the above per 24 hours is a ton of capacity.

Since there are 24 hours in a day, a ton capacity is also equal to the absorption of 1200 B.t.u. per hour; and since there are 1440 minutes in a day, it is also equal to the absorption of 200 B.t.u. per minute.

To arrive at the tonnage capacity of the machine under test, divide the number of B.t.u. of cooling effect produced on the brine per minute by 200, or the number per hour by 1200, or the number per day by 288,000.

The quantity of brine cooled can be arrived at roughly by the use of a meter, still more roughly from the size and number of strokes of the brine pump; but actual weighing is to be recommended where great accuracy is required.

One cubic foot of water at 62 degrees Fahrenheit weighs 62.355 pounds, and one gallon 8.336 pounds. To get the weight of brine of any density per cubic foot or per gallon, multiply these weights by the specific gravity of the brine determined at the same temperature.

If the brine has a strength of 24 degrees Baumé, for example, equivalent to a specific gravity of 1.2, the weight per gallon will be

$$1.2 \times 8.336 = 10 \textit{ pounds.}$$

With brine of these characteristics, the cooling of five gallons through five degrees, making 25 heat gallons per minute, would represent a cooling effect of

$$\frac{10 \times 5 \times 5 \times 0.817}{200} = 1.021$$

tons per 24 hours.

The National Isolated Plant Association

At a meeting of the National Isolated Plant Association, held at the Engineering Societies' building on Monday evening, January 30, a constitution was adopted and the permanent officers elected. These were as follows:

President: C. G. Armstrong, consulting engineer for the city of New York.

Vice-president: F. E. Stiles, chief engineer of the West Street building.

Secretary: E. D. Fieux, of the Wing Manufacturing Company.

Treasurer: W. B. Elliott, of the Garwood Electric Company.

Council: Mr. Buxton, operating engineer; Mr. Kimball, consulting engineer; Mr. Ferguson, manufacturer; Mr. Katten, salesman; Mr. Elliman, plant owner. The president and treasurer are *ex officio* members of the council.

Committee on admission of members is made up of the following members: Mr. Dalbec, operating engineer of the Patten estate; Mr. Wing, of the Gotham Manufacturing Company; Mr. Torrence, of the Carbondale Machine Company; Mr. Spooner, of the Ridgway Dynamo and Engine Company; Mr. Edgerton, constructing engineer; Mr. Bierck, of Borne Scrymser Company, and Mr. DeGress, of the Crocker-Wheeler Company.

Except in the case of the operating engineers actually engaged in the direction or operation of isolated plants, the initiation fee for members is $15 and the annual dues $10. No initiation fee is charged the operating engineer and his dues are $2 per year. Candidates for membership must be proposed by two members, who shall submit to the committee on admissions full particulars regarding the business and qualifications of the candidate.

As yet a complete program of procedure has not been decided upon, but it is planned to make complete tests upon numerous isolated plants now in operation with a view to collecting cost data for the enlightenment of the owner against the encroachment of the central-station solicitor.

PERSONAL

C. A. Tupper, of the Alliance Engineering and Sales Company, Inc., Milwaukee, has sailed for a cruise among Mediterranean ports and a trip through the greater part of Europe in behalf of various manufacturing interests. He is accompanied by his wife and son.

S. F. Jeter has resigned as mechanical engineer for the Bigelow Company, of New Haven, Conn., to accept the position of supervising inspector for the Hartford Steam Boiler Inspection and Insurance Company. With the exception of a short period of time, Mr. Jeter was in the employ of this company from [illegible] to 1900, first as inspector and then as special agent. He will be recognized as the author of numerous valuable contributions to our reading columns.

OBITUARY

Louis R. Alberger

Louis R. Alberger, president of the Alberger Condenser Company, died in New York City on January 31. He was born in Buffalo in 1864 and, after leaving high school, entered Yale, but later left to enter business with his father, who was engaged in the vacuum process of producing salt. In 1887 he went with Henry R. Worthington, where he remained until 1901, leaving to form the Alberger

Louis R. Alberger

Condenser Company and the Alberger Pump Company, both of which he became president of. The interment was held in Buffalo on February 3.

William B. Mason

William B. Mason, president of the Mason Regulator Company, and inventor of numerous valve and engine appliances, died at his home in Dorchester Lower Mills, Mass., on Saturday morning, February 4. He had been ill for some time, the last four weeks of which he was confined to his house.

He was born in Freeport, Me., and at an early age went to work in the Grand Trunk machine shops, where he learned the trade of machinist. Coming to Boston as a young man, he worked on stationary and marine engines, and as an engineer on harbor tugs. He joined the navy as a machinist, and was assigned to the U. S. S. "Omaha," serving for two years on the Pacific station.

Returning to Boston, he entered the employ of Crosby & Noyes, and here perfected his first invention, a governing

William B. Mason

regulator. Soon after this he produced the reducing valve now in use on three-fourths of the locomotives in this country, a device which permits the heating of cars. In [illegible] he formed the company, of which he was the head, for the manufacture of his devices.

At his factory was built the first automobile steam engine used by the Stanley Motor Carriage Company, and subsequently between [illegible] and [illegible] automobile engines were turned out. He remained active in the conduct of his business until a few weeks ago.

Mr. Mason was a member of the American Society of Mechanical Engineers, and also of the New England Railroad Club. He is survived by a widow and one daughter, Mrs. [illegible], of Brunswick, Me.

NEW PUBLICATIONS

An Introduction to Thermodynamics. By John Mills. Published by Ginn & Co., New York, 1910. [illegible] pages, [illegible] inches, [illegible] illustrations. Price, cloth $2.

A purely theoretical treatise adapted especially to the needs of the class room. The text presupposes a knowledge of calculus and is intended to follow a college course in general physics, although a brief résumé is given of such portions of this subject as are essential as a basis upon which to develop the subject of thermodynamics. It is felt that many of the definitions of the fundamental terms could have been expressed less vaguely, and the addition of more tables would have added greatly to the usefulness of the book.

MECHANICAL ENGINEERING. By Charles M. Sames. Published by the author, at Jersey City, N. J. Flexible leather; 218 pages, 4x6½ inches; illustrated. Price, $2.

This is the fourth annual edition of Mr. Sames' handy little pocketbook and, although its thickness does not appear to have been increased appreciably, it contains no small quantity of new material. This achievement, however, has its drawbacks. The contents are so condensed that it is not always easy to grasp the sense of a statement and the typographcial congestion is confusing to the eye.

The reviewer has not looked for errors, but noticed accidentally an incorrect statement at the bottom of page 59 and several at the top of page 61.

SOCIETY NOTES

A meeting of the Boston section of the American Institute of Electrical Engineers, with the coöperation of the American Society of Mechanical Engineers and the Boston Society of Civil Engineers, will be held on Friday evening, February 17, in that city. R. A. Philip, of the Stone & Webster Engineering Corporation, an associate member of the American Institute of Electrical Engineers, will present a paper on certain phases of the general subject of economic limitations to aggregation of power systems.

The Mississippi Electric Association, which represents the central-station industry of the State, had a meeting at Meridian, Miss., on January 19, when, after thoroughly canvassing the wishes of the members and receiving a unanimous indorsement, it was voted to affiliate with the National Electric Light Association. The president, A. B. Patterson, and A. H. Jones, secretary and treasurer, were instructed to make the necessary arrangements with the national body for putting this affiliation into effect. The national society has already a number of members in the State and this new union will be particularly beneficial to the smaller companies that hitherto have belonged to the local organization only.

On Saturday evening, January 28, 1911, Colonel Goethals Branch No. 1 of District 9 of the Institute of Operating Engineers was formed at Yazoo City, Miss., with a charter membership of 13. The election results are as follows: F. C. Holly, branch chairman and representative to district council; L. B. Smith, secretary and treasurer; F. C. Holly, W. W. Brannon, W. G. Richardson, councilmen for three years; Davis Chisholm, W. R. Vernon, Albert Walker, councilmen for two years; Ray Madden, Parks and Wince Hoover, councilmen for one year. W. G. Richardson, lecturer on apprenticeship training and plant operation and chairman of committee on apprenticeship training; W. W. Brannon, lecturer on educational subjects and chairman of committee on educational subjects. The chairman appointed Messrs. Vernon and Walker as assistant lecturers on apprenticeship training and plant operation, and Walker and Chisholm were appointed as assistant lecturers on educational subjects. The meetings of this branch are to be held the second and fourth Saturday nights of each month. The address of the secretary and treasurer is, P. O. Box 297, Yazoo City, Miss.

The annual banquet of the Atlantic City Council of the American Order of Steam Engineers has for some time assumed a more than local color. The fourteenth banquet, held on February 4 at the Hotel Windsor, drew a number of visitors from New York, New Jersey and Pennsylvania, including representatives of the State legislatures of New Jersey and Pennsylvania.

The large banquet hall of the hotel was filled with the members and their guests. After the inner man had been satisfied, an address of welcome was made by John Best, who also introduced the toastmaster, Mayor Franklin P. Stoy, of Atlantic City. The speakers included Senator Walter E. Edge, Postmaster Harry Bacharach, and Assemblyman Isaac Bacharach, who was responsible for Atlantic City getting the State legislature to grant it permission to pass the engineers' license law. Mr. Bacharach spoke of the great advantage to the city of having licensed men in charge of the power plants of the hotels, thus insuring to their guests that the boilers, etc., were in competent hands.

Over two hundred licenses have so far been granted.

Boiler Tube Bursts

It is reported in the daily press that on January 26 two firemen were seriously burned by the bursting of a boiler tube in the plant of the Alkali Rubber Company, Akron, O.

Boiler Explosion in Kentucky

On February 2, a boiler in a grist mill at Bruin, Elliott county, exploded, killing two men and injuring others. At the present writing further particulars are not available.

ENGINEERING SOCIETIES

AMERICAN SOCIETY OF MECHANICAL ENGINEERS

Pres., Col. E. D. Meier; sec., Calvin W. Rice, Engineering Societies building, 29 West 39th St., New York. Monthly meetings in New York City.

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

Pres., Dugald C. Jackson; sec., Ralph W. Pope, 33 W. Thirty-ninth St., New York. Meetings monthly.

NATIONAL ELECTRIC LIGHT ASSOCIATION

Pres., Frank W. Frueauff; sec., T. C. Martin, 31 West Thirty-ninth St., New York. Next meeting in New York City, May 29 to June 3.

AMERICAN SOCIETY OF NAVAL ENGINEERS

Pres., Engineer-in-Chief Hutch I. Cone, U. S. N.; sec. and treas., Lieutenant Commander U. T. Holmes, U. S. N., Bureau of Steam Engineering, Navy Department, Washington, D. C.

AMERICAN BOILER MANUFACTURERS' ASSOCIATION

Pres., E. D. Meier, 11 Broadway, New York; sec., J. D. Farasey, cor. 37th St. and Erie Railroad, Cleveland, O. Next meeting to be held September, 1911, in Boston, Mass.

WESTERN SOCIETY OF ENGINEERS

Pres., O. P. Chamberlain; sec., J. H. Warder, 1735 Monadnock Block, Chicago, Ill.

ENGINEERS' SOCIETY OF WESTERN PENNSYLVANIA

Pres., E. K. Morse; sec., E. K. Hiles, Oliver building, Pittsburg, Penn. Meetings 1st and 3d Tuesdays.

AMERICAN SOCIETY OF HEATING AND VENTILATING ENGINEERS

Pres., R. P. Bolton; sec., W. W. Macon, 29 West Thirty-ninth street, New York City.

NATIONAL ASSOCIATION OF STATIONARY ENGINEERS

Pres., Carl S. Pearse, Denver, Colo.; sec., F. W. Raven, 325 Dearborn street, Chicago, Ill. Next convention, Cincinnati, Ohio.

AMERICAN ORDER OF STEAM ENGINEERS

Supr. Chief Engr., Frederick Markoe, Philadelphia, Pa.; Supr. Cor. Engr., William S. Wetzler, 753 N. Forty-fourth St., Philadelphia, Pa. Next meeting at Philadelphia, June, 1911.

NATIONAL MARINE ENGINEERS BENEFICIAL ASSOCIATIONS

Pres., William F. Yates, New York, N. Y.; sec., George A. Grubb, 1040 Dakin street, Chicago, Ill. Next meeting at Detroit, Mich., January, 1912.

INTERNAL COMBUSTION ENGINEERS' ASSOCIATION.

Pres., Arthur J. Frith; sec., Charles Kratsch, 416 W. Indiana St., Chicago. Meetings the second Friday in each month at Fraternity Halls, Chicago.

UNIVERSAL CRAFTSMEN COUNCIL OF ENGINEERS

Grand Worthy Chief, John Cope; sec., J. U. Bunce, Hotel Statler, Buffalo, N. Y. Next annual meeting in Philadelphia, Penn., week commencing Monday, August 7, 1911.

OHIO SOCIETY OF MECHANICAL ELECTRICAL AND STEAM ENGINEERS

Pres., O. F. Rabbe; acting sec., Charles P. Crowe, Ohio State University, Columbus, Ohio. Next meeting, Youngstown, Ohio, May 18 and 19, 1911.

INTERNATIONAL MASTER BOILER MAKERS' ASSOCIATION

Pres., A. N. Lucas; sec., Harry D. Vaught, 95 Liberty street, New York. Next meeting at Omaha, Neb., May, 1911.

INTERNATIONAL UNION OF STEAM ENGINEERS

Pres., Matt. Comerford; sec., J. G. Hannahan, Chicago, Ill. Next meeting at St. Paul, Minn., September, 1911.

NATIONAL DISTRICT HEATING ASSOCIATION

Pres., G. W. Wright, Baltimore, Md.; sec. and treas., D. L. Gaskill, Greenville, O.

POWER

NEW YORK, FEBRUARY 21, 1911

RECENTLY, a prominent engineer remarked that most people know less about their own business than is known by some outsider.

While this may be putting it rather too broadly, the remark, nevertheless, contains a grain of truth.

The operating engineer, being constantly on the spot, should know his plant better than anyone else.

This does not imply merely a physical knowledge of the plant equipment, such as a knowledge of the function of every valve, etc., but, in addition, all phases of operation, and then some.

Yet, many engineers become so absorbed in their daily routine work that they lose sight of the high points, only to awaken to the sudden realization that some outsider has seen the opportunity and is making capital out of it.

This accounts for the increasing business of the consulting engineer, the lubrication expert and the economic engineer.

Although the present is often referred to as an age of specialists, they should be employed only when necessary.

Undoubtedly, these specialists are able to materially decrease the operating expenses of many plants. In fact, in certain cases the available data at their command and their particular training makes their employment essential. But in the majority of cases a competent operating engineer could carry out the work just as well.

This applies to the more simple forms of construction and erection, as well as innovations in operation. If a new engine, boilers or auxiliaries are to be installed, there is no reason why the chief engineer of the plant, aided by the data and blueprints furnished by the manufacturers, should not be able to cope with the problem without an appeal to outside aid.

This, on the one hand, would save the owner considerable expense in fees to the expert; and, on the other hand, would not only increase the engineer's field of usefulness, but would also save his pride from being sacrificed by the intrusion of an outsider.

To be properly equipped for such work an engineer must be conversant with up-to-date practice. He must know what it should cost to produce a kilowatt-hour in such a plant as the one he is operating. He should be able to judge the quality of the supplies and should know their cost. It is important that he cultivate the habit of observing, not merely seeing, and while keeping a keen eye to the small things about the plant at the same time, he must not become lost among the details. In other words, he must occasionally break away from the regular routine work and view the plant as an outsider through a binocular.

These characteristics, combined with the ability to successfully and systematically carry out a definite purpose, will fortify the engineer against encroachments upon his vocation.

Power Plant of a Newspaper Building

By Osborn Monnett

The interesting features of this installation are the water supply system, the arrangement of pumps and the hydraulic elevator piping. In connection with the latter, advantage was taken of the fact that in this service the load is always on the down trips, and the energy thus developed is utilized to raise the empty elevator.

About two years ago the entire printing establishment of the Cleveland *Plain Dealer* was destroyed by fire and in its place has been erected one of the most complete and uptodate newspaper-publishing establishments in the Middle West.

The power plant is in a well lighted corner of the basement with a 100-ton coal-storage bin conveniently located under the sidewalk. Coal is wheeled from the bin in a one-ton car, and is weighed on a Hunt scale before reaching the boilers. Two 150-horsepower Stirling boilers, equipped with Detroit stokers, furnish steam to three American-Ball engines direct connected to generators of 50, 75 and 125 kilowatts respective capacities.

The water-supply system is especially complete for a plant of this size and is arranged to operate with high-pressure lines to the upper floors and low-pressure to the first floor and basement, the water flowing by gravity from a storage tank supplied from the city mains. A plan of the system is shown in Fig. 2 and the operation is as follows: Water flows from the city mains directly to the storage tank, in which the level is maintained by a float valve. From this tank it flows to the house pumps and is pumped into tanks in which a pressure of about 40 pounds is automatically maintained by the action of the pressure regulators on the line. There is, however, a fluctuation of 20 pounds or more in the city-water supply, and should this pressure at any time exceed that maintained in the tanks, the water would flow directly to the tanks through the bypass and check valve *K*, in which case all floors would be supplied directly from the city mains. When the city pressure decreases below that maintained in the tanks, the pumps begin to operate; the discharge is prevented from returning to the city main by the check valve in the bypass. This arrangement automatically takes advantage of periods of high pressure in the city mains and thereby saves steam, which would otherwise be used in the house pumps during these periods.

Another notable feature of this plant is the pumping equipment. Vertical Cameron pumps are used and are mounted on the engine-room wall, each one on a handsome polished brass panel, as shown in Fig. 4. By this method a large pumping capacity is installed with the minimum of floor space and the pumps are easily accessible for inspection.

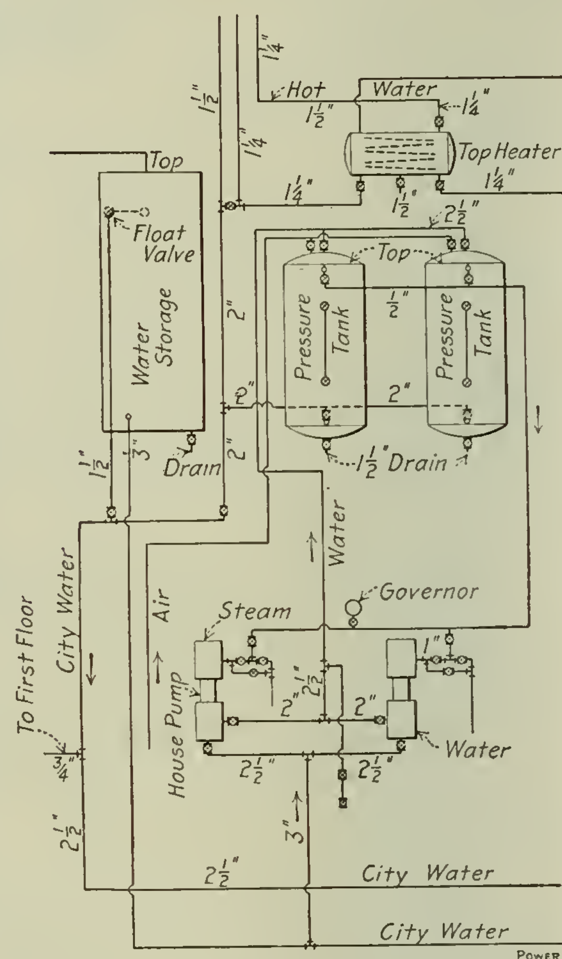

FIG. 2. WATER SYSTEM FOR HOUSE SERVICE

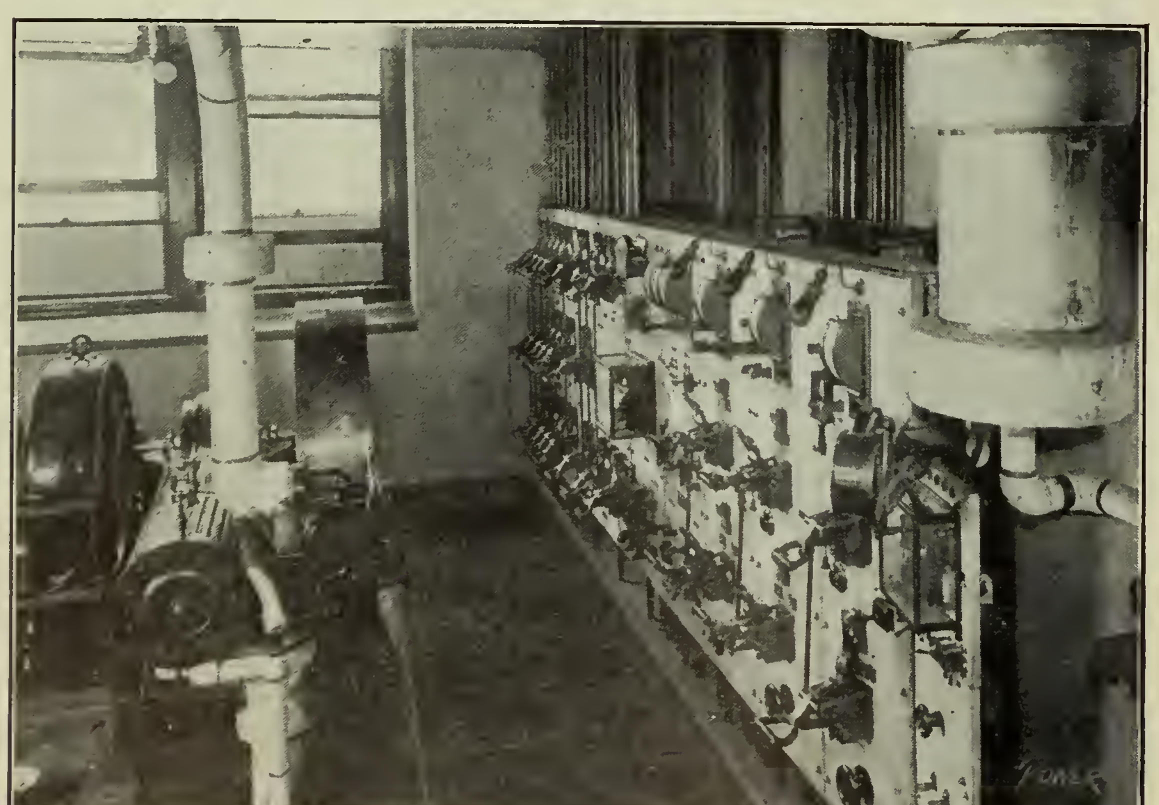

FIG. 1. SWITCHBOARD AND ENGINE

The piping layout for a hydraulic elevator used in the printing establishment is rather unusual. This elevator is employed in bringing rolls of paper from the store room to the press room and conditions are such that the load is always carried on the down trips, and the elevator goes up empty. Advantage has been taken of this circumstance to raise the elevator through the energy developed by the load in coming down; the way in which this is accomplished is shown

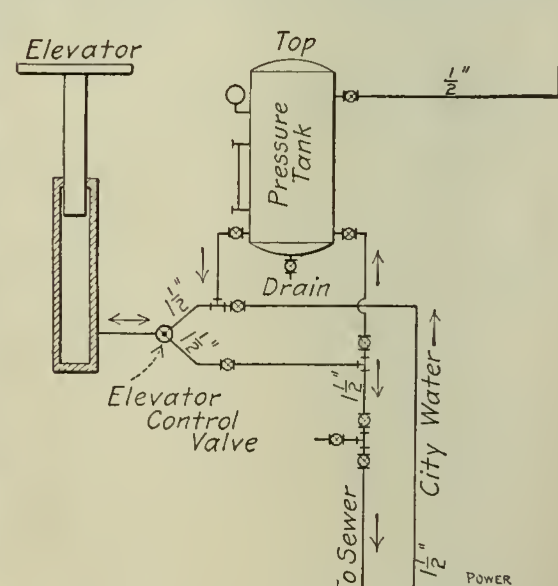

FIG. 3. HYDRAULIC ELEVATOR SYSTEM

in Fig. 3. During its downward travel the elevator discharges into a pressure tank partly filled with water, and this accumulated pressure is utilized to raise the empty elevator. A three-way control valve is placed so that, if desired, the elevator can be worked directly from the city-water mains in the ordinary manner, the water discharging to the sewer in this case.

The electrical distribution is on the 230-volt, three-wire system, with balancer sets supplying lighting current at 115 volts. The switchboard, which is shown in Fig. 1, contains no switches, except for the instruments, their place being taken by circuit-breakers.

Every machine in the establishment is direct-driven by motors, ranging in size from one-quarter to 60 horsepower, and the load on the plant for lighting and power is continuous, a 24-hour service being maintained. H. J. Graham is the chief engineer in charge of the plant.

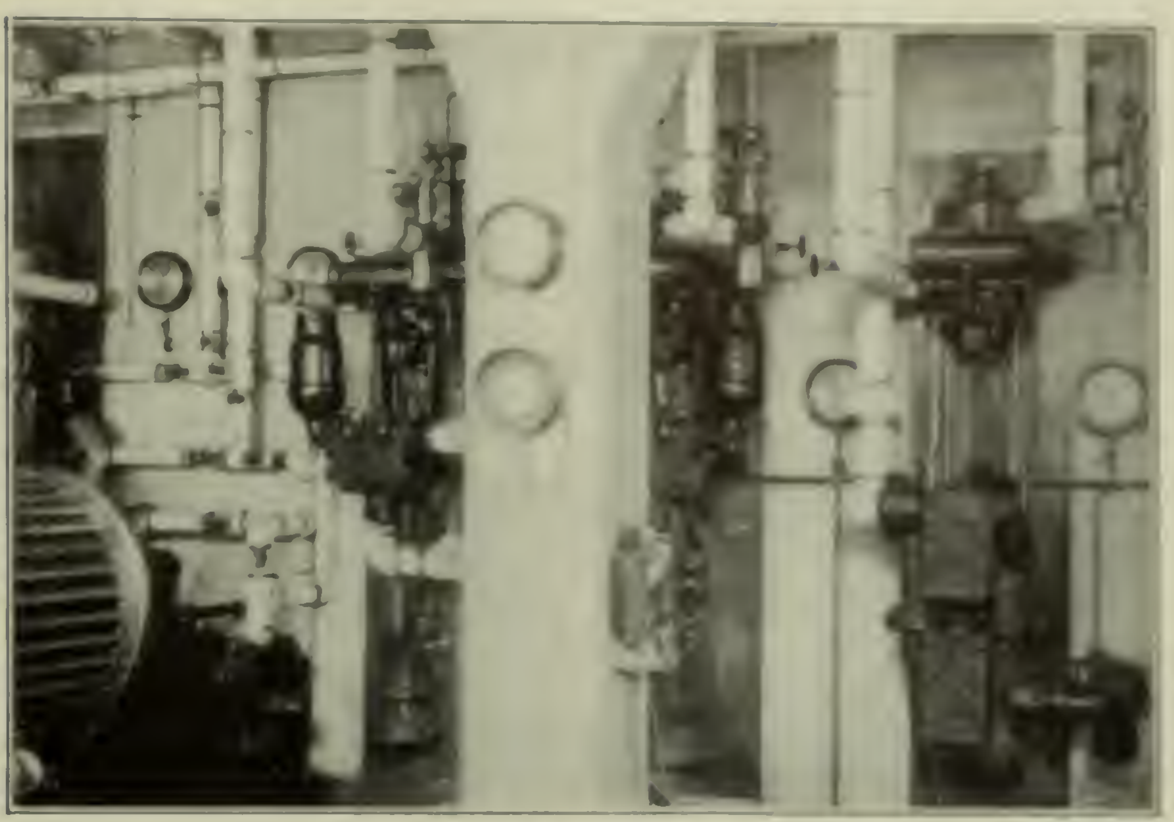

FIG. 4. PUMPS MOUNTED ON WALL

Piping for Central Station Heating*

By B. T. Gifford

General remarks on the manner in which the probable quantity of heating is ascertained. Method of laying out pipe lines and determining the pipe sizes.

*Abstract of paper presented before the American Society of Heating and Ventilating Engineers.

In the design of a central-station heating plant two things must be definitely determined: the location of the central station and the amount and location of the business to be served.

A method which the writer has used for some time with satisfactory results is as follows: First, prepare a map of the city drawn to scale, and of a size convenient to carry in the field; sometimes it is necessary to divide the map into two or more parts. Show on this map all streets and alleys, and the relative elevation of each street intersection. Note also the paved streets and the kind of pavement. Show also each building and mark the kind of building, whether for business, church, residence, bank, hotel or other purposes, together with the number of feet of radiation that will be required to heat it. After this information has been secured, make a survey and a careful study of the different sections of the city, noting on the map the best sections for the central heating plant to serve, taking into consideration at all times the future growth of the city. It is in this part of the design that experience is needed, and many times the engineer will find that he has made a poor guess. The word guess is used because in many cases central heating plants have grown beyond the wildest dreams of their designers.

In a good residential section where the houses are owned by people of moderate wealth, 90 per cent. of the possible business will be connected within five years. Any vacant lots in such a section should be considered as built upon with a building to compare favorably with the surrounding buildings.

In a business section 60 to 70 per cent. of the available business will be connected within five years. This is greatly dependent upon the kind of heat to be sold, whether steam or water, and whether the buildings are already equipped for heating with steam or water. As a rule, steam service is more popular in business sections, while in residential sections water seems to be more desirable.

The rapidity with which business is acquired depends upon the management, but the designer should anticipate a rapid growth in the number of consumers and the amount of business. After having determined the location and the amount of business possible and the central-station location, work on the details can be started.

Commence by laying in the lines on the map, in such a way as to reach the greatest amount of business with the least number of feet of pipe line. This requires [illegible] cut-and-try methods. Whether to use alleys or streets depends upon two things: First, the relative cost of street and alley construction; second, the location of the buildings relative to the street or alley. The writer has found that alley construction, other things being equal, will cost 15 to 20 per cent. more for the labor, owing to the difficulty of working in narrow places. Another thing affecting the cost of construction is the pavement, which has to be taken up and relaid.

In most cities the heating companies are obliged to bring their service pipes to the curb line in the street, and to the property line in the alleys. This item of expense should not be overlooked, for in a wide street the extra cost for service lines will more than eat up the saving in labor effected by street construction.

Assume for calculation a good residence section, as shown in Fig. 1, block 2. It can be assumed that 90 per cent. of the available business on this block, which is approximately 11,000 square feet of water radiation, or approximately 6600 square feet of steam-radiation surface, will be secured.

It is necessary to allow for future extensions for block No. 1, and possibly more yet, but in this layout it will be assumed that eventually block No. 1 will equal block No. 2. Block No. 2 is 400 feet long, and block No. 3 is of the same length. There is then altogether 22,000 square feet of water radiation to be handled, but some of it will be taken off in the first 100 feet, and about 25 per cent. of it will be served by the time the center of block No. 2 is reached; 25 per cent. more will be taken off by the time D street is reached, and 25 per cent. when the center of block No. 3 is reached.

The writer has found it better practice

to throw most of the line friction into the trunk line and to have the friction loss in the laterals very small, and to make the friction loss in the laterals in proportion to the circulating pressure (difference in pressure) at the point at which the lateral begins. As an example, assume that at the point the lateral for blocks Nos. 1 and 2 tap off the circulating pressure is five pounds. Now, there must be at least one pound of circulating pressure at the end of the lateral; therefore, four pounds can be lost in friction between the ends of the lateral, or one pound per 200 feet, which is five-tenths of a pound per 100 feet. Following are the conditions:

First 200 feet of line must handle 22,000 square feet of radiation.
Second 200 feet of line must handle 16,500 square feet of radiation.
Third 200 feet of line must handle 11,000 square feet of radiation.
Fourth 200 feet of line must handle 5500 square feet of radiation.

From the curves in Fig. 2 it will be seen that a 6-inch pipe will handle 22,000 square feet with this friction loss, and a 5-inch will handle 16,500 square feet, a 4½-inch will handle 11,000 square feet with a ½-pound loss, and a 3½-inch pipe will handle 5500 square feet of radiation with this friction loss.

A rule which the writer has followed is never to run a smaller water main than 3 inches in the initial layout; this will always allow for some future extensions.

In figuring a branch line off of a lateral, consider the circulating pressure at the point the branch leaves the lateral, as the originating pressure and one pound as the circulating pressure at the end of the branch.

The writer advocates the use of pipe bends instead of elbows or fittings in the lateral lines.

It has been the practice of some engineers to run a larger return line than flow line; for instance, a 3-inch flow and a 4-inch return line. This method, it is claimed, gives a more equal circulating pressure all over the system. The writer has found that by limiting the heavy friction loss to the main trunk lines, this objection is equally well overcome and the investment is slightly reduced.

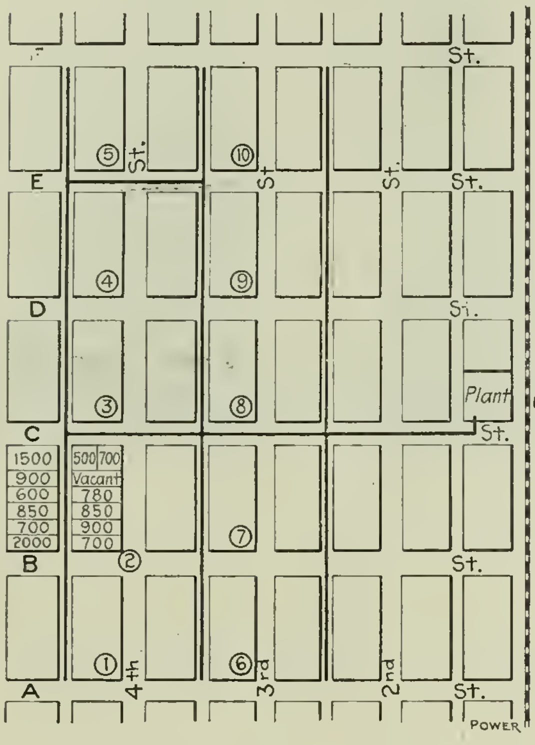

Fig. 1. Plan of Area to be Heated

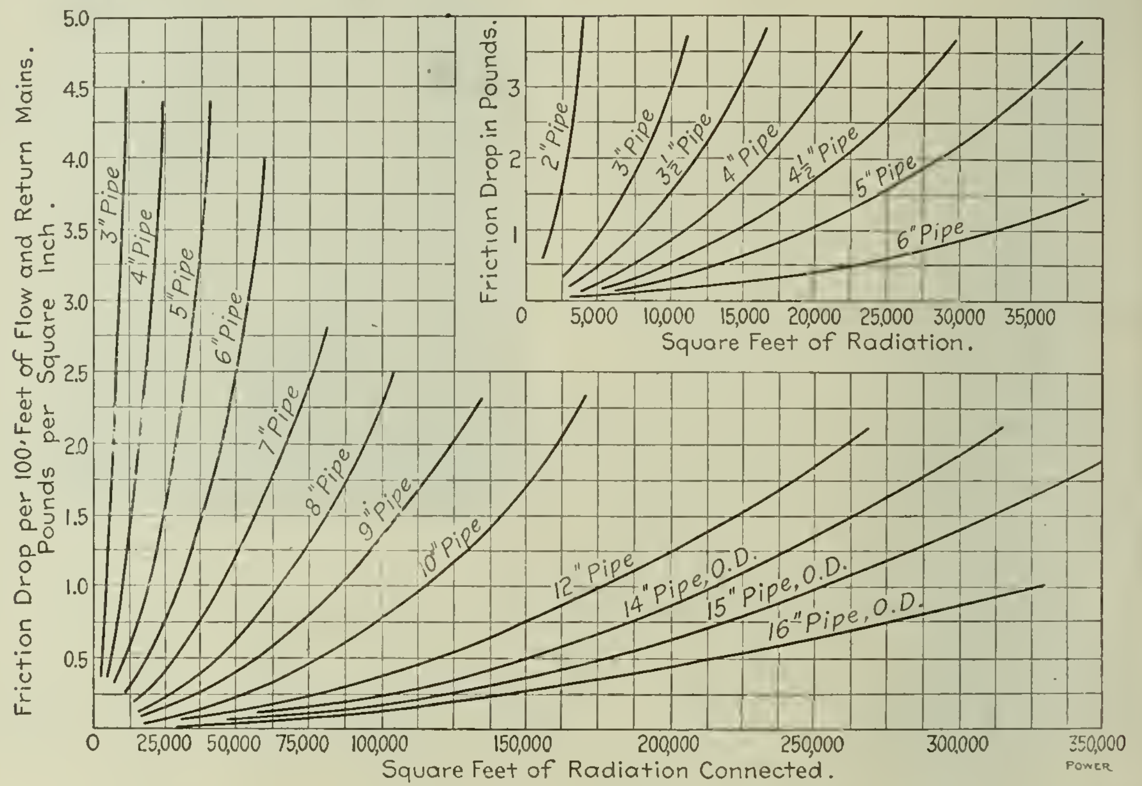

Fig. 2. Diagrams of Pressure Drop Due to Friction in Hot-water Heating Mains

Pipe-line Design for Steam Heating

In designing a central-station steam-pipe line the same general plan is used. In this case, however, the friction loss is dependent upon the maximum back pressure allowed on the engines if connected as a byproduct system. A live-steam central heating plant should be designed along the same general plan as a hot-water heating system, with 25 pounds as the maximum pressure on the pipe line. The curves in Fig. 3 show the steam-pipe capacities.

Assuming the same territory, viz., blocks Nos. 1 and 2, the following calculations would determine the steam-heating pipe sizes. In this case it will also be assumed that the original pressure where the line begins is three pounds. There will be required at least one pound pressure at the end of the line; therefore, two pounds can be lost in friction. This allows 0.25 of a pound per 100 feet of pipe. Following are the conditions for a steam-heating system:

First 200 feet of line must handle 13,200 square feet of radiation.
Second 200 feet of line must handle 9900 square feet of radiation.
Third 200 feet of line must handle 6600 square feet of radiation.
Fourth 200 feet of line must handle 3300 square feet of radiation.

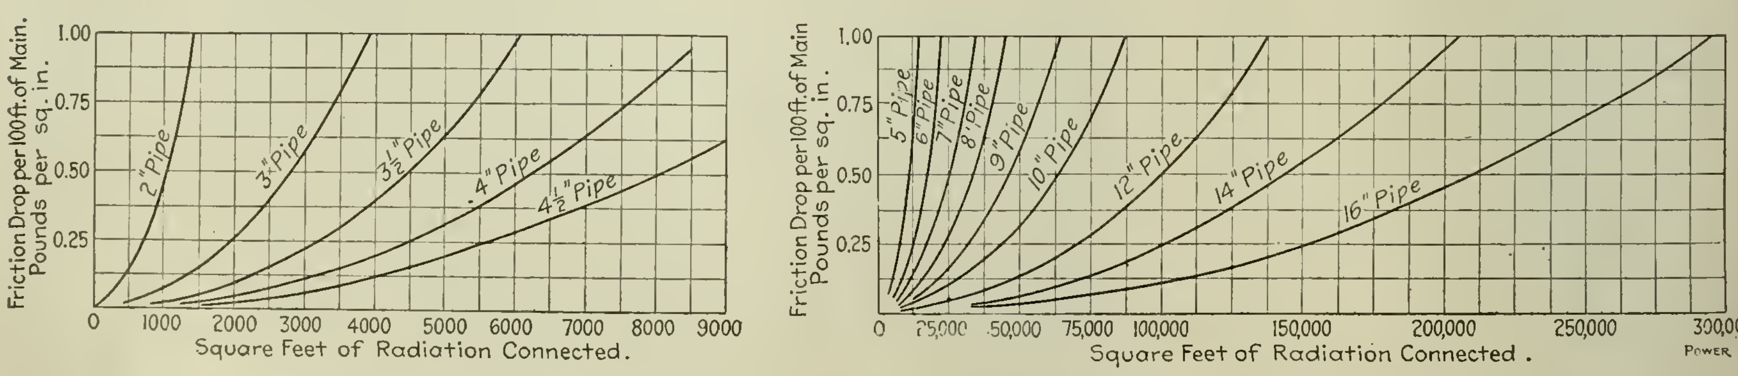

Fig. 3. Diagrams of Pressure Drop Due to Friction in Steam-heating Mains

From the curves in Fig. 3 the pipe sizes may be ascertained in the same manner as in the previous example on hot-water heating.

As in the case of the hot-water heating system, there should be a minimum size of pipe to install as a main and in steam heating the writer has fixed upon 4 inches as the minimum.

Efficiency of Live Steam Feed Heater

By Prof. A. H. Gibson

Use of heater with locomotive boiler raised efficiency 1.08 per cent. Gain attributed to higher rate of heat transmission due to a lower temperature of the plate in the vicinity of the feed inlet.

In view of the diversity of opinion among engineers as to whether the addition of a live-steam feed heater to a steam boiler may in any case lead to increased efficiency of working, the author recently decided to carry out a series of trials to test the effect of such a heater on the steam boiler forming part of the laboratory equipment of University College, Dundee, Scotland.

This boiler is specially equipped for testing; all measurements of fuel burnt, of water evaporated and of temperatures can be made with great accuracy. The steam produced was used for driving a brake-loaded experimental engine whose load could be maintained constant or varied as required from test to test.

The boiler was of the locomotive type with an internal diameter of 3 feet 6 inches; and contains 47 tubes, 3 inches in

Fig. 1. Locomotive Type of Boiler

diameter and 6 feet 10 inches long. It has an effective grate area of 7.5 square feet, with a heating surface of 315 square feet, and its general arrangement is shown in Fig. 1.

The feed water is supplied by a force pump worked from the crosshead of the main engine. When supplied to the boiler cold it enters through an opening in the side of the boiler, as shown at *A* in Fig. 1.

When the live-steam feed heater is in use the cold feed enters at the top of the boiler, at *B*, Fig. 1, and passes through the heater before finally escaping into the water space of the boiler. The heater, Fig. 2, was constructed specially for the tests, and consists simply of three shallow tin-plate dishes superposed and connected to each other by distance pieces. The feed water admitted by the feed pipe to the bottom of the upper dish overflows into the second. A central overflow pipe maintains a constant depth of about ½ inch in this dish, and overflow takes place through this pipe into the bottom dish, from which it overflows and drops into the water space of the boiler. The heater was supported in the steam space of the boiler on two convenient longitudinal stays. It was made as large as could be conveniently got into the very constricted space available, but could with advantage have been made larger, the feed water not remaining in contact with the steam for a sufficiently long interval of time to enable it to attain full boiler temperature before mixing with the water in circulation.

The temperature immediately before overflow was measured by means of a mercury thermometer in a pocket situated as shown in Fig. 2.

The boiler is operated under natural chimney draft regulated by a damper at the outlet from the smoke box, and in order to insure a thorough mixing of the hot gases before taking their temperature, this was measured, by means of a platinum-iridium thermocouple, at the center of the outlet flue at *C*, Fig. 1.

Four tests were carried out, those on Wednesday and Thursday, December 7 and 8, 1910, having the heater in operation but with very different loads on the boiler, and those on Wednesday and Thursday of the following week without the heater, but with rates of evaporation similar to those in the two preceding runs. In each case the boiler was under steam on the Tuesday, while on the days of the trials the actual test did not commence until the plant had been running under normal conditions sufficiently long for a steady state of affairs to be obtained.

From results obtained in the tests it was figured that the relative gain in efficiency by use of the heater was 1.08 per cent. for light loads and 1.083 per cent. for heavy loads. Some of the more important deductions from the tests are given in the accompanying table.

DEDUCTIONS MADE FROM TESTS

	Light Load		Heavy Load	
	With Heater	Without Heater	With Heater	Without Heater
Heat transmitted per square foot of heating surface per hour, B.t.u.	1970	[illegible]	[illegible]	[illegible]
Weight of fuel fired per square foot of grate per hour, lb.	[illegible]	[illegible]	[illegible]	[illegible]
Weight of dry fuel per square foot of grate per hour, lb.	[illegible]	[illegible]	[illegible]	[illegible]
Water evaporated per pound of fuel as fired, lb.	[illegible]	[illegible]	[illegible]	[illegible]
Water evaporated per pound of dry fuel, lb.	[illegible]	[illegible]	[illegible]	[illegible]
Equivalent evaporation from and at 212 deg. F. per pound of dry fuel, lb.	[illegible]	[illegible]	[illegible]	[illegible]
Weight of feed from and at 212 deg. F. per square foot of heating surface per hour, lb.	[illegible]	[illegible]	[illegible]	[illegible]

Reasons for Increased Efficiency

With a view to throwing some light on the reason why such a method of feed heating should lead to more economical working, a series of experiments were afterward carried out on an open cast-iron vessel about 8 inches in diameter and containing about 3 inches of water. This was heated up by means of a ring of gas jets giving a flame whose mean temperature was 2000 degrees Fahrenheit. The temperature of the water side of the plate was measured by means of a platinum-iridium thermocouple placed in intimate contact with the plate, a shallow depression, 1/64 inch in diameter, being made in the plate to receive the point of the couple. The temperature of the water was taken by means of a mercury thermometer, and the results of the experiments are as follows:

Temperature of water, degrees Fahrenheit	120	160	180	200	212
Temperature of plate, degrees Fahrenheit	140	208	212	200	212.4
Difference, degrees Fahrenheit	20	48	32	40	0.4

In these experiments the water was stirred vigorously during the whole period of heating, and they do confirm what has been pointed out by previous experimenters that, under given conditions of heat transmission, the difference between the temperature of the water and of the water side of such a plate is very much greater when the water is being heated up to boiling point than when it is in ebullition, and this, although the water is circulating vigorously over the hot surface.

Fig. 2. Primary Heater

In these experiments, too, however great the ebullition, it was found impossible to increase the temperature of the water side of the plate to more than 213 degrees Fahrenheit, and in the great majority of cases the temperature was, as nearly as could be measured, identical with that of the water.

As a result of these experiments it

would appear reasonable to assume that over the tubes, in the neighborhood of the feed inlet to a boiler, the temperature of the water side of the plate, and, therefore, of the fire side of the plate for a given rate of heat transmission, would be appreciably lower—possibly as much as 40 degrees Fahrenheit lower, and probably at least 20 degrees Fahrenheit lower—with the heater in operation than without it. At first sight it would appear that such a small difference is totally inadequate to account for any appreciable difference in heat transmission and hence in the efficiency, for since the temperature of the gases has a mean value of probably 1200 degrees Fahrenheit, the mean difference between the temperature of the gases and that of the tube surface will be about 850 degrees Fahrenheit, and a difference of 20 degrees Fahrenheit in this, assuming heat transmission to vary as difference of temperature, would only affect heat transmission by a little over 2 per cent. Assuming the heat transmission from gas to plate to vary as the square of the temperature difference, this would increase the effect to, roughly, 5 per cent.

Even though the great proportion of the heat is transmitted by conduction from gas to metal, it appears, however, that a cooling of the metal surface is likely to be much more effective than a corresponding increase in the temperature of the hot gases. As is well known, transmission of heat by conduction from stratum to stratum of a hot gas is a mass phenomenon, and depends on the velocity (therefore greatest near the center of a tube where velocities are greatest), on the difference of temperature, and increases directly as the density. Owing to the rapidity of the motion, heat is readily transmitted from the central filaments in such a tube to those nearer the walls, but with considerable less ease in the immediate neighborhood of the walls where the motion is comparatively sluggish. In the neighborhood of the walls, however, the gas is cooled down to a temperature approximating much more nearly to that of the cool surface; its density is considerably greater than in the center of the tube, and is greater as the tube surface is cooler, so that any cooling of this surface has a double effect in increasing the rate of transmission.

On the whole it would appear that these differences in the rates of heat transmission, though severally small, when acting cumulatively offer a possible explanation of the gain in efficiency undoubtedly obtained in the present series of tests by the use of the live-steam feed heater.

The reason for the greater gains in efficiency, in the case of the more heavily worked boiler, is probably due to a greater portion of the heating surface being occupied in heating up feed water rather than in the process of evaporation, in such a boiler, than in one more lightly worked. With feed water at 40 degrees Fahrenheit over 25 per cent. of its total heat is given to the water during this process of heating up, and the proportion of the whole heating surface affected by this must be roughly proportional to the weight of cold feed per minute. From this and other considerations it may be expected that such a heater will be found to be most effective:

1. In a given boiler when this is most heavily worked.
2. Where no economizer is fitted to take advantage of the heat rejected in the flue gases.
3. Where the boiler is fed with cold feed water.
4. Other things being equal, in a boiler in which the heating surfaces are somewhat incrusted.

Could Not Damage the Turbine

When a 1500-kilowatt Westinghouse steam turbine was loaded on a flat car at the company's works, ready for shipment to the Cia Minera Las Dos Estrallas mines at Tultenango Est de Mexico, there was every reason to believe that the shipment would reach its destination in good shape.

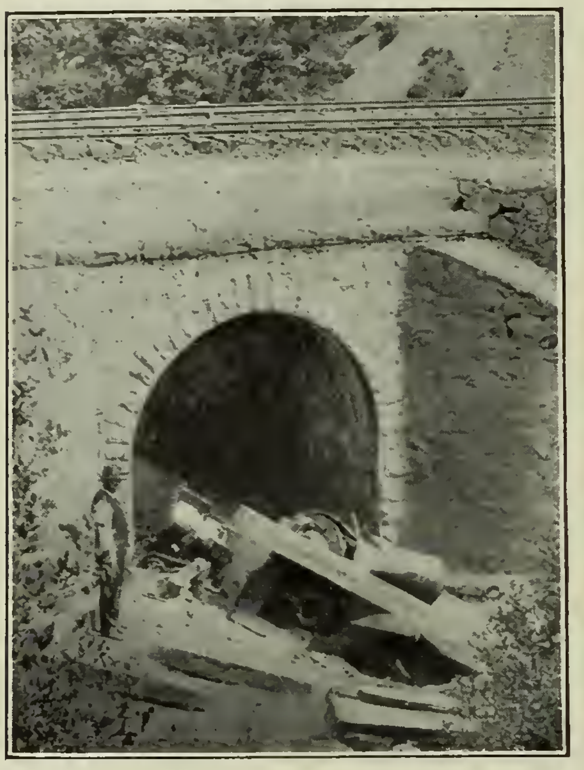

Fig. 1. Showing Where the Turbine Landed

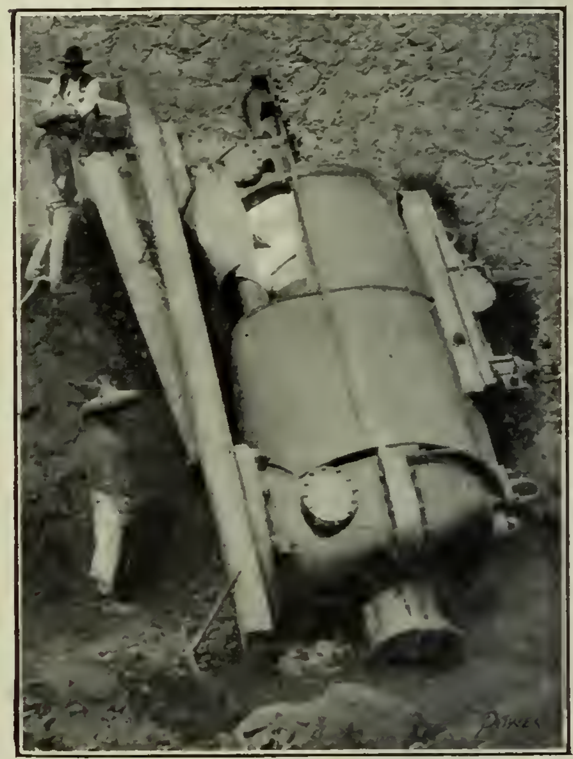

Fig. 2. Broken Platform and Lagging

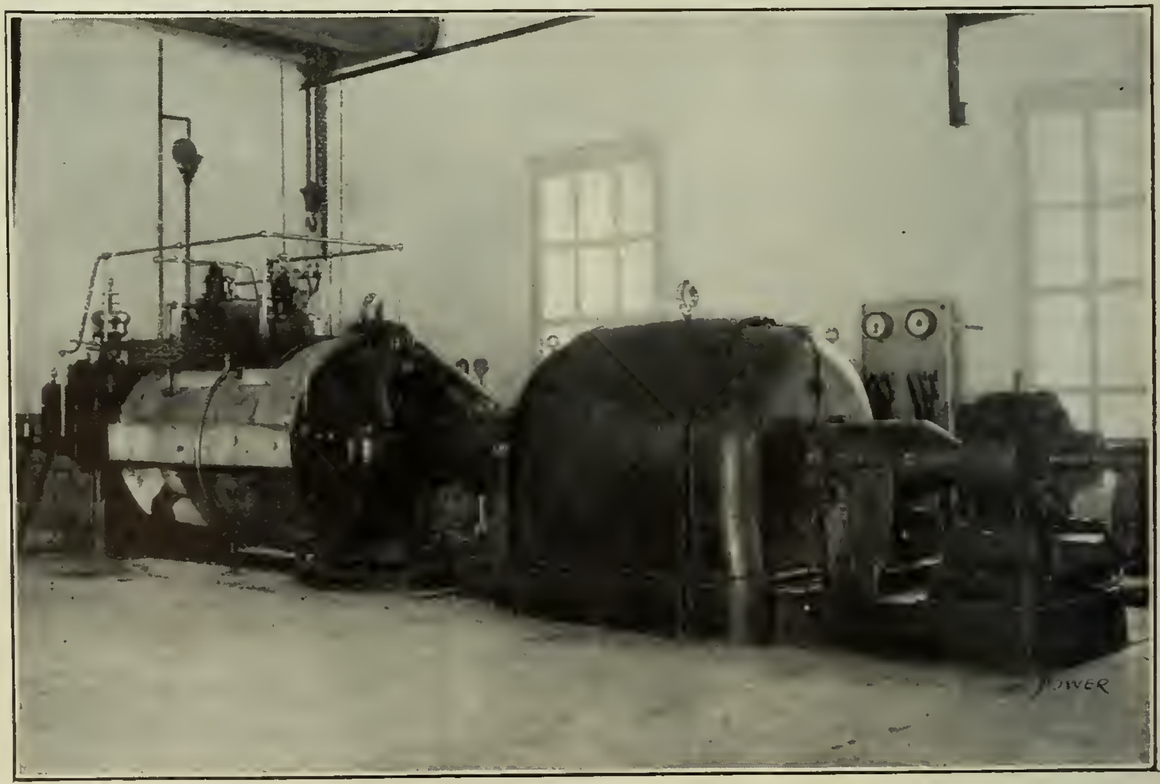

Fig. 3. Turbine Set Up and Put in Operation before Any Repairs Were Made

Matters went well until the train reached a 20-foot embankment in which a stone bridge had been built. Just as the car on which the turbine was loaded reached this bridge the car collapsed and the turbine took a drop of 20 feet, making one complete revolution in its descent and landing in the river bed, as shown in Figs. 1 and 2.

For three weeks the turbine lay where it fell, while a spur track was being built to it, as no tackle was available for hoisting the turbine onto a car on the main track. The turbine finally reached its destination, was set up and had been in operation for some time before the manufacturers were aware of the accident.

After a month's delay a man was sent from the factory, who took the turbine down and examined every part. No injury to the machine was found, with the exception of the breaking of the polished steel lagging and the upper platform, as shown in Fig. 2.

Fig. 3 shows a view of the turbine after it had been set up and before the lagging had been replaced.

There may be a prevailing idea among engineers that the general run of steam plants in Mexico are of ancient design. There are, however, many modern steam installations, and the plant in which this particular turbine is installed is uptodate in every particular. The turbine is rated at 1500 kilowatts and is run condensing. Steam pressure at 150 pounds gage is carried and the boiler-room equipment is every bit as modern as that in the engine room.

Capacity of Refrigerating Plant

How much refrigeration will be required to cool a cold-storage compartment, 8x9x10 feet high, to a temperature of 35 degrees, and cool 1000 pounds of butter through 20 degrees every 24 hours. The cooler walls consist of two layers of tongue and groove sheathing with paper between, a 4-inch air space, two more layers of sheathing with paper, a second 4-inch air space and finally a third pair of layers of sheathing with paper between. Will a single-cylinder single-acting ammonia compressor operating at 70 revolutions per minute about six hours per day do the required work?

Which is the best, an open or inclosed type, vertical or horizontal compressor?

How much direct expansion piping will be required?

How much condenser surface?

The heat transmission through insulation of the above construction has been given, in a series of values of different types of insulation published by the Armstrong Cork Company, as 3.43 B.t.u. per square foot per degree difference in temperature inside and outside for 24 hours. The superficial surface of a cooler of the above dimensions is 484 square feet, the maximum difference in temperature is

$$90 - 35 = 55 \textit{ degrees}$$

from which the total heat transmission is found to be

$$3.43 \times 484 \times 55 = 91{,}770 \textit{ B.t.u.}$$

or

$$91{,}770 \div 144 = 637 \textit{ pounds}$$

per 24 hours.

The cooling of 1000 pounds of butter through 20 degrees Fahrenheit requires

$$1000 \times 20 \times 0.5 = 10{,}000 \textit{ B.t.u.}$$

or 69.4 pounds per 24 hours, making a total duty of 706.4 pounds, or 0.353 ton.

A 5x5-inch single-cylinder single-acting compressor operating at 70 revolutions per minute when producing temperatures around 36 degrees, should develop a capacity of 0.64 ton per 24 hours and would consume approximately 1⅓ horsepower.

To operate only six hours per day the compressor would have to be increased in proportion to the reduced operating time. The required cooling effect, as determined above, is 0.353 ton per 24 hours. If the work is to be done in twelve hours, the capacity of the machine must be twice as great, or 0.706 ton, and if in six hours, four times as great, or 1.4 tons. Since the capacity of the compressor operating at 70 revolutions per minute was found to be only 0.64 ton per 24 hours, the speed of the compressor will have to be increased in the ratio,

$$0.64 : 1.4 :: 70 : S$$

which gives for S, the required speed, 153 revolutions per minute. The horsepower will have been increased in proportion to the speed, or,

$$70 : 153 :: 1.33 : H.P.,$$

which gives $H.P.$, the required horsepower to perform the cooling work in six hours, as 2.9 horsepower.

If possible to do so, it would be much better to operate the compressor in question twelve hours per day, in which case about 75 revolutions per minute would be a sufficiently high speed, and only about 1½ horsepower would be consumed.

It would not be safe to use less than a three-horsepower motor for operating the machine as single-acting machines and especially single-cylinder single-acting ones require a considerable initial starting power over that required to drive the machine under the conditions of normal operation.

Double-cylinder machines, while somewhat more expensive to build, are much more satisfactory in this respect than single-acting ones, and they possess the additional advantage of having half their capacity available in case of a broken suction or discharge valve on one of the cylinders. Operating one side of the machine above its normal speed longer than its usual time of operation may save the stored products, while repairs for the other are being procured.

As regards the relative merits of open and inclosed crank-case types of compressor, each has advantages over the other. The inclosed crank-case machine, which is also a vertical machine, would in all probability be found most satisfactory for the limited requirements. Packing against ammonia pressure in this type of machine is made on the rotating crank shaft instead of on a reciprocating piston rod as in other types. It is much easier to keep the former packing tight, especially where the machine is not to be operated continuously.

It would be good practice to use a compressor with the suction valve located in the piston head, as the effect of inertia at the lower end of the stroke causes the prompt closing of the valve, thereby preventing any undue opportunity for gas that has entered the cylinder, to escape without being compressed. Similarly, inertia tends to open the valve as the piston begins its downward stroke, thereby giving full opportunity to fill the cylinder during the whole of the downward stroke.

If the machine is to be operated only six hours per day at 27 pounds back pressure, on which the capacities previously given were calculated, about 5400 running feet of 1¼-inch direct-expansion piping should be used. If the machine is to be operated twice as long, the piping can be reduced, but not in the same ratio, 3500 to 4000 running feet being required.

If cooling water at the usual temperatures is available and the condenser is to be of the double-pipe type in which the cooling water passes through the inner pipe and the ammonia gas between the inner and the outer pipes, about 20 running feet per ton is a good ratio, or for the above machine operating six hours per day, about 28 feet. If it is to operate twelve hours, about 20 feet would be ample so far as the actual work to be done is concerned. It is customary, however, to put in condensing and expansion surface equal to the entire capacity of the machine as first indicated.

The *Manchester (England) Union* is sponsor for the following addition to the gaiety of the nation:

"The story is told of the times of Aretas Blood and the old Manchester Locomotive Works, that a student came to Mr. Blood once and wanted to study the business of locomotive building in his vacation days. The student came well recommended, and Mr. Blood, who never had much use for these 'tech' people, sent him down to the boiler shop and placed him in charge of the old foreman. The old man took the 'tech' chap around, and in the course of the inspection of the shop they came across one boiler on the inside of which was a man at work.

"'How does that man get out?' inquired the 'tech' man.

"'Oh,' said the venerable pilot, 'he doesn't get out. We always count upon losing at least one man in building a boiler.'"

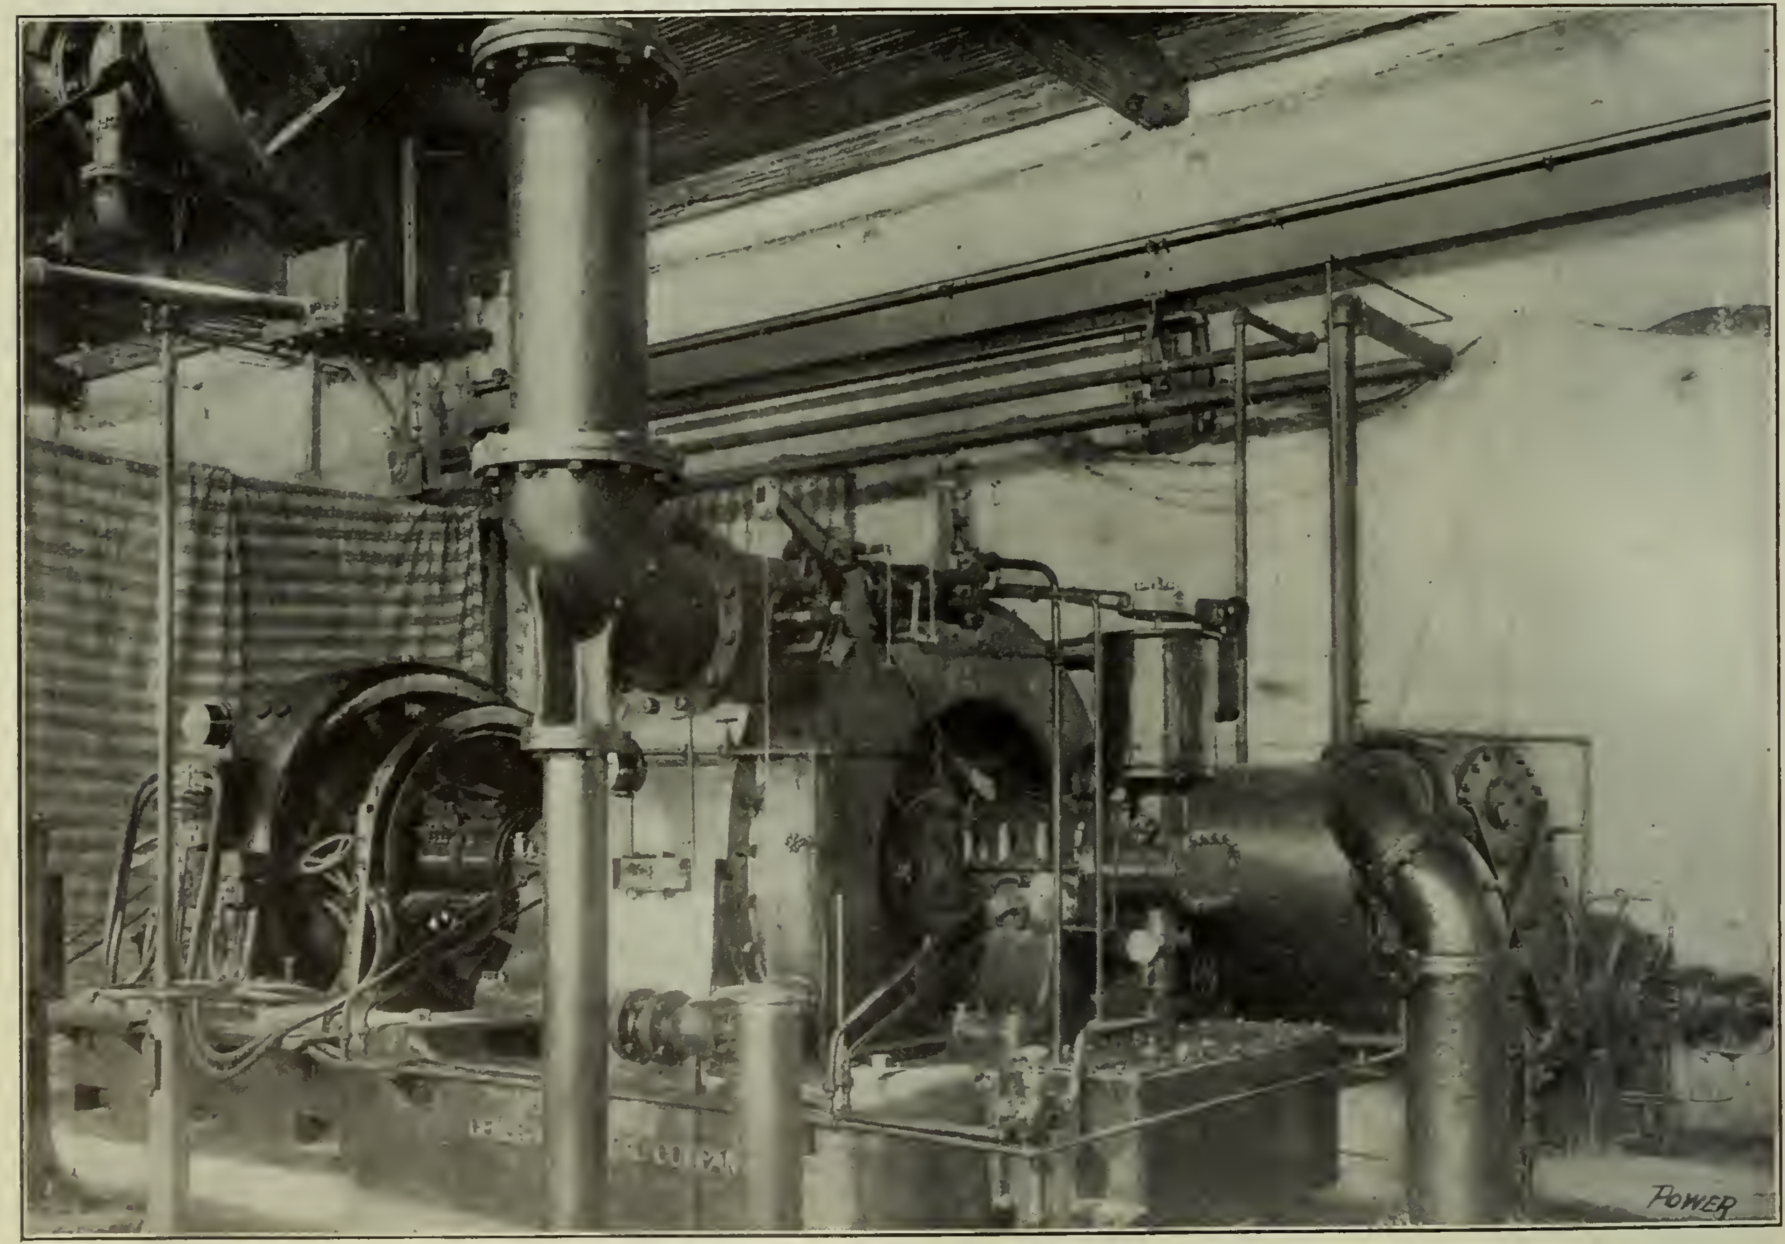
Low Pressure Turbine in Davenport

By P. Bendixen

A 500-kilowatt unit takes exhaust steam from engines, pumps and air compressor and develops about three-fourths of the energy delivered to the primary units.

About two years ago the Bettendorf Axle Company, of Davenport, Ia., was considering an addition to its electrical equipment, due to the growth of the plant, and made a thorough investigation of the various prime movers suitable for the purpose. Taking into consideration the heating of the shops in winter and the fact that the old power plant was running noncondensing, all factors pointed to the low-pressure or exhaust turbine as the most suitable power unit to install, from the standpoint of reliability, simplicity, economy and maintenance.

The power equipment at that time consisted of two 100-kilowatt direct-connected high-speed tandem-compound engine-driven units, a number of hydraulic pumps and an air compressor exhausting into one header, making an ideal arrangement for connection to an exhaust turbine. The company decided to install a 500-kilowatt horizontal Curtis turbine. This turbine was put in operation in September, 1909, and has been in service for about 14 hours per day since. It supplies all electrical power required by the plant, which at present amounts to 250 kilowatts average load, this power being used mostly for the operation of cranes, the lighting of shops, and for lifting magnets. When machinery now under construction is completed and installed, the load will be increased to about double. The main steam supply is derived from the exhaust of the hydraulic pumps, but, owing to the fact that these pumps are subject to interrupted service, due to breakdowns on the system, other means of supplying steam had to be provided and a connection was therefore made from the exhaust header to the high-pressure steam pipe through a 4x8-inch Foster pressure-reducing valve. By means of this connection the required amount of steam to keep the turbine in operation is secured. This arrangement works very satisfactorily, as the valve operates within a range of one-half pound drop in pressure. The average back pressure is about three pounds, and to take care of an excessive back pressure the exhaust header is provided with a 12-inch relief valve set to operate at five pounds pressure. All steam to the turbine passes through an 18-inch two-stage separator, which separates all oil and moisture from the steam. A Worthington condenser with 3150 square feet of surface is installed, the condensed steam being returned to the boiler feed-water heater.



Low-pressure Turbine Installation in Plant of the Bettendorf Axle Company

While no figures are available to substantiate a statement as to the exact performance of the turbine, it is thought possible, when running with 28-inch vacuum, to recover 75 per cent. of the energy delivered to the pumps, compressors and reciprocating engines. In cool weather it has been possible to run for weeks with a vacuum of from 29 to 29½ inches, this, of course, making quite a difference in the steam consumption. In order to maintain a good vacuum, it has been found necessary to pipe the steam seal in which the carbon-packing rings are located with high-pressure steam to insure against any leakage of air around the shaft. The amount of steam required for this purpose can best be found by experiment, and when once adjusted requires very little attention.

Before putting the turbine in service it was run for a few days under various loads, the generator being loaded on a water box. It was found that sufficient exhaust steam was available to furnish 425 kilowatts continuously, and as much as 575 kilowatts for short periods. Six boilers of about 120 horsepower each were in service at that time. The results of the test would indicate that 75 to 80 per cent. of the energy delivered to the engines and auxiliaries was recovered.

With a load fluctuation of about 500 amperes, the variation in potential does not exceed two or three volts. The lighting load consists of inclosed-arc, flame-arc, mercury-vapor and incandescent lamps.

Good results are obtained without the use of a receiver generator between the units and the turbine, as the reducing valve makes up for any deficiency in the steam supply which might be due, as stated before, to the stoppage of one of the engines or pumps. With this arrangement a sufficient supply of steam is always assured.

The longest continuous run so far made with this turbine has been five days and nights. No shutdowns due to trouble of any kind with the turbine have occurred since the turbine was first put in operation, and this company can conscientiously recommend the installation of a low-pressure turbine in any place where a sufficient supply of exhaust steam is available for its operation.

Verdict in Pabst Explosion Case

Growing out of the boiler explosion described in Power, November 9, 1909, this interesting case has been decided in favor of the Pabst Company, a verdict of $97,400, with interest from December 1, 1909, being awarded. The case was immediately appealed.

The case of the Pabst Brewing Company versus the Hartford Steam Boiler Inspection and Insurance Company, growing out of the boiler explosion which occurred at the Pabst plant on the morning of October 25, 1909, has just been heard in Milwaukee before A. L. Sanborn, United States district judge for the western district of Wisconsin.

The Pabst Brewing Company sued on two counts, the first being that the Hartford company "represented and held itself out to the public as skilled and expert in the examination and inspection of steam boilers and that its inspectors would make the skilled and careful examinations necessary to determine the safety and condition of the exploded boilers and that the results of all inspections would be promptly and truly reported to the Pabst company so that the latter would be kept continuously and accurately informed as to the true condition and safety of said boilers."

The plaintiff alleged "on information and belief that on and prior to the fourth day of September, 1909, said boilers were not free from dangerous defects and were not in good condition, but that each of said boilers contained, among others, the divers and dangerous defects following: Checks, cracks and openings along, and in connection with, the reinforcing strip or plate of the drum of each of said boilers; defective, imperfect and broken rivets on each side of said reinforcing plate and elsewhere in each of the drums of said boilers, and other dangerous defects which this plaintiff is unable of its own knowledge or on its information and belief to particularly set forth and specify."

The plaintiff further alleged "that the boilers were in an unsafe and dangerous condition and said defects were of such a nature as to be obvious to anyone having any knowledge, skill and experience in the examination of steam boilers, and that the defendant ought, in the exercise of ordinary care and prudence and reasonable skill, to have discovered said defects and advised and informed the plaintiff thereof, prior to the explosion."

Also it was alleged "that the defendant was careless, reckless and negligent in making inspections, failed to observe and discover the dangerous defects, and wrongfully and negligently failed to inform the plaintiff as to the true condition of its boilers." "That by reason of said wrongful and negligent inspection the boilers were continued in operation and did explode on the 25th of October, 1909, and that by reason thereof the plaintiff was prevented from carrying on its business and suffered damage to the amount of $11,060.57."

For a second cause of action the plaintiff alleged "that the defendant contracted to insure against all loss or damage, which might result from the explosion of any one, or all, of the six Manning boilers contained in the boiler house which was damaged, not to exceed the sum of $150,000 and that three of these boilers did explode while the policy was in force, causing a property loss of $114,361.91."

It will be seen that the suit was first for the recovery on the ground of negligence, of $114,000 direct damage, subsequently reduced by conference to $97,400, and some thirty-odd thousand indirect damages; and, secondly, for the recovery under the contract for the direct damages only.

The question from the standpoint of the defense seemed to hang largely on the wording of the policy, in which there was a limiting clause covering damage due to any one explosion. The policy affected to insure the Pabst Brewing Company "for $150,000 against all immediate loss or damage except by fire to the property specified in the policy, or resulting from loss of life or injury to persons caused by the explosion, collapse, or rupture, of any or all steam boilers covered by the policy." It further covenanted "that by the terms 'explosion, collapse or rupture' was to be understood a sudden substantial tearing asunder of the boiler or any portion thereof or the sudden crushing or forcing inward of the furnace or flues, etc." In a "rider" on the policy, however, it was further provided "that the total liability of the company from loss or damage from any one explosion should not exceed the sum of $50,000, and in case of more than one explosion the entire liability of the company should not exceed the sum insured by the policy, viz., $150,000."

Immediately following the explosion the Pabst company engaged a committee of four engineers, consisting of C. J. Davidson, H. D. Tomlinson, E. E. Adams and Owen P. Davies, to make an examination of the exploded boilers and report their opinion as to the probable cause of the disaster. In the testimony for the plaintiff the result of this investigation was brought out. All four of the investigators were unanimous in their belief that the initial rupture occurred along the center line of a reinforcing plate riveted to the drums of the boilers as is the regular construction for that make of boiler, and shown in the accompanying sketch. They testified to their belief that the presence of this strip of metal, which was ½ inch thick, riveted to the ½-inch drums was, owing to the unequal expansion and contraction of the two pieces of metal, a serious menace to the life and safety of the boilers. The history of the boilers was brought out quite thoroughly during the presentation of the case. It developed that extensive leaking had been noticed along this reinforcing seam and that many rivets had become loose and been replaced in the effort to stop this leaking. Also the outside edge of the plate had been repeatedly calked with the same object in view. The examining committee had investigated the condition of Nos. 5 and 6 boilers, which did not explode, and testified to finding cracks easily visible between the row of rivets holding the reinforcing strip to the shell of these boilers, these cracks being attributed to the breathing action resulting from holding a portion of the boiler shell rigid under the reinforcing strip, allowing the remainder of the shell to expand and contract with the steam pressure, and also to the unequal expansion and contraction due to the different thickness of the two pieces of metal. It was contended by the plaintiff that, inasmuch as Nos. 5 and 6 boilers were found to be in this condition, it was reasonable to suppose the exploded boilers, being of the same age and having the same general treatment throughout their lives, were in the same weakened condition, making them dangerous for the working pressure carried in the plant.

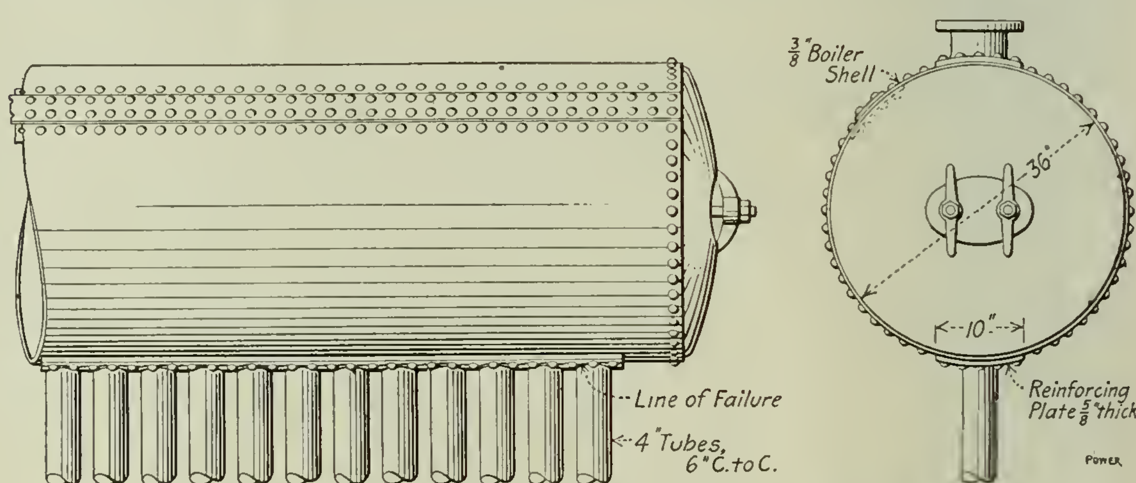
In answering the charges, the defendant alleged "that in the event of an explosion of all, or any, of the boilers the total liability for all loss or damage resulting from any one action, or explosion, however caused, should not exceed the sum of $50,000. That said boilers and property mentioned were destroyed and injured by one accident or explosion within the meaning of the policy, and that by reason thereof the liability did not exceed the sum of $50,000; and that the explosion was caused by the neglect and carelessness of the plaintiff. That, in case of more than one accident occurring during the three-year period covered by the terms of the policy, the entire liability of the defendant should not exceed the sum of $150,000."

In opposition to the claim based upon negligence the defense, while denying any lack of diligence in this respect, maintain that, although the policy gave the defendant permission to make boiler inspections, still it was not bound to do so, and that what inspections were made were simply and solely for the information of the defendant itself, and that it was not obligatory that these reports should be given to the owner of the insured boilers. In all cases, however, it was contended that such information had been given after each inspection.

Answering the technical features of the case, B. J. Morrison, of St. Mary's, O., testified for the defense, that in his opinion the initial rupture came in the main steam line of the plant or some of its principal connections and that the water, flashing into steam, caused an overproduction of pressure which exploded the boilers. He also believed that the leaking around the reinforcing seam came from where the tubes were expanded into the drums. In his opinion the cracks between the rivet holes were caused by rolling the plates in process of manufacture and after the row of rivet holes had been punched.

These cracks, he believed, were entirely covered by the reinforcing strip in such position as to be impossible of detection when making boiler inspections. He admitted that it would be only a question of time until the drum would fail under these conditions, as there would be a breathing action along this row of rivets. In regard to the effect of differential expansion he believed that this could be set down as negligible, the movement, if any, being so absolutely small as not to warrant serious consideration. Mr. Morrison was of the opinion that none of the cracks between the rows of rivets in the reinforcing seam could have been visible before the explosion and believed that if six or more cracks had existed entirely throughout the sheet, between the rivet holes in the reinforcing seam, it would have been impossible to keep water in the boiler or maintain steam pressure. In answer to the contention that Nos. 5 and 6 boilers were found to have dangerous cracks in the shell along this reinforcing seam, he testified that in his opinion these cracks were not there before the explosion but were caused by the violent concussion of the explosion. Nos. 4 and 5 boilers, it developed, were connected to the line at the time the explosion occurred, while No. 6 was disconnected, and not under steam. He believed that the reason Nos. 4 and 5 did not explode was because Nos. 1, 2 and 3 happened to be the weaker, owing to the breathing action along the reinforcing seam, and that they were unable to stand the concussion brought about by failure in the steam line.

Prof. L. P. Breckenridge, of New Haven, Conn., also testified in the defense. It was his belief, according to the testimony, that the primary cause of the explosion had been a failure in the steam line or some of its principal connections and that the sudden release of pressure had created an instantaneous steam pressure higher than the drums could stand. He criticized severely the design of the boilers, testifying that he believed the drums were prevented from assuming a true circle, owing to the presence of the heavy reinforcing plate having a tendency to make this part of the drum rigid and flatter than the other points. This, he believed, contributed largely to the failure of the boilers, as during the entire life of the boilers there would have been a breathing action, setting up stresses along the length of the drums. He also criticized the boiler with respect to circulation, although he did not think that any of these points had a direct bearing on the cause of the explosion, and the fact that all the drums let go along the reinforcing strip showed merely that this was the weakest part of the boiler and that the failure would naturally occur at this point after being set off by the breakage of the steam line.



Drum of Munoz Boiler, Showing Line of Fracture

Regarding the cracks found in Nos. 5 and 6, he testified that in his opinion they were developed by the concussion when the other boilers exploded and that these cracks could not have been in the boilers before; otherwise it would have been impossible to keep water in them or maintain the steam pressure. He also believed that differential expansion between the boiler shell and the reinforcing plate was of very little consequence, owing to the fact that this part of the boiler was not subjected to the direct heat of the fire and was considerably removed from the zone of high temperature.

The judge held that whether or not there were negligence on the part of the defendant, the Hartford Steam Boiler Inspection and Insurance Company could be held only for the amount and kind of damages specified in the contract, so that had the jury decided that there had been but a single explosion the damage would have been limited to the $50,000 admitted by the defendant. He did, however, allow the jury to determine what the indirect damages would be, in case of reversal on appeal, and they placed them at $810. The jury found also that there was more than one explosion within the meaning of the contract and awarded the $97,400 agreed upon as direct damages. The case was immediately appealed.

Methods of Governing Steam Engines

By John Davidson

The two general methods of governing, requirements for speed regulation of different types of engine and a description of several well known throttle governors.

In nearly all cases where a steam engine is used, it is of primary importance to maintain the speed constant, or nearly so. The two principal conditions affecting the speed are the steam pressure and the resistance which the engine has to overcome. Therefore the governor must be able to regulate the quantity or the pressure of the steam, so that the power developed by the engine is just sufficient to overcome all the resistance when running at its normal speed.

The degree of accuracy required depends generally upon the kind of machinery to be driven. For many purposes a governor which is capable merely of preventing the engine from running at an excessive speed is sufficient, whereas for other purposes it is necessary that the governor should maintain the speed under all conditions of load and steam pressure within very closely defined limits, which in special cases are within 1 to 1½ per cent. of the normal speed. Also, the load required of the engine may vary rapidly, and in this case it is necessary that a very sensitive governor be used; or, on the other hand, the variation in load may take place gradually, in which case a slow-moving governor will serve the purpose.

The governor of a steam engine can control only the mean speed of rotation, as the steam is admitted periodically to the cylinder. Between each admission of steam, a variation in the angular velocity of the rotating parts takes place, and this can be minimized only by adding flywheel power. For many purposes it is necessary that this angular variation should be kept within fine limits, in addition to the mean speed of rotation, and under these conditions heavy flywheels are generally used. Besides maintaining a uniform speed of rotation during each revolution, the flywheel greatly assists the governor in cases where a variation in load takes place very rapidly, as is the case where the engines are used for rolling mills and for driving electric generators supplying power for electric railways.

There are two principal methods of governing engines: by throttling the steam and by altering the point of cut-off, that is, varying the degree of expansion. In the first case the quantity of steam admitted to the engine is constant under all loads, the pressure being varied to suit conditions; in the second case the amount of steam admitted to the engine is varied to suit the load, the pressure remaining constant, or practically so. Sometimes the two methods of governing are combined, and when this arrangement is used the engine is usually controlled by the throttle governor entirely at light loads.

Throttle governors are used mostly for small engines, in nearly all cases for high-speed engines of all powers and in cases where the load changes very little and the governor is required principally as a safety device, as for pumping engines, etc. As is generally understood, with throttle-governed engines the most economical load is the maximum load the engine will develop with any fixed cut-off. Therefore, it follows that where a wide variation in load takes place the throttle governor does not give the highest efficiency. It should be noted, however, that where the variation in the load is not very great the difference in economy between variable expansion and throttle governors is practically a negligible quantity.

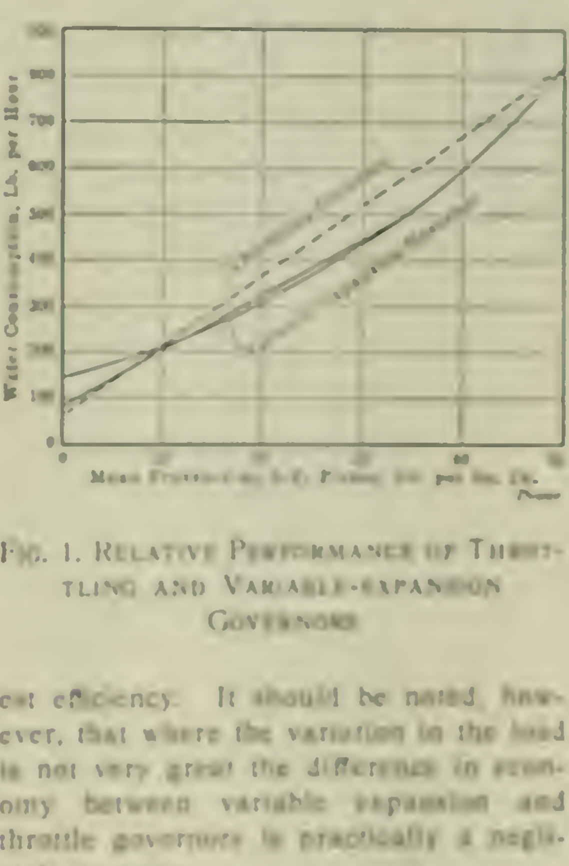


FIG. 1. RELATIVE PERFORMANCE OF THROTTLING AND VARIABLE-EXPANSION GOVERNORS

At light loads nothing is to be gained by variable expansion; consequently by carefully designing an engine it is possible to arrange the cylinders for a degree of expansion which will give good economy over a large range of load. To make this clear, in Fig. 1 is shown the relative steam consumptions of an engine under the same conditions of load when controlled by variable expansion and by throttling.

Suppose that the engine be altered in capacity so that the mean effective pressure referred to the low-pressure piston in pounds per square inch is about 32, then the steam consumption with the throttling governor will be as shown by the full straight line. This shows that, between 32 and 12 pounds mean effective pressure, very little is gained by a variable expansion, and below that load the throttle-governed engine is the more economical.

To maintain maximum economy in throttle-governed engines of the compound and triple-expansion type, when they are required to develop overloads for short periods, bypass arrangements are often fitted, to enable high-pressure steam to be admitted directly to the second cylinder, thus converting the triple-expansion engine for the time being into a compound engine, and a compound into a simple engine. This arrangement is simple, and enables an engine to develop heavy overloads in cases of emergency. However this practice is not to be recommended, as the distribution of power between the cylinders of the engine when dealing with overloads is very unequal, and unless the moving parts are specially designed to suit these conditions, it is liable to cause unequal wear and overheating. As regards the speed regulation, there is practically no advantage in one method of governing over the other, as the controlling mechanism may be made to act instantaneously in either type.

For special purposes it is often necessary to maintain the speed of the engine constant under all conditions of load. With an ordinary governor, in which the controlling force is due to weights revolving about a given center, it is an impossibility to fulfil this condition, as it is necessary that the speed of the engine vary before there is any change in the position of the governor and consequent variation in the amount or pressure of the steam; that is, the governor itself takes up its position by a change in the speed of the engine. To maintain an engine at a constant speed it is necessary to have a regulating device which automatically speeds up the main governor as soon as a change in the load has taken place.

Types of Governors

For throttle-governed engines the governor and the throttle valve may be combined and driven from the engine crankshaft by means of a belt, ropes or chain. This arrangement of governor gear is generally used for small engines, where a device for preventing the engine from running at an excessive speed is practically all that is required. In every case where the governor is driven from intermediate gearing, such as a belt or ropes, an automatic arrangement should be fitted to shut off steam entirely in case the ropes or belt should break. Many serious accidents have occurred through engines not being fitted with an arrangement of this kind.

Engines running at a high rotative speed usually have the governor attached directly to the crank shaft, thus dispensing with all gearing and making a very compact and safe arrangement. The throttle valve is usually connected directly to the governor, and the latter is fitted with a speeder device, the spring of which acts in such a manner as to close the throttle valve in case the governor itself should break down. The

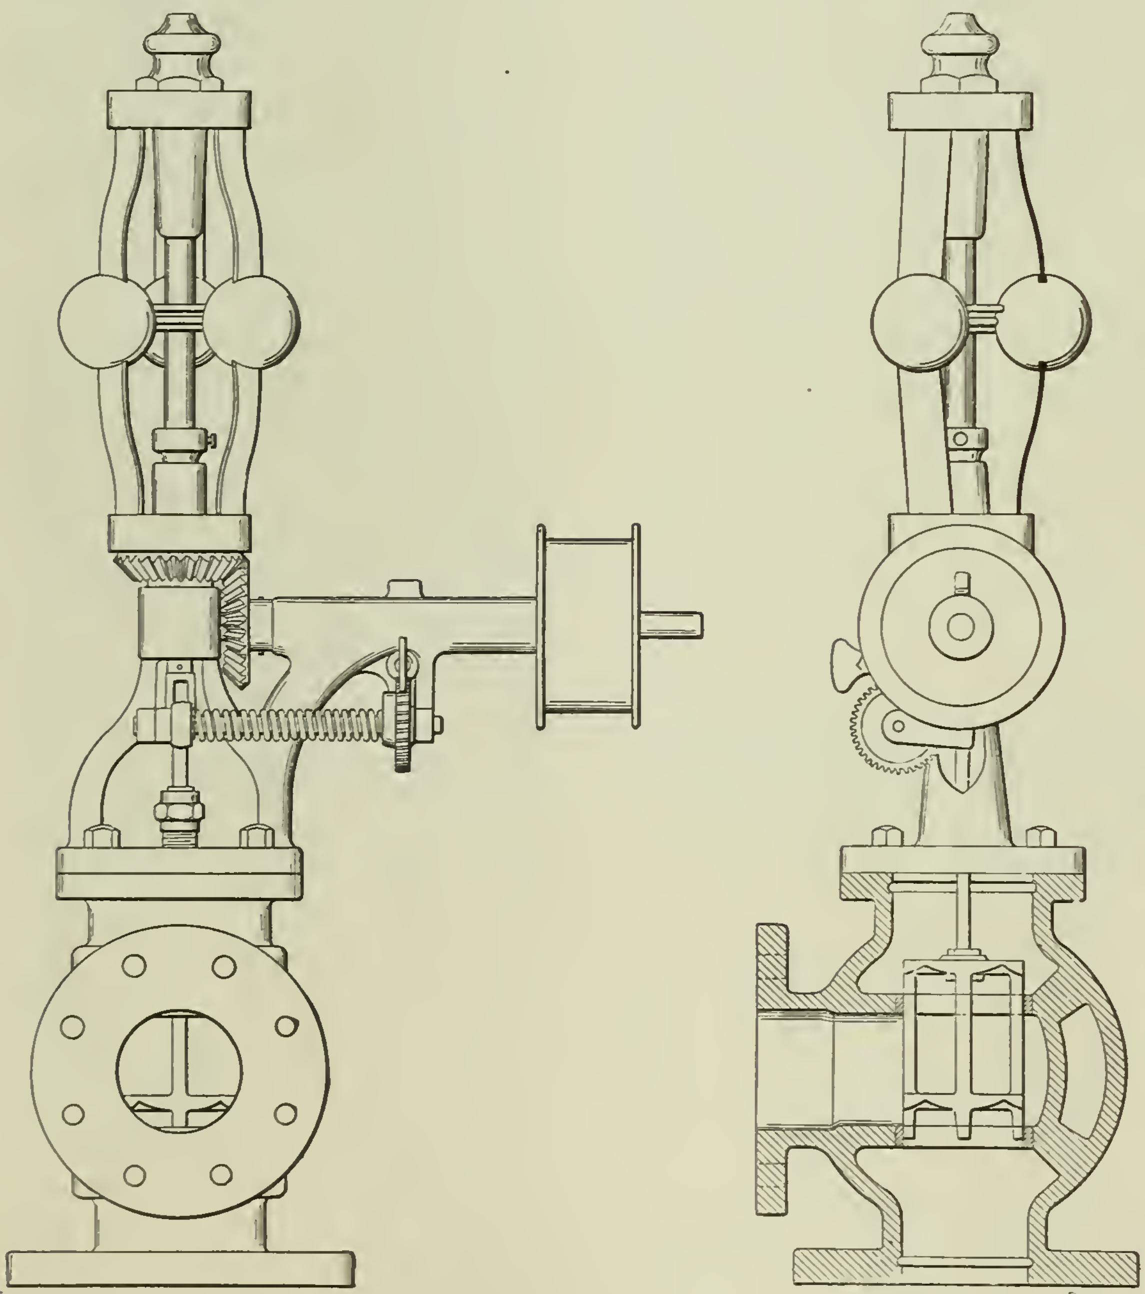

Fig. 2. Pickering Governor

high speed of rotation makes it possible to adopt this arrangement; but, of course, with slow-speed engines it is absolutely necessary to provide intermediate gearing if a powerful high-speed governor is required.

Slow-speed engines are usually fitted with steam-distributing valves actuated through trip gears; consequently the governor acts upon the tripping device to modify the point of cutoff. Very little power is required to operate the governor in proportion to the size of engine, as the gears are easily tripped. In the case of engines fitted with rotary cutoff valves, similar to the Ryder gear, a more powerful type of governor gear is necessary, and a governor controlling a relay motor is by far the most satisfactory.

Medium-speed engines are sometimes fitted with governors of the crank-shaft type. In this case the governor has to drive the valve in addition to modifying the position of the gear to change the point of cutoff; hence they are usually of massive construction. This type of governor at one time was extensively used for engines of a high rotative speed but it has now been almost entirely abandoned by English engineers, the throttle type taking its place. A few designs of this type of governor are made, and will be described later.

Owing to the demand for economical high-speed engines, especially for large powers, variable-expansion governing has again been adopted, but in combination with throttle governing. Governors of the flywheel type are not used, and the piston valve is driven in the usual way from an eccentric having a constant travel, the cutoff being varied by slightly rotating the valve which is provided with angular ports, with the liner having angular ports to correspond. Even in this type of governor, as considerable power is required to rotate the valve on its spindle, relay motors are generally adopted in place of putting this additional work on the governor. The governor then simply controls the main throttle valve, and alters the position of a small piston valve in connection with the relay motor.

As a full consideration of the theory and workings of governor gears would be out of place in this article, only the principal designs of governors in general use will now be illustrated and described.

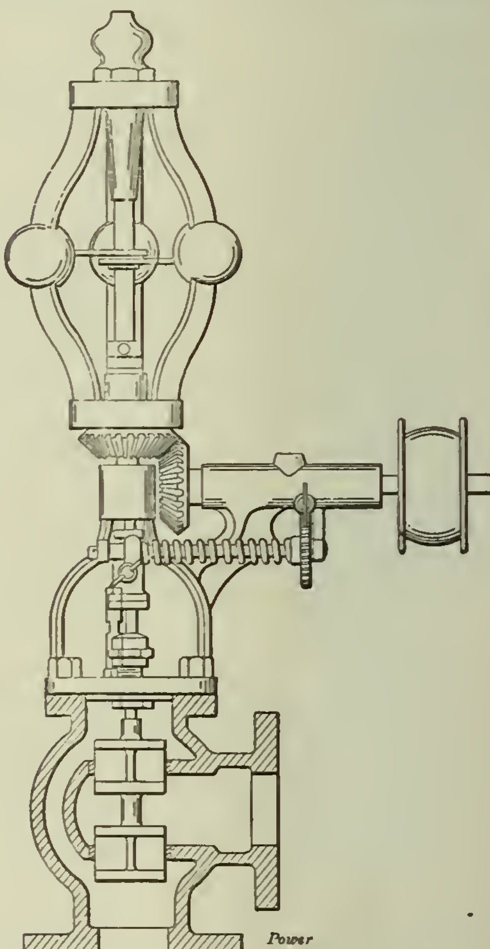

Fig. 3. Pickering Governor with Equilibrium Valve Attached

Throttle Governors

The most common form of combined governor and throttle valve is the Pickering, the general design of which is shown in Fig. 2. In this governor all arms and joints are replaced by flat springs, dispensing with all pin joints and the consequent wear and friction. A neat form of speeder gear is generally fitted, consisting of a torsional spring which tends to close the throttle valve by means of a lever, the pressure being adjusted through the small worm and wheel. The throttle valve being of the double-seated type is balanced, and the edges are vandyked so as to give a gradual opening.

A very effective type of knockoff gear is manufactured by Pollock, McNak & Highgate, of Glasgow, under "Smith's" patent, for this type of governor. The ordinary knockoff gear for governors driven through a belt or ropes consists of a loose arm carrying a jockey pulley, the pulley running on the driving belt or ropes, and dropping in case they should break. This arrangement is not altogether satisfactory for the following reasons: It places the whole stress of the governor on the tension spring, which has to carry the weight of the valve and knockoff gear acts only when the belt breaks, the action of the arm then releasing the spring and causing the valve to close. It does not act when the belt

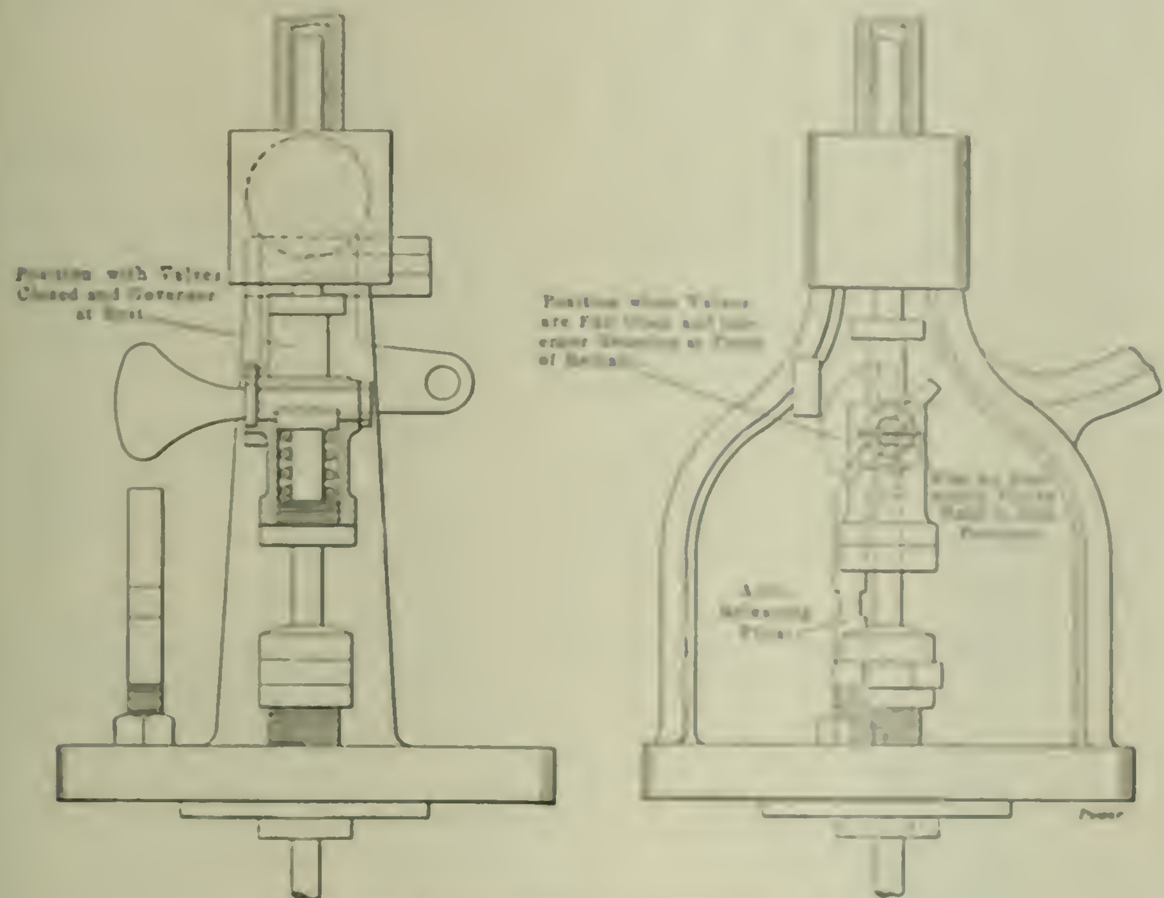

Fig. 4. Attachment for Starting Engine

spindle; and any downward pull of the leaf springs, when the governor is being expanded by an excess of speed, makes the governor less sensitive and interferes with its exact working. The slides, or the pulley slips on the shaft, nor when a pin or key comes out, but only when the belt gives way.

With Smith's patent automatic knockoff gear fitted to the governor, these objections are obviated, and if from any cause the governor stops or slows down, it brings the bottom valve of each pair, the two together constituting an equilibrium valve, into action and shuts off the steam from the engine. These valves are shown in Fig. 3. Neither the action of the governor nor its regulation of speed is interfered with in any way. When the engine is at rest these bottom valves are closed, and, in order to start, a small eccentric is used to open them. This is operated by hand, and its action may be understood by reference to Fig. 4. The eccentric is released automatically by the action of the governor after the engine has been started. This arrangement is simple and it is claimed that it is not liable to get out of order, and has the advantage of utilizing the lifting power of the leaf springs.

Sometimes the governor throttle valve and the stop valve of an engine are combined as shown in Fig. 5, which represents a type of governor largely used for all purposes, and known as the "Acme."

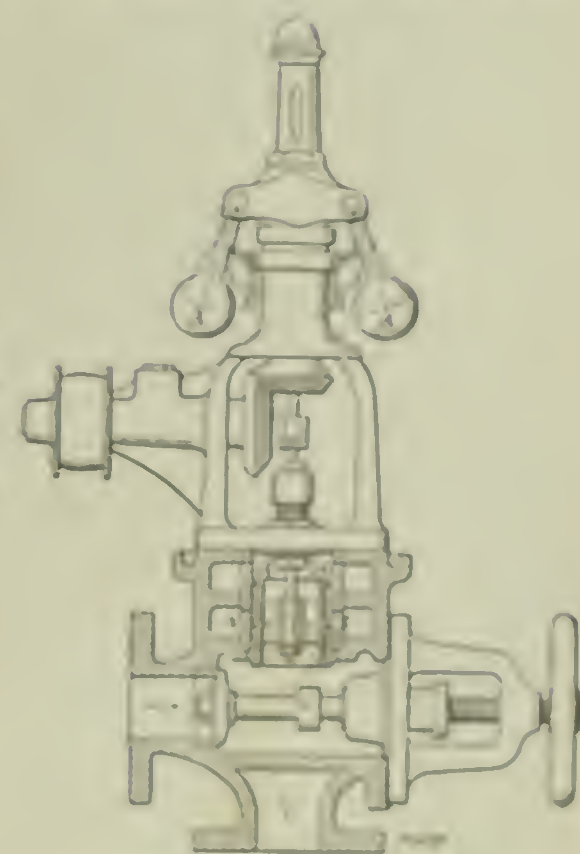

Fig. 6. Soho Governor

Another type of combined governor which is fitted with a safety device is illustrated in Fig. 6; this is known as the Soho safety governor and is manufactured by Messrs. Tangyes, Ltd., of Birmingham. The governor is so designed that if it should stop from any cause, such as breakage of the belt, the throttle valve would automatically close and prevent the engine from racing. The valve is of the equilibrium piston type with double steam ways, thus affording a large area for the passage of the steam with a short travel. To start the engine the balls *A A* must be held up by the supports *B B* as shown in the illustration, and the valve is then full open. When the engine has reached its normal

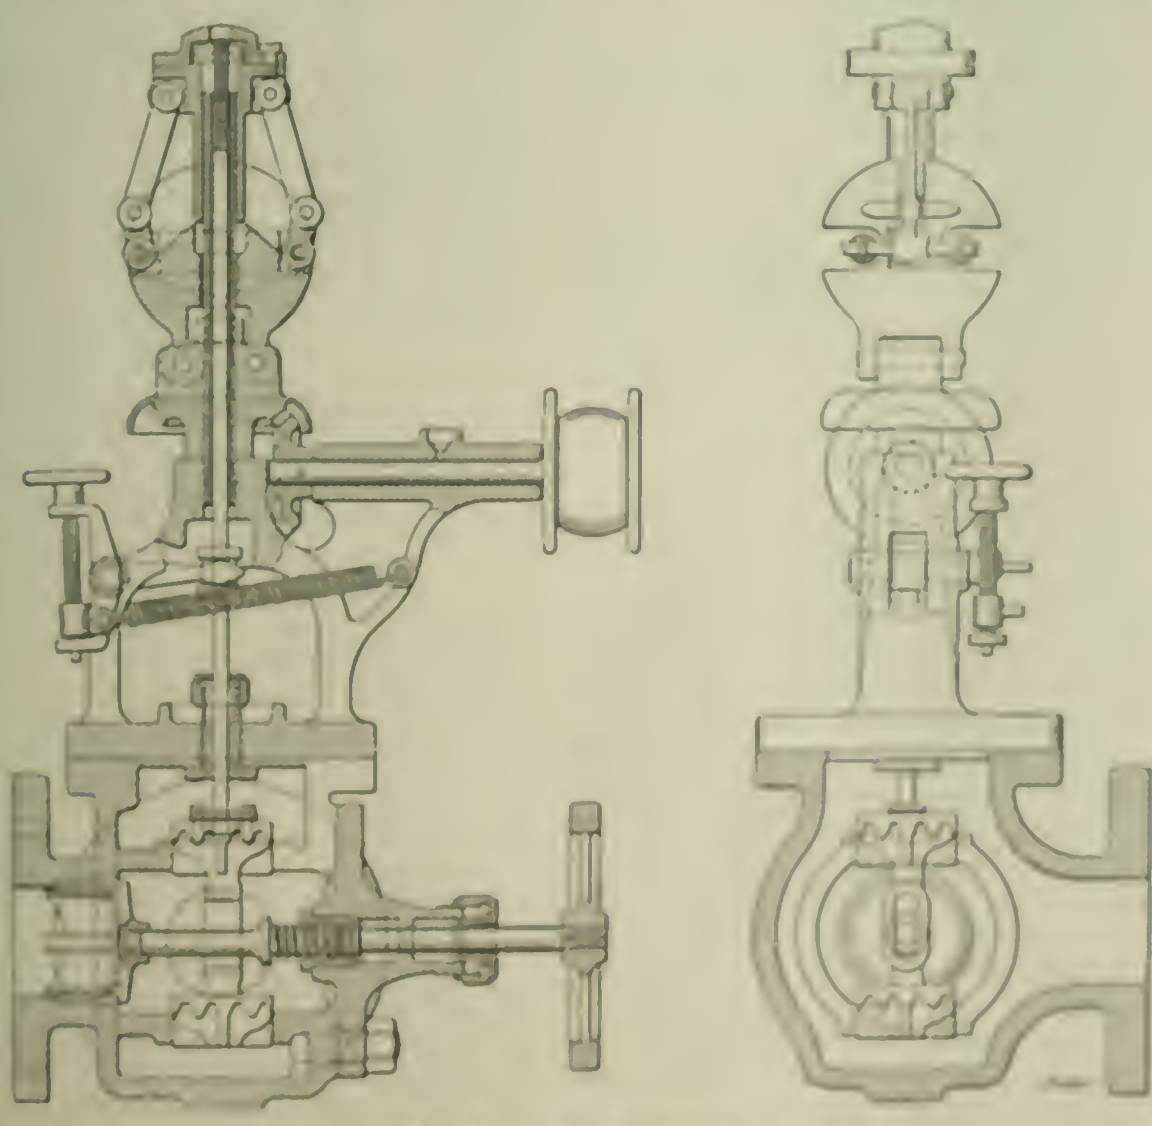

Fig. 5. Acme Governor

speed the balls will have lifted and the supports fallen out of the way, leaving the balls free to drop to their lowest position, closing the valve and preventing the engine from running away in case the

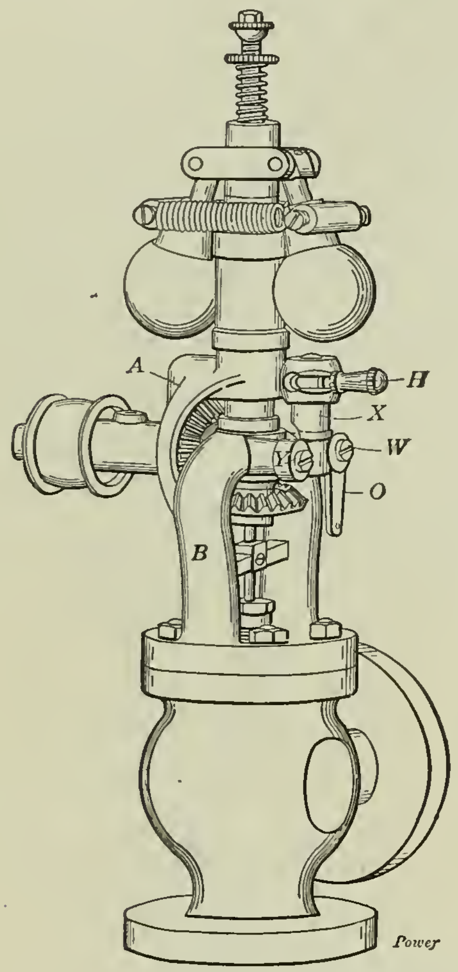

Fig. 7. Precision Governor

governor should cease to run from any cause whatsoever.

In Fig. 7 is shown the Precision spring governor, made by Schaeffer & Budenberg, of London and New York. This governor, although of simple design, is very sensitive, the aim being to reduce friction to a minimum and at the same time to make all parts easily accessible. The governor gear is mounted on a vertical spindle which runs in ball bearings. The tension of the springs increases with the outward swing of the pendulums, the two forces (the tension of the springs and the centrifugal force of the weights) practically balancing each other. The increase in the tension of the springs is practically constant for every equal movement of the weights; consequently the governor is almost astatic. A special type of knockoff gear is fitted which comes into action in case the governor should stop rotating.

The bracket *A*, carrying the governor head and the horizontal spindle with the pulley and bevel wheels, is arranged to slide on and turn round the hollow pillar on the bridge *B*. The bracket *A* is held in the upper position by the collar on the pivot, *X* resting on the rollers *Y* and *W*. In this position the governor acts like any ordinary governor; that is, when the weights are in their "in" position the ports of the valves are full open. If the strap is placed on the pulley, the knock-off motion is put into action by turning the pivot *X* so that the notched portion is opposite the roller *Y;* the bracket *A* is then held in the upper position by the pull of the belt pressing the collar on the pivot *X* against the roller *W*. If the strap breaks, the pivot immediately slides off roller *W*, and bracket *A* with the governor, etc., drops, thus shutting off the valve until the weights fall into their "in" position. By turning the handle *H* on the pivot, the knockoff motion can be adjusted to act for a belt pulley from the opposite direction. The roller *W* is notched and provided with a small lever *O* by which the knockoff motion can be actuated by hand, if necessary, from a distance. If rope or wire connected to the lever *O* is passed under the main belt of the engine, the knockoff motion will be actuated if the belt should slip off the pulley, thus immediately shutting down the engine.

In Figs. 8 and 9 are illustrated a governor, also made by Messrs. Schaeffer &

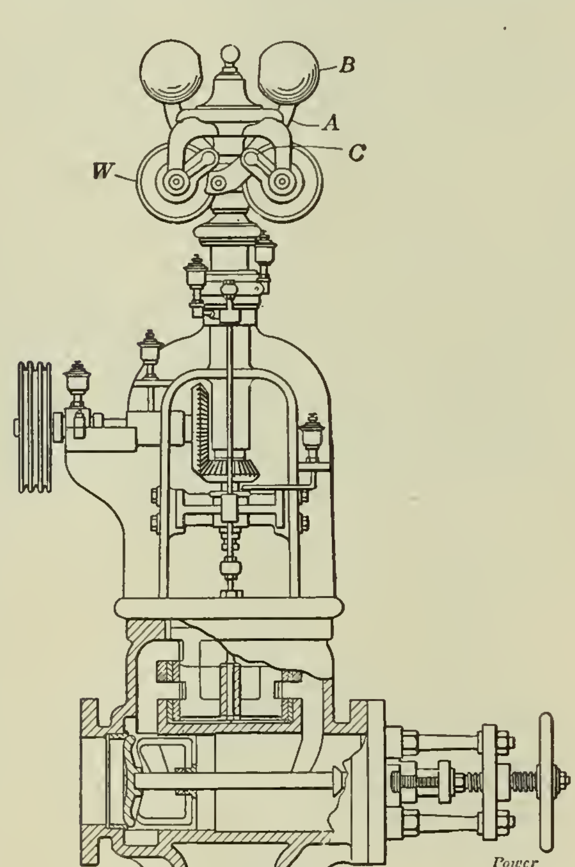

Fig. 8. Buss Governor

Budenberg, and known as the "Buss" type. In this governor a compound pendulum is employed, consisting of a bell crank *A*, one end of which carries a ball *B*, and the other a cylindrical weight *W*. There is one pendulum of this description supported on each side of the rotating axis in such a manner that the arm carrying the cylindrical weight *W* extends across the axis. Each pendulum is fitted with a stud *C*, which engages with and imparts movement to the muff. By a suitable choice of weights the system can be made absolutely isochronous within an angle of oscillation of about twenty degrees; beyond this angle the pendulum is in unstable equilibrium. The condition of equilibrium is such that the resultant of the weights and the centrifugal force must pass through the virtual center, which in this case is the axis of support of the pendulum. That is, in Fig. 9 let *F G* represent the resultant of the weights passing through the center of gravity of the pendulum, and *F K* the direction of the resultant centrifugal force, then *F O* represents the direction of the resultant of these forces, and completing the parallelogram *F G H K F, F K* represents the magnitude of the centrifugal force. In the middle position this acts upon the weight *B* alone, and therefore the speed may be computed as before. In the other positions, the effect of the centrifugal force must be proportionately distributed over the weights *B* and *W* in order to determine the speed. Between the two extreme positions, the governor shows a variation of only 2 per cent., and it could easily be made more sensitive if desired.

If a governor is made extremely sensitive throughout its lift, it is liable to overrun or hunt. This may be checked —at the same time retaining the highest degree of sensitiveness—by making the governor extremely sensitive about its middle position, but less sensitive upon approaching the highest and lowest positions. This is one of the objects aimed at in the construction of the four-pendulum governor shown in Fig. 10. In this there are four pendulums *A* which are suspended in such a manner that under the influence of their own weight alone they would fly apart until they had nearly reached their extreme outer position, corresponding to the highest position of the governor. They are, however, held in the inner position by the weight of the muff *W* which is applied through the pivots *B* of the pendulums. The latter are supported by short links *C* from the spindle *D*, and the sliding weight, which is made in one piece with

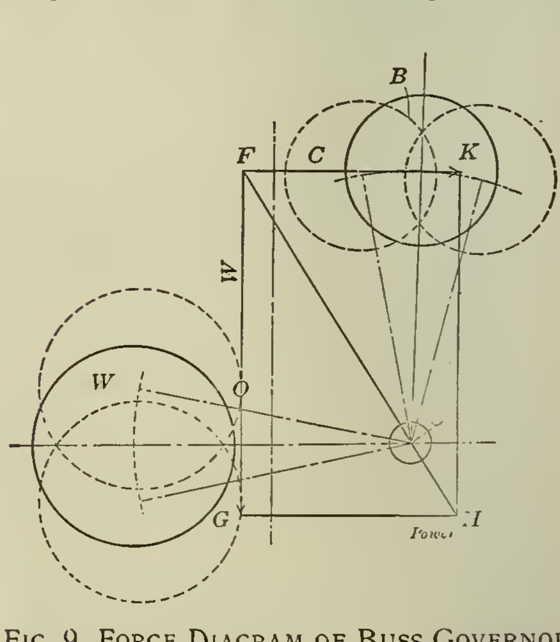

Fig. 9. Force Diagram of Buss Governor

the muff, incloses the whole governor. A light spring *E* is inserted to add to the stability and for adjusting the speed. The small view on the left of the pulley represents an arrangement for varying the speed of the governor while in operation. For this purpose the spindle is elongated and the muff is loaded by means of a spring *S*, which is held down by a nut *F*. By turning the milled wheel *G* the nut is moved on the spindle, and the tension on the spring is varied,

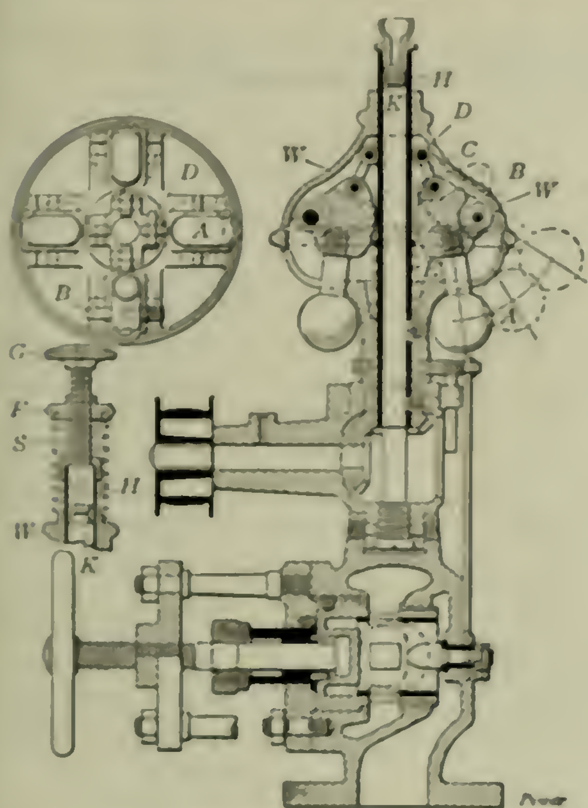

FIG. 10. FOUR-PENDULUM GOVERNOR

which in turn changes the effect of the weight of the muff. By the use of this arrangement the speed of the governor may be varied by about 50 revolutions per minute. This governor is so proportioned that it is almost isochronous about its middle positions, but a velocity difference of 3 per cent. is required to move it from the lowest to the highest position.

A governor constructed in such a manner that the hight of the cone of revolution is constant in all positions of the balls could be in equilibrium only at the one particular speed which corresponds to this hight, and the governor would therefore be absolutely isochronous. This result is obtained if the balls are guided so as to describe a parabola, and supported in a direction normal to the parabola at every point. One possible method of obtaining this consists in hanging the balls from a flexible leaf spring wound upon a base curved to the evolute of a parabola. There are practical difficulties in the way of carrying out this idea, but a feasible approximation to these conditions is found in the Watt governor with crossed arms, if proportioned so that within the range of movement required the arc of a circle described by the balls coincides approximately with an arc of a parabola having its axis in the axis of revolution of the governor.

HIGH-SPEED ENGINE GOVERNORS

As previously stated, the governors of high-speed engines are usually attached directly to the crankshaft and, therefore, revolve at the same speed as the engine. These governors are generally of very simple construction, as illustrated in Fig. 11.

The weights *W W* are pivoted on pins *P P* and by means of extended arms *A A* the motion of the weights is transmitted to the sleeve *B*. One end of the bell crank *C* engages this sleeve and the other end is attached to a throttle-valve spindle. The weights consist of plain steel castings, and adjustment is made by adding weights on either side.

It is now general practice in the case of high-speed, inclosed, forced-lubrication steam engines, to lubricate the main fulcrum pins by oil under pressure. To accomplish this a hole is drilled through

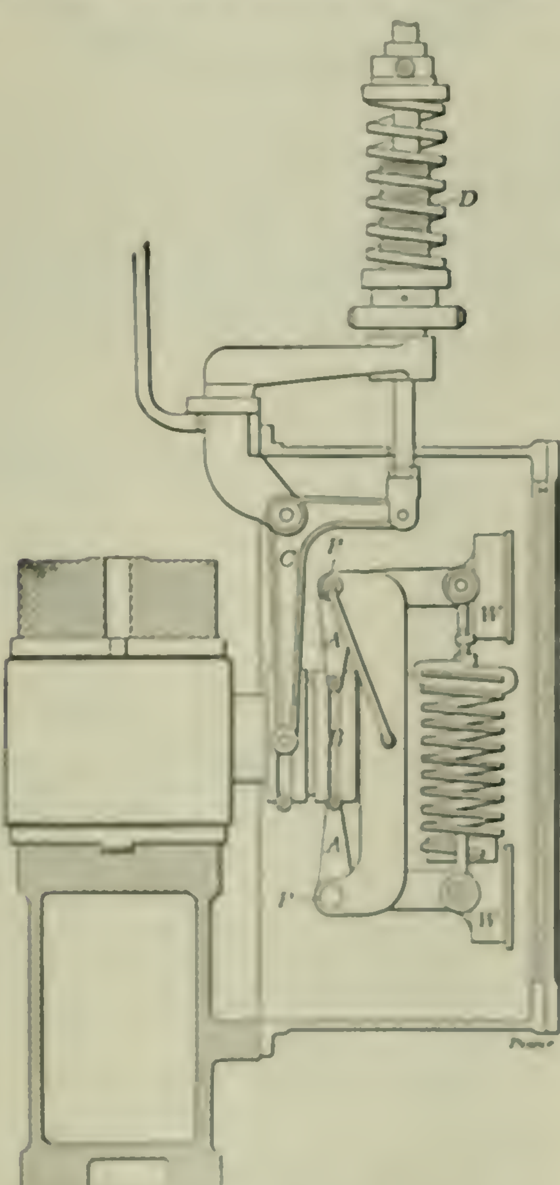

FIG. 11. HIGH-SPEED GOVERNOR

the center of the shaft at the end, connecting with the groove in the nearest end bearing, and from this hole connections are made by means of small pipes to the fulcrum pins.

Referring to Fig. 11 it will be seen that a speeder gear is fitted at *D* just above the casing containing the governor. This consists of a compression spring carried between a bracket fixed to the governor casing and an adjustable collar carried on a screwed bushing attached to the throttle-valve spindle. By means of a handwheel the bushing can be raised or lowered and the compression on the spring modified, thus altering the speed of the engine. As the throttle valve closes upward it will be seen that should the governor break down or become disconnected from the throttle valve, the spring *D* will immediately close the valve and shut down the engine.

The throttle valves used in connection with this class of engines are generally of the double-beat balanced type as shown in Fig. 12. Steam enters at the top and passes out to the cylinder through the two faces shown. The thickness of the metal in the valve and liner is made as nearly uniform as possible, and being cylindrical in form they retain their shape very well, even when subjected to great variations in pressure and temperature. With a view to reducing friction to a minimum, and at the same time preventing the possibility of an engine attendant interfering with the governing, as might be possible if an adjustable type of gland packing were fitted, a plain bush of considerable length is used. This method of preventing leakage of steam has proved very satisfactory, and a bush will remain tight for several years, providing ordinary lubrication is supplied, and as it is usual to feed the cylinder oil into the pipe next to the throttle valve, the spindle easily obtains ample lubrication.

Throttle valves of the piston type have been largely used, as they can be made perfectly balanced and are easy to actuate; but owing to the fact that it is difficult to adjust them when wear takes place, they have been abandoned by most builders of high-speed engines. With a throttle valve of the double-seated type the wear is automatically taken up by the governor itself, for when the weights

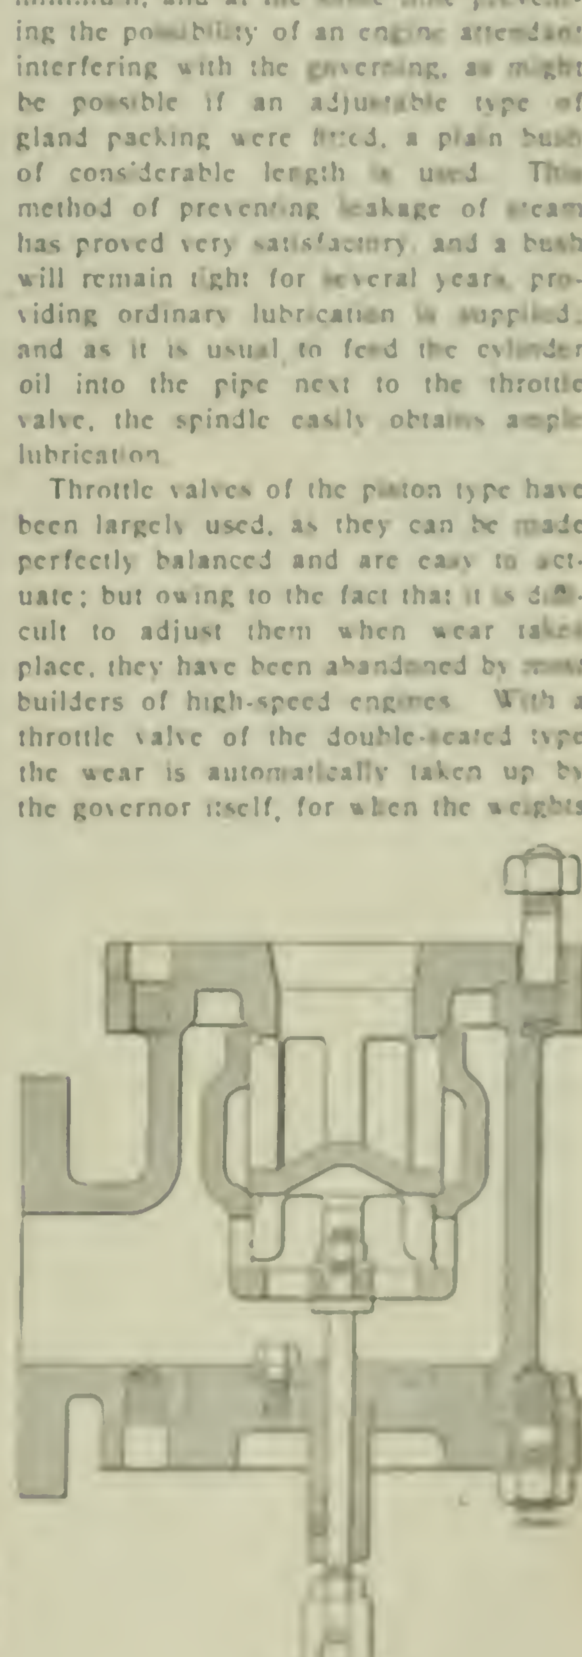

FIG. 12. DOUBLE-SEAT VALVE

are in their out position the throttle valve is forced hard on its seats, and even if it is found necessary to regrind in the valve, the governor will still bring it to its seats.

Other types of governor will be taken up in a subsequent article.

Gas Power Department

Everything worth while in the gas engine and producer industry will be treated here in a way that can be of use to practical men

A Unique Gas Power Pumping Plant

By Osborn Monnett

The city of Toledo, though rated as an important lake port, is situated so far back on the Maumee river that it is impracticable to take advantage of the lake as a means of water supply, and it has therefore gone through all the various processes of evolution common to inland cities which have to depend on river supply, such as Cincinnati, Louisville, St. Louis and others in the Middle West.

The original high-duty pumping station took water from the Maumee river at a point about one mile south of the center of the city. The equipment at this point consists of two 5,000,000-gallon Worthington compound duplex horizontal pumping engines; one 7,000,000-gallon Knowles pump of similar type and two vertical compound duplex Worthington pumping engines of 15,000,000 gallons capacity each, making a total pumping capacity of 47,000,000 gallons in 24 hours. Under ordinary conditions the water at this point in the river is moderately turbid except when it is disturbed by high wind or when the clear water has been displaced by highly turbid water from upper portions of the river. The quality of the water on the whole was not satisfactory and a plan was finally worked out of operating the original pumping station in connection with a filtration plant, using the original station, which had ample capacity, for distributing the purified water, and holding the old intake in reserve.

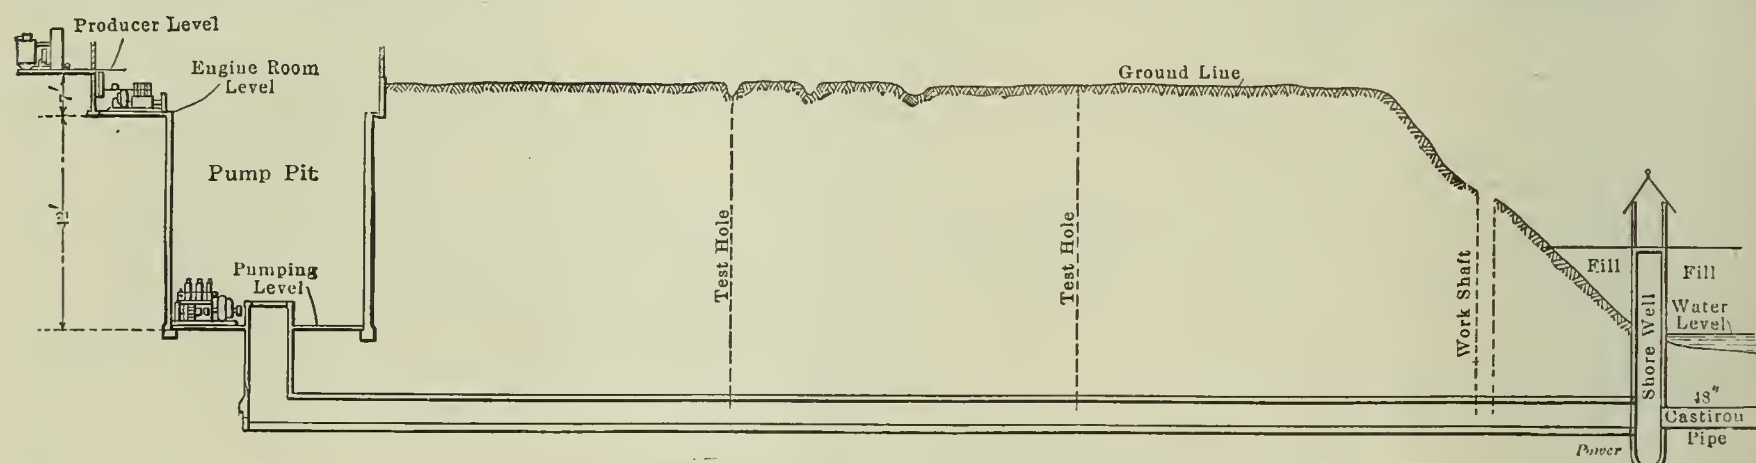

Fig. 1. Sectional Elevation of Pump Pit and Profile of Pipe Route

The filtration plant, as finally built, is located at a point 2½ miles up the river from the original station. The water is supplied to the pumps at this station through a 6-foot concrete tunnel by gravity from the filter beds. In connection with the filter plant a low-service gas-power pumping station has been installed for raising the water up to the point where it is purified. This pumping station was originally intended to be located at the water's edge, but upon investigation it was found that the difficulties of obtaining a satisfactory foundation and the danger from high water and ice gorges were such as to make it advisable to adopt another location. It was therefore decided to build the pumping station at a point about 500 feet nearer the filter plant at a considerable distance from the river, as shown in the profile, Fig. 1.

In order to deliver the water to the pumps in the new location, an intake pier or submerged crib was located approximately 800 feet from the shore toward the channel of the river. From this intake the water flows through a 48-inch cast-iron submerged intake pipe to a concrete shore well 10 feet in diameter; the bottom of this well is 27 feet below mean water level. At a level about 18 feet above mean water level is the pump floor, above which is built a concrete gate house, circular in plan. From the shore well the water flows through a 5-foot brick tunnel, as indicated, 500 feet long, to the suction well in the engine room of the pumping station.

The New Pumping Station

The pumping station proper is a steel and brick structure 65 feet wide and 180 feet long. Fig. 2 gives an idea of the layout as at present installed, with future producer and pumping units indicated in dotted lines. Fig. 3 shows the coaling arrangement. Coal is delivered at the pumping station on a siding elevated some 6 feet above the general ground level. From the cars the coal is either dumped or shoveled into a concrete underground coal bin having a capacity of approximately 250 tons. Underneath this bin is a pit which permits the coal to be drawn from the bin, crushed and delivered to a bucket elevator by which it is deposited in an elevated coal bunker over the stokers, from which point it is spouted by gravity to the charging hoppers. This overhead bin has a capacity of about 70 tons.

Two gas-producer units are in operation but the producer room is planned for a total capacity three times that of the present equipment. Each of the producers now in service is capable of gasifying 300 to 400 pounds of bituminous coal per hour, which will permit each unit to furnish gas for 300 to 350 engine horsepower or to carry a maximum load for two or three hours of 500 horsepower. The generators are of the Wood water-sealed type, 8 feet in internal diameter, with a fire-zone cross-section of 50 square feet. In connection with them are installed two vertical wet scrubbers of the ordinary type and two motor-driven rotary scrubbers which serve also as tar extractors and blowers. The generators are partly shown in Fig. 4 and one of the tar extractors is shown in Fig. 5.

The coal used is Hocking Valley bituminous washed pea, which costs $2.30 per ton delivered at the plant. Up to the present time there has been no attempt to utilize the extracted tar for fuel purposes and considerable thought has been

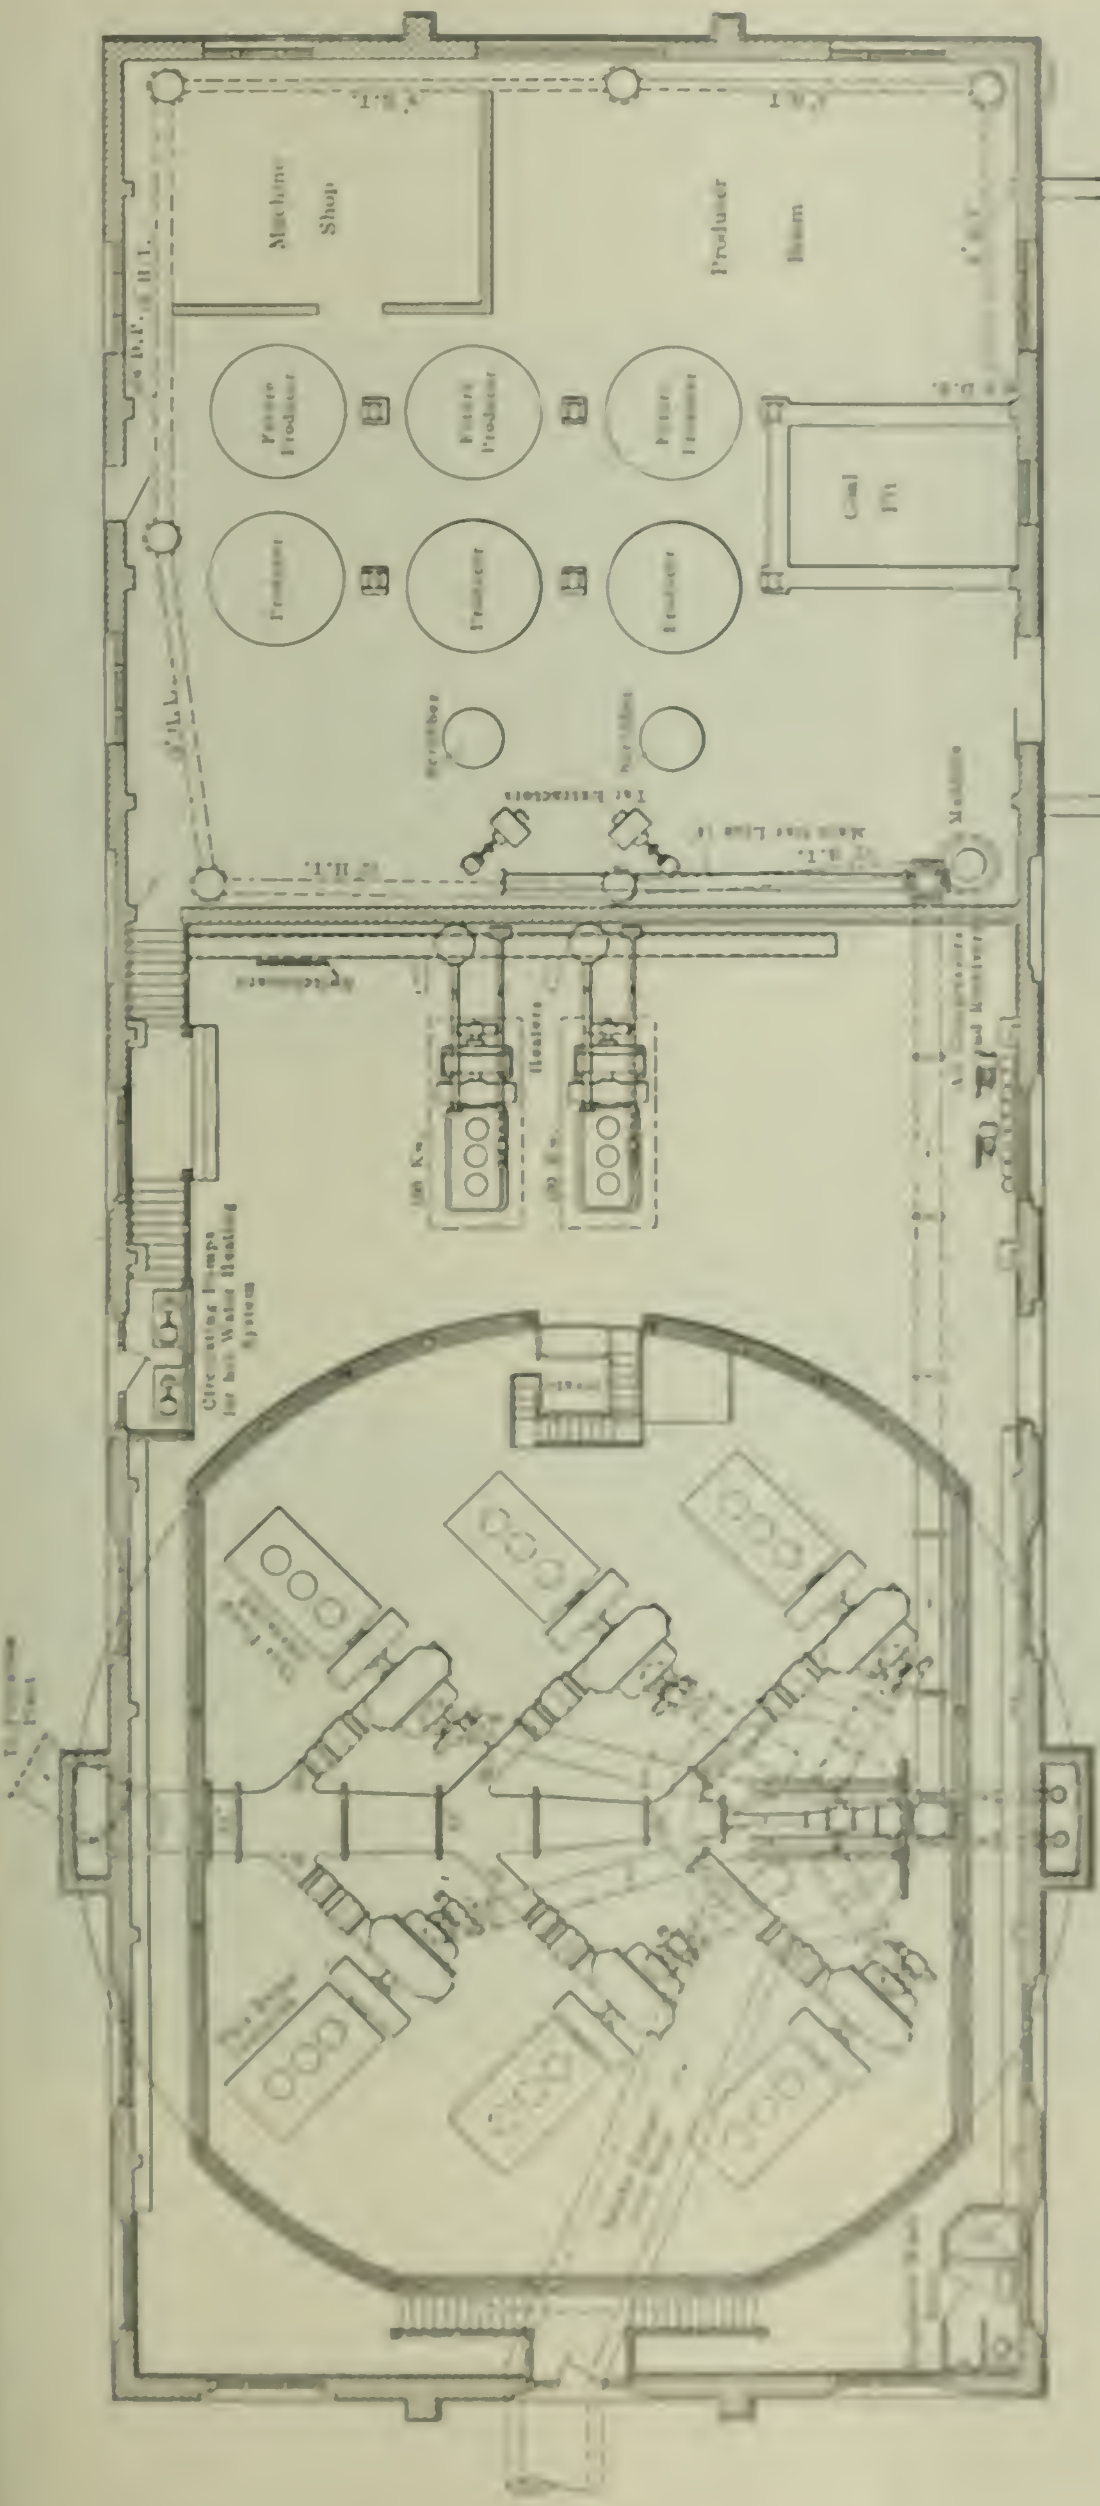

Fig. 2. Layout of the Gas-power Pumping Plant of the Toledo Waterworks

given to the problem of disposing of this byproduct in the most economical way. The method finally adopted and successfully employed at the plant at the present time is to catch the tar discharged from the rotary scrubbers in a water-sealed sump and pump it from there into a storage tank outside the building; from this tank it can be conveniently loaded by gravity into tank cars for shipment. The pump used for transferring the tar from the sump to the tank is a Marsh pump of special design, driven by steam from a small vertical auxiliary boiler. A ready sale for the tar thus produced has been found, its use being principally for paving material. The purified gas passes into a main header 20 inches in diameter which extends out over the pump

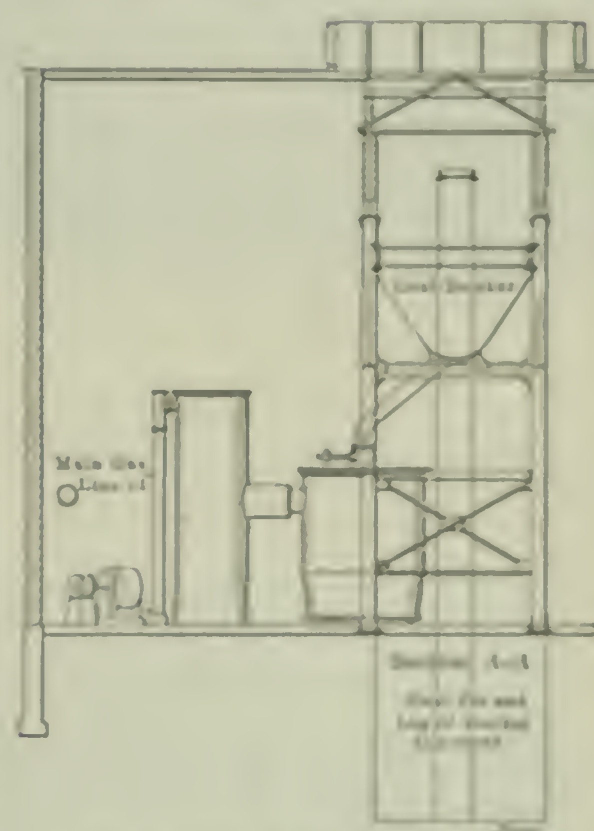

Fig. 3. Coal-handling Scheme

pit on one side and leads to the engines below. In the construction of this header precautions have been taken to provide for the cleaning of any tar deposit, all angles being provided with cross fittings, enabling the pipe to be cleaned from either direction.

The floor of the machinery room, which occupies the easterly 115 feet of the building, is located 7 feet below the level of the producer-room floor and is in part occupied by a circular pump pit 75 feet in diameter and 42 feet deep below the engine-room floor. On the main floor of the machinery room are located two 100-kilowatt generating units consisting of Buckeye three-cylinder vertical gas engines direct connected to General Electric direct-current dynamos which deliver current at 230 to 250 volts (Fig. 6). These units furnish electric current for lighting and a variety of power purposes throughout the pumping plant and the filtering plant, including the operation of the rotary scrubbers and a number of electrically operated valves, in-agent mixers, etc., in the other part of the works, and an electric elevator in the pit.

Waste-gas Heating System

One of the interesting details of this plant is the arrangement for heating it with the exhaust gases of the engine. It

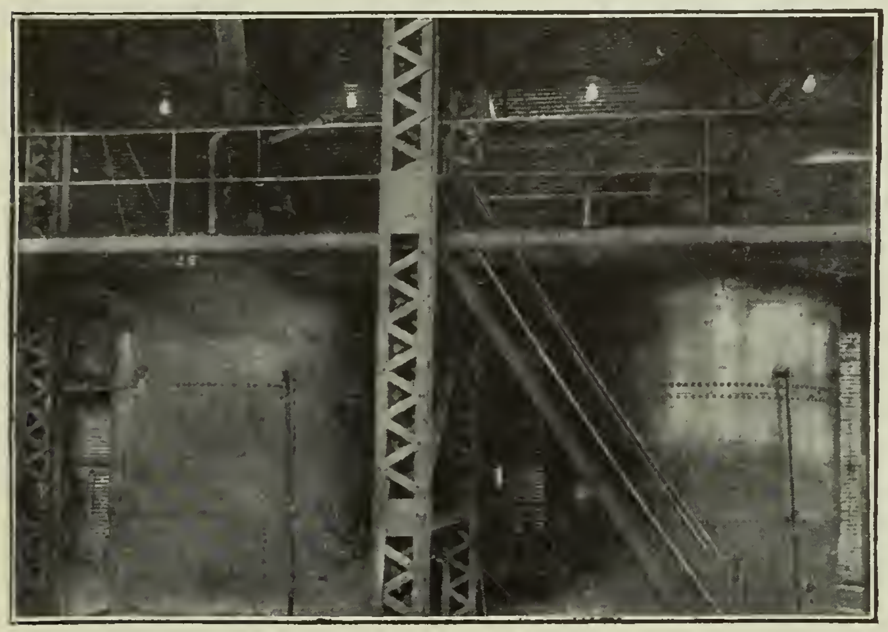

Fig. 4. Upper Part of Gas Generators

Fig. 5. Motor-driven Tar Extractor

was originally intended to install in the pumping station two 80-horsepower horizontal return-tubular boilers to furnish heat for the buildings and steam for operating some of the auxiliaries. On investigation, however, it was found that the waste heat from the gas engines would be more than sufficient to accom-

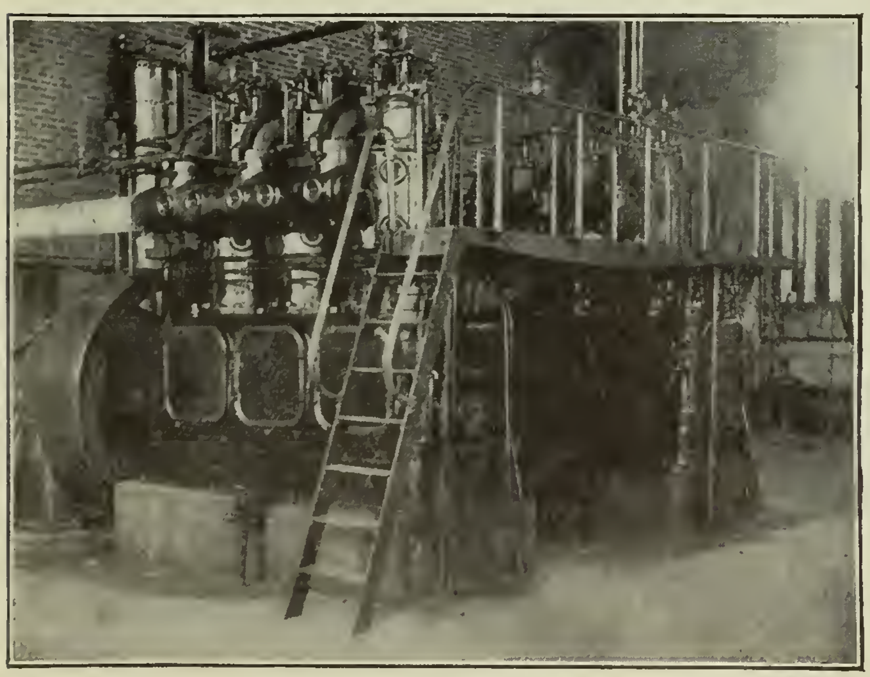

Fig. 6. The Electrical Units

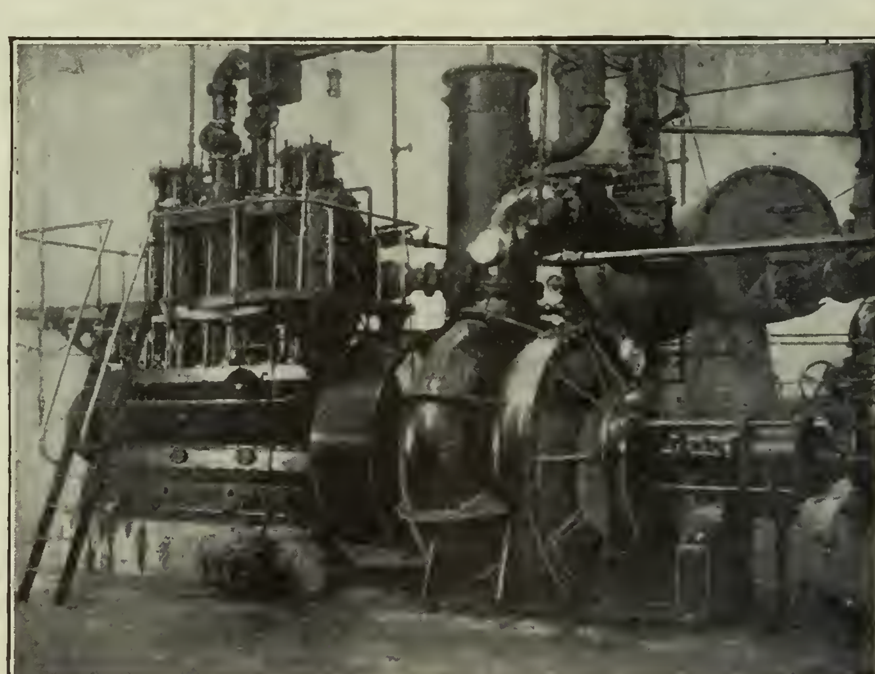

Fig. 7. A Pumping Unit

plish the heating. The method whereby this was accomplished is as follows:

The jacket water from the cylinders of each engine goes to a vertical heater through which the exhaust from the engine is passed. The heaters, one of which is installed for each of the four units, consist of ordinary tubular construction similar to a vertical boiler, with the bottom corresponding to the fire box inclosed to receive the exhaust gases, which pass up through the tubes and out at the top. This muffles the exhaust very effectively and furnishes water at a temperature of 210 degrees Fahrenheit. This water passes through an ordinary system of pipes and radiators heating the different buildings and returns to be again passed through the jackets of the cylinders, heater, etc.

To provide for a proper circulation of the jacket water there have been installed two electrically driven turbine pumps. The water returns to the low-service pumping station from the heating system at a low pressure, which is increased to about 40 pounds by the circulating pumps; this is enough to force it through the jackets, heaters and radiating system and return it to the circulating pumps. The flow is controlled by a hand-operated valve between the circulating pumps and each engine. A thermostat and valve operated by it are located near where the water passes into each jacket and the thermostat is adjusted so that if the temperature of the water entering the jacket should rise above the predetermined temperature, the thermostat valve will open a connection to the mains, where the pressure is about 60 pounds, and admit sufficient water to reduce the temperature of the water entering the jackets to this predetermined temperature. When the heating system is not in use in the summer, water from the mains passes through the jackets and heaters and is wasted.

Pumping Equipment

The main pumping engines, shown in Figs. 7 and 9, are located at the bottom of the pump pit and take their suction from the 12-foot well, as indicated in Fig. 2. These units consist of Rathbun three-cylinder vertical engines, with 20x20-inch cylinders, direct connected to two-stage Wood centrifugal pumps, which have a rated capacity of 15,000,000 gallons of water in 24 hours. There is at this point a maximum variation of about 25 feet in the water level of the river and the intake tunnel is provided with a throttle valve, operated by hand, for preventing the suction well from overflowing. The water from the two pumping units is discharged through a check and hydraulically operated stop valve into a 54-inch main riser, from which it is taken to the filtration plant.

FIG. 8. EXHAUST HEATERS

The engines of these units, as well as those of the electrical units, are of the standard construction regularly used by the builders, but they embody a new valve gear which has not been described in POWER. A lay shaft is located in the crank case and on this shaft are mounted two eccentrics for each cylinder, one to operate the inlet valve and one the exhaust valve. These eccentrics operate, through bored crosshead guides, the push rods which actuate the valve mechanism; the latter is all on top of the cylinders and in plain sight of the operator. Make-and-break ignition is used; the current is supplied from storage batteries which are charged from the dynamos.

In addition to the pumping units there is an auxiliary motor-driven centrifugal pump, having a capacity of 5,000,000 gallons per 24 hours. The motor is arranged to take current from the generators above, enabling them to supply some of the pumping energy in case of necessity.

FUEL ECONOMY OF PLANT

The output of the pumps is measured by means of a venturi meter in the main discharge line and the coal is accurately weighed as it is fed to the producers. Through the courtesy of D. H. Goodwillie, superintendent of filtration, it is possible to present the running results for August and September, 1910, a period of 61 days, under average conditions. The coal consumption was 694,700 pounds and the total output was 560,837 brake horsepower-hours. This gives a record for 61 days of 1.24 pounds of coal per brake horsepower-hour. The coal figures represent the total fuel used for all purposes, including standby losses. The proximate analysis of the coal was as follows: Fixed carbon, 50.25 per cent.; volatile combustible matter, 37.32; sulphur, 0.93; moisture, 5.73, and ash, 6.70 per cent. The heat value was 13,200 B.t.u. per pound of coal as used.

In interpreting the results of this run it must be understood that the volume of water being pumped did not provide full load on both of the pumping units; one of them had to be run on a load considerably below its rating, which would naturally lower the efficiency of operation.

The Diesel Engine in Service

BY EDWARD B. POLLISTER

The article by G. H. Kimball in the January 17 issue, on Diesel engine operation, invites a few pertinent remarks from other operators. The article mentioned is instructive—"disadvantages and drawbacks" are not generally found described in catalogs. But do not judge a Diesel engine too hastily. All engine manufacturers have some installations that prove unsatisfactory. Some recent steam-turbine plants have required a couple of years of manufacturers' nursing to secure acceptance.

Do not forget that combustion, with a Diesel engine, takes place in the cylinder—a running jump from the boiler grates in economy. In the ordinary lighting plant of a town of 5000, clear a space say 8x20 feet in one corner, and install a 100-kilowatt Diesel unit. Close your boiler doors, cut down your force, cut out your fireman, divide your fuel bill by four. Your engineer will have plenty of time to figure out how much cheaper he is manufacturing kilowatt-hours than the city of Boston.

Take good care of the engine; there is good stuff in it. The shaft is nickel steel and probably bears the welding stamp of some expert in the Krupp works in Germany. But run it 24 hours a day except Sunday; then shut it down for five hours—that is plenty of time for inspection and adjustments. You will finally lose your skepticism, say in six or twelve months' time, with uninterrupted service. And then it is time to start the old steam plant for a few days' run. Take the cylinder heads off for the first time, take the piston out, put some new rings if needed, and spend some more maintenance money—there will be plenty in the bank by this time. Ten years of average operation of a Diesel engine should leave enough of a fair depreciation fund to replace all the working parts.

A new plant in southern Illinois, consisting of a single three-cylinder unit, operated during the first six months on 24-hour uninterrupted service, with the exception of regular Sunday shutdowns. It showed a total maintenance expense of $4.50 and a switchboard cost of 7½ mills per kilowatt-hour.

The nice thing about the Diesel engine is that it must be kept up. What percentage of 300-horsepower steam engines are regularly or even frequently indicated? You have got to check up the valves on the internal-combustion engine and even a small knock is a nuisance.

Look about a bit. Visit some Diesel plants five years old and upward. Investigate their prosperity—you will find some that are getting on well. I have done so, and without exception have heard praise of the Diesel.

FIG. 9. LOOKING DOWN INTO THE PUMP PIT

Primer of Electricity

By Cecil P. Poole

Connections of Compound Field Windings

There are two ways to connect up the field windings of a compound-wound dynamo. Fig. 86 shows the method which is generally used; it is called the "short-shunt" connection. Fig. 87 shows the other one, which is called "long-

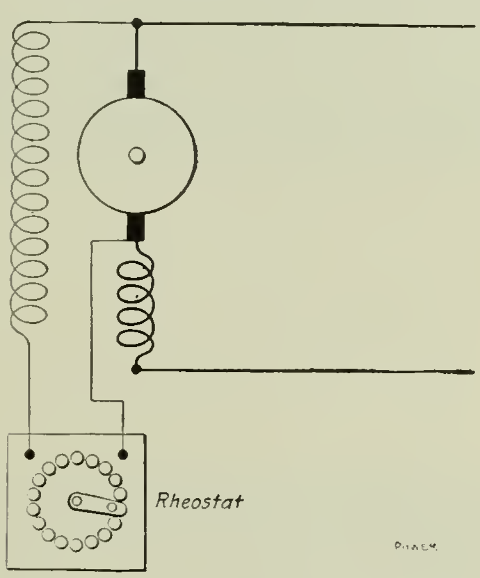

Fig. 86. Short-shunt Connection

shunt" connection. The reason for these names is that the shunt field winding is connected across the armature terminals only in one case and across the entire armature circuit in the other. In other words, the "short-shunt" connection shunts only the armature but the "long-shunt" connection shunts both the armature and the series field winding.

There is practically no preference between the two methods. A dynamo will work just as well with one as with the other if the windings are designed for the method of connection that is used.

If a dynamo built with the "short-shunt" connection (Fig. 86) is changed to the "long-shunt" connection (Fig. 87), it will not compound as it was intended to. If it is flat compounded, the voltage will be slightly less at full load than at no load, instead of being the same. If it is overcompounded, the voltage will not rise as far at full load as it was intended to rise.

The reason for this is that the voltage across the brushes is higher than it is across the brushes and series winding, because of the drop in the series winding. Therefore, with the short-shunt connection the full-load voltage at the terminals of the shunt winding is higher than it is with the long-shunt connection.

For example, suppose the no-load voltage at the brushes is 220, the resistance of the series winding is $\frac{1}{70}$ of an ohm, the full-load current 350 amperes and the full-load voltage at the terminals of the dynamo is 240 volts.

At full load the drop in the series field winding will be

$$\tfrac{1}{70} \times 350 = 5$$

volts, and the voltage at the brushes will be

$$240 + 5 = 245$$

volts. Therefore, if the shunt winding is connected to the brushes, it will get 245 volts, but if connected to the outside terminals of the dynamo, it will get only 240.

For the reason just explained, if a dynamo originally built for long-shunt connection should be changed to the

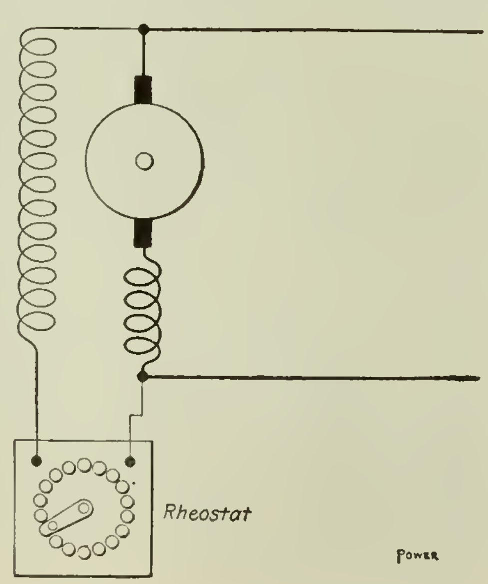

Fig. 87. Long-shunt Connection

short-shunt connection it will give a higher full-load voltage than it was intended to give.

Worse still, if the drop in the series winding is unusually high, changing a compound-wound dynamo from long-shunt to short-shunt may cause the shunt field winding to overheat because of the higher full-load voltage. As a general thing, however, the drop in the series winding is so small that neither the difference in full-load voltage nor that in the heating is of much importance.

Since the full-load voltage at the terminals of the shunt field winding is higher with the short-shunt than with the long-shunt connection, the series field winding does not need to supply as large a proportion of the total field excitation when the short-shunt connection is used.

For example, take the machine described in the last lesson. The no-load voltage was 220; full-load terminal voltage, 232; full-load current, 350 amperes; drop in the armature, 5 volts; drop in the series field winding, 3 volts; no-load ampere-turns per field-magnet pole, 7500;

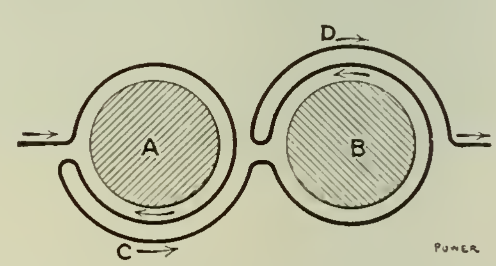

Fig. 88. Effect of Coil Connections

full-load ampere-turns, 8700. These figures supply the following comparison:

	Short-shunt.	Long-shunt.
No-load volts at shunt-winding terminals	220	220
No-load ampere-turns	7500	7500
Full-load volts at shunt-winding terminals	235	232
Full-load ampere-turns in shunt-winding	8011	7909
Total ampere-turns needed	8700	8700
Ampere-turns to be supplied by series winding	689	791

This comparison is not strictly accurate because the resistance of the series field winding would be slightly less in the first case than in the second, but it illustrates the principle well enough.

Adjusting the Compounding

In the comparison just given, the series field winding was expected to give at full load 689 ampere-turns in one case and 791 in the other. Now, these figures were taken from a machine that delivered 350 amperes at full load, so that in order to get exactly 689 ampere-turns from a series coil it would have to be made with

$$\frac{689}{350} = 1.9686$$

turns, which, of course, is absurd. If two turns could be put in the coil, it would have 700 ampere-turns at full load instead of 689. This would be slightly too much, but in practice it would be considered close enough. However, it is impracticable to get a whole number of turns in one coil of a field winding when there are two or more coils in a row, all connected together. You can get 1½ turns, 2½ turns, 3½ turns, and so on, but not 1, 2, 3 or 4 turns per coil, unless an inconvenient method of connection is used, and not always even that way.

The reason that each coil will usually

FIG. 89. MAGNETIC EQUIVALENT OF FIG. 88

have half a turn extra will be made clear by looking at Fig. 88 closely. This shows the arrangement of one-turn coils on two magnet cores, *A* and *B*, and their connections. It is evident that the current in the connection *C* neutralizes the current in that half of the *A* coil next to it. Also, that the current in the connection *D* similarly neutralizes the current in the half of the *B* coil beneath it. The result is exactly the same as though the poles were wound each with a half-turn, as in Fig. 89. This neutralizing of half a turn of the winding by the connecting lead almost always occurs when the coil has a whole number of turns in it. Therefore, the effective number of turns is ½ turn less than the whole number.

Now to return to the problem in hand. With 2½ turns per coil 350 amperes will give

$$2\tfrac{1}{2} \times 350 = 875$$

ampere-turns, which is far too much excitation for either case. The remedy is to reduce the current in the series winding and this is done by means of a "shunt" strip connected across the terminals of the series winding, as shown in Fig. 90, where the shunt strip is represented by the zig-zag line at *S*.

With the machine connected up short-shunt fashion, the series winding is to give 689 ampere-turns per pole. With 2½ turns per pole, therefore, the current in the winding must be reduced to

$$\frac{689}{2\tfrac{1}{2}} = 275.6$$

amperes. To do this, the shunt strip must carry 350 − 275.6 = 74.4 amperes.

Now the relative resistances of two parallel conductors are exactly the same as the relative currents flowing through them, though the larger current flows through the smaller resistance. Since the ratio of currents in this case is

$$\frac{275.6}{74.4} = 3.704$$

the ratio of resistances must be the same, thus:

$$\frac{\textit{Resistance of strip}}{\textit{Resistance of winding}} = 3.704$$

and as the resistance of the winding is 0.0086 of an ohm, the resistance of the strip must be

$$0.0086 \times 3.704 = 0.03185$$

of an ohm.

Let us see how this proves up. With 0.0086 of an ohm resistance in the series winding and 275.6 amperes going through it, the drop at the terminals will be

$$275.6 \times 0.0086 = 2.37$$

volts. And with 0.03185 of an ohm in the shunt strip 2.37 volts at its terminals will cause

$$\frac{2.37}{0.03185} = 74.4$$

amperes to flow through it, which is the required proportion of the total current; 74.4 amperes in the strip and 275.6 in the winding make

$$275.6 + 74.4 = 350$$

amperes, total.

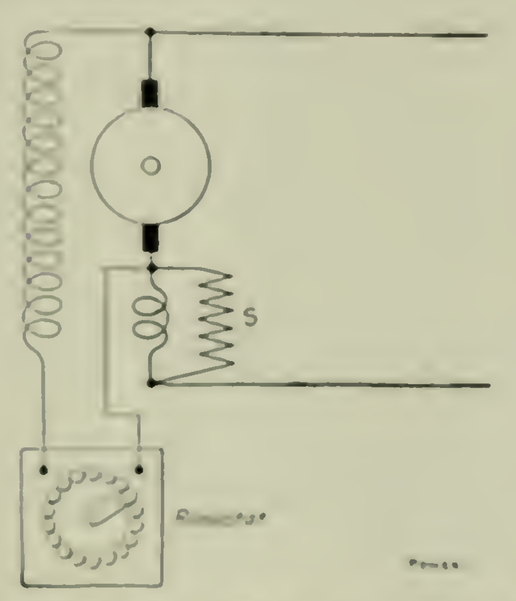

FIG. 90. SHUNT STRIP CONNECTIONS

The case of the long-shunt connection would be figured in the same way, except that the current through the series winding and its shunt strip will be the full load 350 amperes plus the current in the shunt field winding. Thus, to get 791 ampere-turns with 2½ turns in a coil, the current must be

$$\frac{791}{2\tfrac{1}{2}} = 316.4$$

amperes. Suppose the shunt field winding takes 9 amperes; then the total armature current will be 359 amperes, of which 316.4 must go through the series winding, leaving 42.6 to go through the strip.

The ratio of currents is

$$\frac{316.4}{42.6} = 7.43$$

and the ratio of resistances must be the same. The strip, therefore, must have

$$0.0086 \times 7.43 = 0.0639$$

of an ohm resistance. With 42.6 amperes flowing through this resistance the drop would be

$$42.6 \times 0.0639 = 2.72$$

volts, and this voltage at the terminals of the series winding will force through it

$$\frac{2.72}{0.0086} = 316.4$$

amperes, which is the desired current value.

This last case is not presented with strict accuracy because it was assumed that the drop in the series winding would be 3 volts; the calculation shows that it would be only 2.72, and the shunt ampere-turns would therefore be greater, necessitating fewer ampere-turns in the series coil.

In order to make the results check with each other numerically, a good many more decimal places have been used than are necessary in practice. With the actual machine the shunt strip for short-shunt connection would be figured about this way:

Ampere-turns desired, about 700; amperes necessary, about 280, leaving 70 amperes to go through the strip; current ratio about 280 ÷ 70 = 4; strip resistance, about 4 × 0.0086 = 0.034 of an ohm. A strip having about 0.05 of an ohm would be selected and the active length of it would be reduced by attaching one lead to a point within the length of the strip instead of at the end. Fig. 91 illustrates one way in which this is done. One end of the shunt strip is bolted to one terminal block of the series field winding, commonly referred to as the "solid terminal," and the strip is clamped to the other terminal of the series winding at a point which depends on how much resistance is desired.

If more current is needed in the series winding, the clamp is loosened and the end of the strip pushed inward so as to

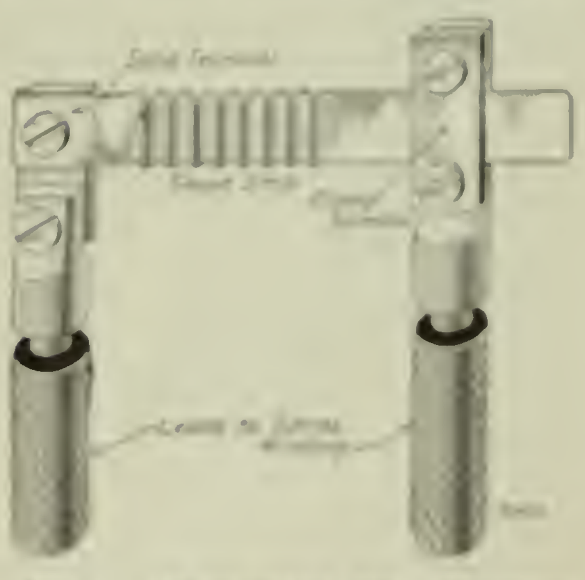

FIG. 91. ARRANGEMENT FOR ADJUSTING SHUNT STRIP

increase the length of strip between the terminal blocks. It is "crimped" to allow this sort of adjustment. Reduced to a few words:

Increasing the active length of the shunt strip increases the effectiveness of the series field winding and, therefore, makes the voltage higher at all loads; this is true for both short-shunt and long-shunt connections.

LETTERS

Static Electricity around Printing Presses

I notice in your January 24 issue an inquiry by A. W. Fish regarding static electricity around printing presses; and I have to offer the following suggestion, which has, in at least two cases, solved the difficulty:

Static electricity is generated usually by friction on the paper and about the press and its parts, and usually during dry, cold weather or cool weather. It is not found to any great extent during damp weather, and this should offer a key to the solution. Most printing establishments are heated either by water or steam, and no arrangement is made for keeping the air moist. My suggestion is to place pans on the steam or hot-water radiators, filled with water, these pans being rather long and deep rather than broad and shallow, so as to hold a considerable amount of water. If the room is a large one, with radiators or coils around the sides, it may be necessary to use artificial means such as small fans for distributing the moisture from the pans around the room. It may require some simple experiment to determine the proper amount of surface to be given to the pans in order to completely eliminate the trouble. The theory of this is that the moisture in the air will allow the dissipation of the frictional or static electricity as fast as it is formed, the moisture acting as a carrier.

I would suggest that it be made the duty of one man to see that these pans are constantly supplied with water, and that the pans are located over coils that are constantly kept in service. If the building is heated by means of hot air from an ordinary furnace, hot-water pans should be installed in the air ducts so that the heated air will pass over them and pick up sufficient moisture to produce the same results.

This expedient has been tried and proved successful in a number of instances. I should be pleased, however, if Mr. Fish would let us know through the columns of POWER what results he obtains if he should try it.

HENRY D. JACKSON.

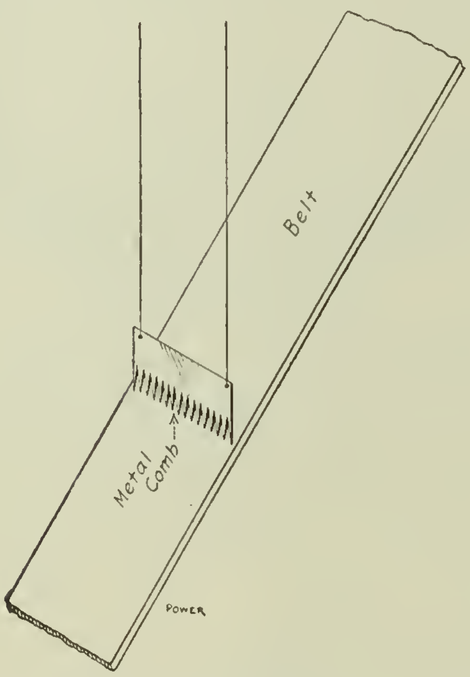
Boston, Mass.

Referring to A. W. Fish's question on how to overcome static electricity around printing presses, I would suggest a method that I found to be of great help to me. Tie one end of a piece of wire to a metal part of the press and attach the other end to any pipe that is grounded, such as a gas or water pipe, preferably the latter. This will enable the electricity to pass off to the ground, just as the ground connection of a lightning arrester takes static discharges off an outdoor line.

EUGENE M. HILBERT.

East Rutherford, N. J.

A simple and efficient method of overcoming static electricity in belts or other moving devices that cannot be easily grounded is to suspend a strip of metal, one edge of which has been cut to form a number of points somewhat like the teeth of a coarse comb, a short distance above and crosswise of the belt; the comb is hung on wires which are grounded to any convenient object, such



TAKING STATIC ELECTRICITY OUT OF A BELT

as a water pipe. I should think this would work also with the paper on a printing press.

EARL F. POTTER.

Urbana, Ill.

A homemade "neutralizer" which I have used with success consisted of an automobile induction coil with one secondary terminal grounded and the other terminal connected to a homemade "comb" mounted with its teeth close to the paper passing from the press; the coil was supplied with primary current from a low-voltage "Mazda" transformer connected to the 110-volt alternating-current lighting mains. I short-circuited the vibrator of the induction coil because with alternating current it was not needed and the coil worked better without it. The grounded secondary terminal of the coil was connected to the water pipe and the frame of the press was similarly grounded. High-tension cable of the kind used on automobiles was used to connect the other secondary terminal to the comb.

The comb consisted of a piece of ½-inch brass pipe to which were soldered brass pin points in a single straight line, spacing them about ½ inch apart along the pipe. The comb was mounted on brackets attached to the press frame in such a way that the comb extended at right angles across the sheet of paper, the pin points projecting to within ¼ inch of its surface. Heavy fiber sleeves and washers were used to insulate the comb from its supports. If the discharge from the points is visible, it is liable to set fire to the paper, and the voltage applied to the primary of the coil should be reduced until no sparks can be seen.

S. H. HARVEY.

Hamilton, O.

Static electricity in printing presses may be partially removed by grounding the frame of the press and stretching copper wires along the side of the fly-sticks upon which the paper travels after leaving the cylinder. If the press has automatic jogger boards they may be lined with metal and grounded. This practice proved more successful in my experience than the electric neutralizer, which is expensive and hard to maintain. The draw sheet may be frequently wiped with a rag wet with glycerin, although some pressmen prefer a "dope" made of glycerin two parts and nitric acid one part, which is rubbed over the draw sheet after the mixture has cooled.

It is claimed that this mixture does not swell the packing as much as pure glycerin. In any method so far in use, the electricity is removed only on the press, the sheets again being charged when fed into the folders, where we have no means of removing the electricity

THOMAS H. WATSON.

Chicago, Ill.

Tinsel cord so placed that each sheet of paper is brushed by it as it passes into the press and another piece of cord where the paper comes out will carry off the static charge. This cord must be connected to the metal frame of the press or to some other good ground. When the static manifestations are particularly troublesome it may be necessary to discharge both sides of the sheet of paper in this manner.

This method of getting rid of the static charge is an old one. It operates upon the same principle as the copper comb so often used in drawing the static charge from moving belts, and if desired a comb may be made for use on the printing press. The easiest way to do this is to take a piece of heavy copper wire sufficiently long to reach across the press and fasten to the frame; strip the insulation from a piece of old lamp cord and cut it into lengths of about four inches or less, as required; solder these to the heavy wire and spread the free ends to form "combs," arranging them so that the sheet of paper passes under them.

A. D. WILLIAMS.

Practical information from the man on the job. A letter good enough to print here will be paid for. Ideas, not mere words wanted

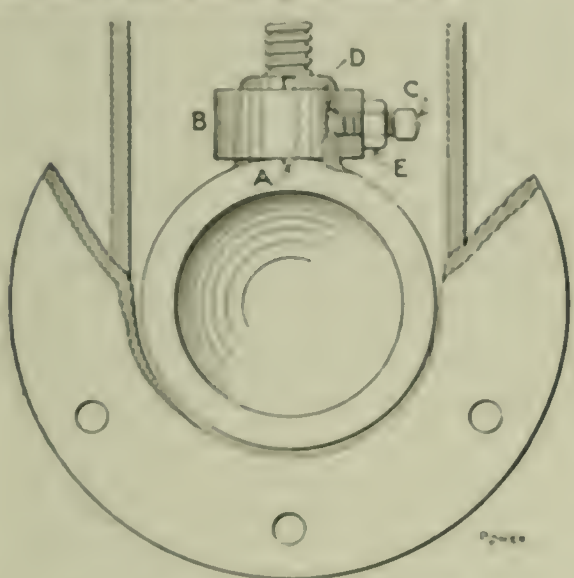
Gate Valves of the Inside Screw Spindle Type

One evening when shutting an 8-inch injection valve connected to a jet, I found that the valve spindle turned without coming to a stop.

This valve was of the straightway inside-screw spindle type and was located so that the spindle stood upright.

I removed the valve cap and found the threads on the spindle and in the plug so worn that the plug would slide over the threads on the spindle.

As the valve had to be in condition to use the next morning in order to regulate the supply of water to the pump, I made a temporary repair about as shown in the accompanying illustration.



SECTION OF GATE VALVE

With a back saw I cut a slot *A*, inserted pieces of sheet iron in the opening and then sawed down through the hub again until the cut was of the desired width.

In a box of odds and ends a collar *B* with a set screw was found. With a half-round file I tapered the hole in the collar to fit the hub on the plug or gate, and also filed a flat place *D*, on the hub, for the set screw to seat against.

After slipping the spindle into the plug, I tightened the set screw *C* against the hub, which closed it around the spindle, and to prevent the set screw from turning after being adjusted the check nut *E* was used.

When assembled, some pulverized glass and oil was put on the spindle and the plug was screwed back and forth a few times to fit the thread. This was then cleaned off and the spindle coated with graphite and cylinder oil. The valve was then put together and used until a new plug came from the manufacturers.

Experience has taught me that a valve of the outside-screw and yoke type is preferable in such places, because the thread on the spindle can be readily cleaned and oiled.

Another instance where I had trouble with a 3-inch inside-screw straightway valve was where the collar on the spindle roughed up and it was impossible to open or shut the valve. This valve was in a direct steam line, so that there was no chance for lubrication.

I took the valve apart, put the spindle in the lathe and smoothed up the collar and coated it with cylinder oil and graphite before putting it together; but fearing a recurrence of the trouble, I replaced it with one of the outside-screw and yoke type at the first opportunity.

Low Water Causes Leaks

I had the day shift in a small steam plant at a mine a little over a year ago and the way that boiler was handled by the night engineer was outrageous. In the first place, the boiler was not large enough to run the mine machinery, being of 45 horsepower and furnishing steam for a 35-horsepower single drum, direct-motion hoisting engine and an air compressor of the same horsepower.

One night I went up to the engine room and found no water showing in the glass, and the engineer was at the hoist with the throttle wide open, hoisting from the shaft. He said he could keep up steam better with low water in the gage glass. A few days later we had to shut down to expand all of the tubes in the three upper rows, and one week after I counted 27 leaky rivets.

I left soon after as I would rather run chances with men using dynamite with care than with a bad boiler and a man working in ignorance and with carelessness.

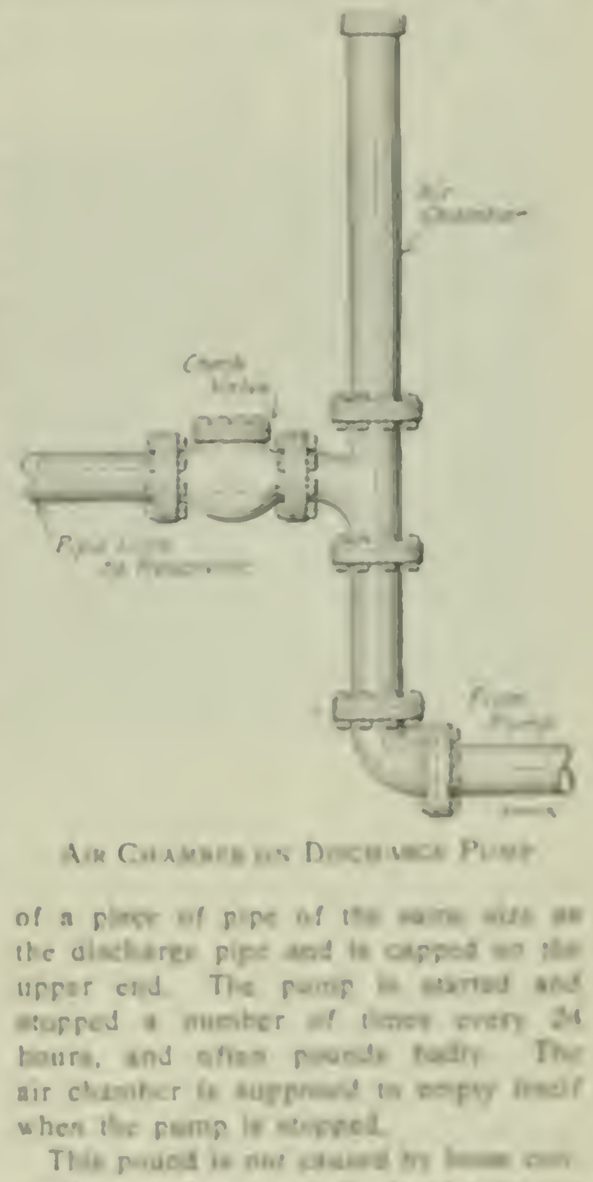
C. F. PINKNEY.

Grass Valley, Cal.

Size of Air Chamber

Can some of the readers of POWER give me any information on the comparative effects of long or short air chambers on the discharge line of a pump?

The accompanying sketch shows the discharge of a deep-well power pump, located in a pit. The discharge-pipe line runs to a reservoir on top of a hill 200 feet high and 1100 feet from the pump. The 8-inch by 8-foot air chamber is made



AIR CHAMBER ON DISCHARGE PUMP

of a piece of pipe of the same size as the discharge pipe and is capped on the upper end. The pump is started and stopped a number of times every 24 hours, and often pounds badly. The air chamber is supposed to empty itself when the pump is stopped.

This pound is not caused by loose connections, and some of the local wiseacres say the air chamber is too short; others say it is too long, and one thinks an air pump is required to force air into the top of the chamber.

Does good practice fix any definite relation between the diameter of the discharge pipe and diameter of the air chamber; between the diameter and length of the chamber, or between the length of chamber and the pressure in the pipe line? Has a long air chamber any advantage over a short one? What is the effect of a small inlet, as usually seen in cast-iron chambers?

F. A. DOW.

Niles, Cal.

Steam Plant Repairs

Some years ago I was called upon to repair an old whale-back Corliss engine that had a very bad pound, apparently in the crank. The valves had been reset a short time before in an attempt to stop it, but to no purpose. A new cylinder had been put on a year before, so I looked for trouble there. Upon lining up, it was found that the cylinder was ¼ inch too thick from the center line to the side where the bed bolted on, and although the crosshead and crank were in

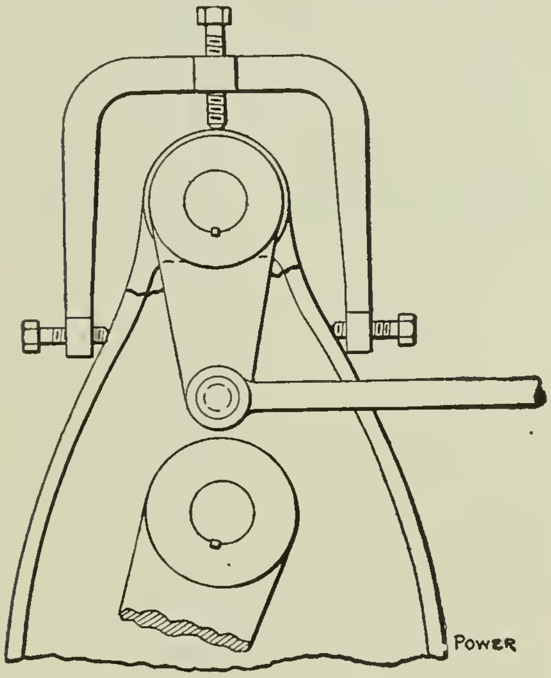


Fig. 1.

line the cylinder was out. This was one of the get out of it cheap cases, so ¼ inch was taken off the front side of the crank-pin box in a lathe and a like amount pinned on the back.

To bring the crosshead in line was more work, but was done by taking the babbitt out of the shoes, and putting the parts all in place, then pouring the new shoes with the crosshead in position. This made the babbitt thicker on the back than on the front, but put the engine perfectly in line.

A boiler feed pump in a central station was repaired as follows. This was a broken rocker-arm stand, and in looking

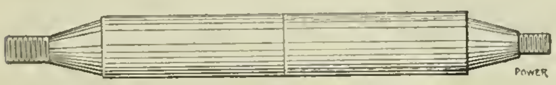

Fig. 2.

over the stock room a clamp was found with which a very good repair job was made and permitted the pump to be kept in service for some time. The two bottom set screws of the clamp, Fig. 1, were set into the casting solid before the top set screw was tightened. These three set screws held the broken part in place until a new part was secured.

In one case a large duplex pump gave a good deal of trouble with leaky packing. The rods of the water end were of steel and badly pitted on the surface. To save the expense of brass rods, I had the steel rods turned down to a forced fit for 2-inch brass tubing, Fig. 2, which was pushed on over white lead that had been smeared on the steel rods. This made a rod as good as if made of solid brass.

Medford, Mass.

Economy in the Boiler Room

A problem which every electrical-power station engineer has before him is to deliver a kilowatt-hour of electrical energy to the busbars with the least possible consumption of fuel. This may sound easy, but many times it is a problem difficult to solve.

Before an engineer is in a position to deliver electrical energy to the switchboard at a low cost, it is absolutely necessary that the installation in its entirety shall be in its best possible condition, and every precaution taken against losses which are always occurring.

In order to know just what is being done, a record should be kept as to the output of each unit and also of the coal and water used. With this in hand the engineer is in a position to seek out the losses that are taking place and determine whether they are due to low boiler efficiency, steam losses or wasteful engines, etc.

There are many electric-light and power plants operating at small profits, and there is a great field for improvement in their economical operation. A mistake made by engineers is that of letting what they think is "well enough" alone, instead of making tests and determining whether a certain performance cannot be bettered.

It is a fact that the greatest loss in all steam-generating plants is found in the boiler room; therefore, that is the place to begin an investigation as to the cause for losses.

One matter which should first engage the attention is the analysis of the fuel and also fuel gases, and a general supervision as to the condition of auxiliary apparatus, radiation, feed-water apparatus, method of firing, superheating of steam, if any, and the load factor.

A fireman, to get the best results, must know his fuel. The best results cannot be obtained, however, if frequent changing of the quality of the coal is made, and the engineer should insist that the coal from one mine should be delivered and not accept a cargo of coal from several mines. This applies, of course, where coal is bought in carload lots. It is not a bad idea to ascertain the quality of the coal by repeated tests of these carload lots. When the character of the coal has been determined in a satisfactory manner, the engineer's next duty is to make a complete analysis of the gas from the boiler, keeping a record of the temperature, draft and chemical constituents.

With this information at hand, the chimney losses may be reduced to a minimum; and a greater loss occurs right here than might be imagined. If the maximum efficiency is to be obtained, the quantity of excess air must be as small as possible, and this can only be determined by frequent tests, and generally depends upon the quality of the fuel and on the available draft. Enough oxygen should be combined with the carbon to produce CO_2, which in everyday practice with reasonable attention will be about 12 per cent. with a stack temperature of 600 degrees Fahrenheit or less. In order that this may be known, a recording apparatus should be installed for ascertaining the percentage of CO_2. Without such an apparatus it is impossible to detect air leakage, while with the device the result will be such as to more than repay for the cost. Even with a supposedly tight boiler setting, there will be air leakages which are not detected, and which may become excessive unless constantly attended to.

Any steam boiler should be kept free from scale. The scale question has been discussed so often and so thoroughly that there is little call for any extended remarks upon the subject.

After the engineer has been over his boiler plant and checked all the leakages in the brickwork, has a record of the CO_2 and has secured a good grade of coal at the lowest possible cost, it is then up to the fireman to produce better results and it is a case where the engineer must give his personal attention to the matter and see that the fireman follows out his instructions.

A desirable saving can be made if the load-factor conditions are studied. If it is such as to require banked fires, the load factor should be improved, because the effect is more pronounced in the boiler room than in the engine room, as a banked fire wastes coal. A saving can be made by reducing the number of boilers under steam and increasing the draft by some method to help out at peak loads.

All radiation should be reduced by covering all heat-radiating surfaces with some good nonconductor. In larger plants this will be found to be already accomplished, but in small power stations there is room for considerable improvement.

Ouimet, Can.

Piping a Lubricator to a Reservoir

I would be pleased to see a discussion and illustration of the best method of piping up a lubricator to an oil reservoir published in Power.

L. J. Pierce.

Ottens, N. J.

Deplorable Steam Plant Conditions

About one year ago I took charge of the mechanical department of a mill engaged in the manufacture of tin plate. The condition of the machinery of this plant had become such that the continuous operation of it was utterly impossible. Shutdowns in various departments were of hourly occurrence, due, not to the incapacity of the machinery, but to the man in charge.

The accompanying illustration shows two views of a lead gasket that had been placed in an 8-inch steam line directly over the throttle of a 30x60-inch engine. The steam line at this point made a quarter bend, and had been made too short on the end, not meeting the throttle valve by several inches.

To overcome this, the entire line had been sprung down, and the bend stretched out to meet, causing the flanges on the pipe and valve when touching on one side to stand open 5/16 inch on the other. This lead gasket had been made to fill this irregular opening. The inside has not been cut out, but a narrow slit cut through with the idea, perhaps, that the steam would cause it to bend away and leave a free opening, which it did only in part, and the cutting of the steam, as it was wire drawn through it, is shown. Full power could not be obtained from this engine, and the cause was not discovered until leakage required the removal of this gasket. A steel filler faced on each side at a proper angle made this defect right.

On this same engine the valve gear was in very bad shape, and after the valves had been set and the valve rods adjusted to length, the eccentrics were found to be keyed to the shaft (having been done since the engine was erected), and the steam eccentric was so late that the valves did not open until the piston had traveled 4½ inches. The exhaust valves were late in opening, the piston having traveled 2½ inches before this event occurred.

Alongside of this engine is another of a different make, but of the same dimensions, which worked very badly as regards steam consumption and output. The application of the indicator demonstrated the cause, and the eccentric was found, as in the other case, keyed to the shaft and was 5½ inches of the stroke late. The valve stems and bonnets showed excessive wear, although the superintendent stated that they had been bushed only a short time previous. When taken down for repairs they were found to have been bushed with steel pipe cut to length and forced in.

All steam lines leaked in every joint from the boiler drums to the engines, and in many places there was as much as 2 inches of gasket blown out. One of the flanges were found to be cracked entirely through. Upon inquiry, I ascertained that it had been the custom to sling a chain block from the steam lines to remove the engine-cylinder heads, and on at least two occasions to remove the piston and rod.

It was impossible to make the boilers develop enough steam to run the engines, consequently the management was getting quotations on a new boiler. The boilers were fired with natural gas, using one of the very best designs of burner. They had been formerly fired with coal, but it had been abandoned, as under the conditions it was impossible to keep up steam.

Gas was burned with a pressure of 16 ounces, and at times was raised as high as 45 ounces. The battery consisted of two water-tube boilers rated at 300 horsepower and one boiler rated at 250 horsepower.

All of the boiler settings were cracked, frames and castings were loose, the

Two Views of Lead Gasket

dampers were entirely removed and lying on the bottom of the connections to the stacks, bridgewalls had fallen down and were lying in the combustion chambers, checker work for breaking up the gas flames had fallen and were useless, and the feed-water discharge pipes were disconnected and lying in the steam drums.

In the larger boilers a covering of baffle brick 2 feet wide had been laid over the first row of tubes in front of the bridgewall. This was filled up by a deposit of dust and ashes solid to the top row of tubes; the baffle plates and brick linings were in a ruinous state.

In the small boiler the same condition existed in regard to bridgewall and checker work. The baffle brick had been removed over the first row of tubes for 16 inches in front of where the bridgewall should have been. The top course was more than half gone. All blowoff valves were leaking a stream as thick as one's finger. Of the three safety valves, one was in working condition, but the others were corroded fast. The steam gages registered from 10 pounds heavy to 20 pounds light. With the exhaust from 1000-horsepower engines blowing into the air, water was fed to the boilers at from 100 to 120 degrees Fahrenheit.

Included in the power equipment was a 50-horsepower gas engine. This engine was running about three-fourths of the time, the balance being taken up in starting and tinkering.

The exhaust-valve stem had worn the adjusting screw down and almost half way through the lever, causing compression of the spent gases during almost one-fourth of the exhaust stroke. The body of the gas cam was cast integral with the bevel gear for operating the governor, the hardened-steel cam being recessed into this. Probably on account of a stripped gear, at some time this cam had been replaced by a new one. The cam was keyed to the shaft, and the new cam, having its keyway planed, was put on as received and was so located that the gas valve was open on the compression stroke, and all the gas that the engine could get was by having the adjustment so that the valve continually leaked. A new exhaust valve had been made, which was only 1/8 inch larger than the seat, but this valve was worn down to within 1/16 inch of being through the seat. Making a new valve, boring out the seat and driving in a new seat ring remedied this trouble.

These are the most prominent examples among the hundreds which could be told of the conditions existing in this plant at that time.

Bellaire, O.

Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

Connecting High Pressure Drips to Heating Mains

In the issue of December 27 appears a letter from W. T. Meinzer, describing how "one of our boys" hit on a plan that worked successfully and eliminated the trouble of digging up the lawn and driveways, also the cost of 500 feet of pipe that would have been necessary to return to the boiler room the condensed water from about 15 high-pressure traps in the adjoining buildings.

I think that if he had made the high-pressure traps perform their function, there would not have been very much heating done in the sewers, no more than there would be now to help the low-pressure heating system.

Mr. Meinzer gave us a sketch showing how the pipe connections were made to accomplish the saving of the vapor from the drips. He says "This line was connected to a water seal about 4 feet deep, from the top of the seal in the inlet side. A 2-inch vapor or equalizing pipe was run to the low-pressure heating main to prevent any steam or pressure blowing the seal out into the return to cause water hammer."

I wonder why he did not think of putting in a back-pressure valve. This would undoubtedly have been more effective in preventing back pressure from blowing the seal back into the drip return. Also, it would have been more simple.

As it is now, according to his sketch, both sides of the seal are of the same hight; the slightest amount of back pressure will force the seal back into the return, it being lower than the low-pressure heating main, to which it is connected by the "vapor or equalizing pipe."

This same "vapor or equalizing pipe" will also cause a lot of heat to be wasted through condensation, or, if there be sufficient pressure in the low-pressure main, live steam will blow right through into the returns, not doing any work at all.

Mr. Meinzer fails to state for what purpose they wanted to return the waste from the drips to the boiler room. By returning the water, two purposes might be served. First, the price of the water so returned is saved; second, if the returned water is used for feeding the boiler, and the feed water be heated with live steam, a saving will be made due to the difference between the temperature of the returned water and that taken from the city main, river or well, as the case may be. In any event, I do not think that the saving in this case would justify the expenses incurred by laying a 500-foot return line and tearing up the lawn and driveways.

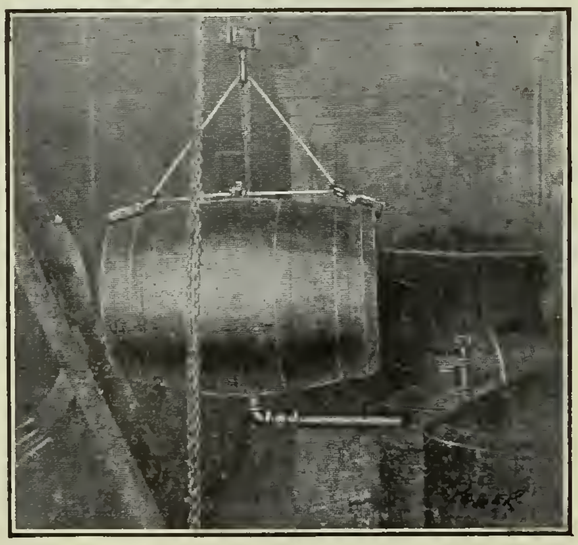
I think that if the high-pressure traps had been put in good working order, there would not have been any loss to speak of on account of letting the drips run into the sewer.

New York City. VICTOR BORM.

Barrel Emptying Device

In a recent issue of POWER there was described a device for emptying liquids from a barrel.

The idea is not a new one, similar schemes have been described before. About four years ago I tried a device like the one described on a barrel of heavy crank-case oil with unfavorable results. The discharge pipe was 1 inch and the air pipe was ¼ inch. The barrel was placed in an alleyway beside the oil tank, about 30 feet from the front of one of the boilers.



ARRANGEMENT FOR DRAINING BARREL

The air was turned on and I stepped to the tank to see if the oil was flowing. Suddenly, I heard a loud crack and a sort of slopping sound. Turning around, I quickly discovered what had happened. The air had fed into the barrel faster than the heavy, thick oil could flow out and the result was that one of the barrel heads broke. The barrel head hit the front of the boiler. Between the point where it hit and the barrel was distributed the greater part of the oil, slopped all over everything.

After that, I devised the scheme shown in the figure herewith. I had two grab hooks made with a clevis in each one. Then I ran a piece of ½-inch steel cable through them and fastened the ends. I threaded a piece of tapered pipe to fit the bunghole of the barrel. To this I fitted a 1½-inch elbow and on that a valve.

After this piping arrangement was screwed into the barrel, the barrel would be hoisted up with the chain blocks, and a piece of pipe of the right length screwed into the valve. After being hung up, the barrel required no more attention until drained out. While I do not in any way condemn the air-lift device, I think that it should be used with good judgment. The air must be admitted to the barrel very slowly, especially at the start, or the gain in pressure will burst the barrel as in the instance I described.

Glenfield, Penn. L. M. JOHNSON.

Trouble with a Heating Plant

That was interesting reading, the account of his troubles by T. H. De Saussure in the issue of January 10. I know that it must be wearing on the brain and a menace to health to have a problem like his bothering a person.

There is a question I would like to ask him, how did this water that at times filled the boilers up to the top of the water glasses get into the system? If a contractor did a job of piping for me like the one shown, I would have the law on him.

Judged as a heating system that will not work successfully, that shown in his Fig. 1 is a success. Why in the name of "Mike" did he want to have the water pocket in the return from the coils or radiators marked *X*? If he would like to know what change is necessary at the point he writes about to make the system work O. K., I can tell him. All that is necessary is to remove the pipe from the main to the return at the point *A* and take out the pocket in the return, leaving it straight.

The secret of all of his trouble is that the steam pipe has access to the return pipe above the water level in the receiver; the pocket or water seal, as he calls it, only aggravates the trouble.

GERALD GRIFFIN.

Hartford, Conn.

Belt Lacing

I read in the January 10 issue William L. Kiel's article, "Two Methods of Lacing Belts," and, while I admit that the lacings shown have a neat, finished appearance, and are fairly satisfactory when the work the belt has to do is only moderate in proportion to the size of the belt, they are anything but reliable when there is a heavy load on the belt, or where belts have to be run extremely tight, and I have found from my own experience that a much more reliable method is the hinge type of lacing.

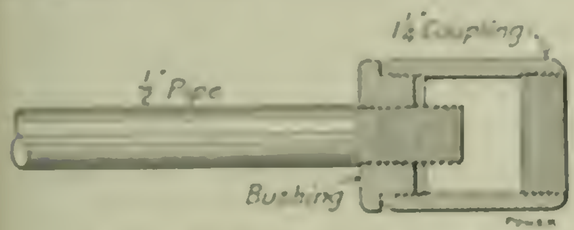
Nemours, W. Va.

Soot Blowers

I have recently read in POWER the articles by W. O. Rogers on soot blowers and suckers and I believe that a little discussion on this subject may be of interest. Mr. Rogers makes a statement that "the simplest form of soot blower is a piece of ½- or 1-inch pipe attached to a hose, and that while such a device will partly clean a tube, an excessive amount of air is drawn into the tube and that soot is blown about the room."

While the objection to having soot blown about the room is well founded, according to my understanding of the principles of soot blowers the air is not



THE HOMEMADE SOOT BLOWER

objectionable as the end in view is to secure the greatest velocity of steam and air through the tube. Therefore, there can be no excessive air; in fact, some of the blowers are so designed as to draw all the air possible into the tube and thus increase the efficiency of the blower.

A fallacy (so it seems to me) expressed in some of the designs is the apparent effort to make the steam travel along the tube surface with a greater velocity than it does in the center. This is impossible; in fact, the opposite is really the case owing to friction.

Referring to the description of the blower shown in Fig. 25, page 2145 of the issue for December 6, in the last paragraph, it is stated: "The air and steam current is directed by the inverted cone at the front end of the cleaner against the inner wall of the tube for its entire length." I believe that this cleaner would be improved if the cone were removed as the steam and air would then have a free passage to the tube surface, thus insuring the greatest possible velocity. A blower should have a steam nozzle so designed as to convert pressure into velocity and be efficient in drawing air into the tube.

I recall an experience I had with a flue blower when I was running a small plant (my first). The manager asked the engineer of a larger plant to rig up a blower for me. He made one as shown in the sketch. I tried it and not being satisfied with the results I removed the bushing and coupling and got better results; the tubes were 2 inches in diameter.

The statement by Mr. Rogers that the tubes are only partially cleaned is very true, for the blower will only remove the loose matter in the tubes and should be used as an aid to the tube scraper, not as the only means of cleaning them.

I do not agree with his statement in the instalment for December 20 that blowers fixed in the wall are as efficient as the hand blowers, because with the hand blower the steam jet is in the most favorable position to produce a strong blast through the tube, while with the fixed blower the effect is comparatively weak, owing to the distance from the tubes or to the large area of steam opening necessary to take in a number of tubes.

EARL JUBBE.

Climbing the Ladder

There have been many salary-raising and encouraging articles in POWER. None has been much superior to the leading editorial in the January 10 issue.

This feeble effort of mine is intended to help some brother engineer or fireman who is discouraged so that he will take a fresh hold of things and keep trying to "climb the ladder," the rungs of which might represent positions in the following order: Laborer, coal passer, fireman, head fireman, oiler, fourth-, third-, second-, first-assistant engineer, chief engineer, consulting engineer, superintendent, general manager and, lastly, president, who is on the top rung.

Not a few men have started from the first and attained the last position. How? The answer is given in the following, which was written by one who knew:

"Heights by great men reached and kept
Were not attained by sudden flight,
But they, while their companions slept,
Were toiling upward in the night.
Standing on what too long we bore
With shoulders bent and downcast eyes,
We may discern—unseen before—
A path to higher destinies."

What chief engineer who has come up from the ranks cannot look down along the rungs and feel that this experience or that experience has made him a better chief engineer and a better man? Who cannot remember the times he has helped other fellows solve some knotty problem in engineering or lifted other men to better positions by saying to employers, "Mr. A is just the man you want"?

WILLIAM M. GLASS.

Pasadena, Cal.

Selection and Use of Packing

I was very much interested in the communication on the "Selection and Use of Packing" in the January 3 issue of POWER by Charles H. Taylor.

I am what is considered an "old timer." When I was an apprentice, we plaited hemp for packing and with a liberal use of tallow and beeswax it answered very well. However, in these days of high-pressure and superheated steam this kind of packing would not last long. At present I am using a metallic packing and find it to be quite satisfactory. Of course, there will never be a packing to suit all engineers, for there are as many different kinds of engineers as there are packings.

J. A. EVERLY.

Thomasville, Ga.

Driving Keys

Mr. Stewart, in the January 3 number, in trying to criticize Mr. Taylor on the subject of driving keys has made the matter worse than Mr. Taylor left it.

I believe that Mr. Stewart's method of driving a key is the correct one, but his idea of the effect that the "driving" has on the connecting rod is wrong unless he refers to a type of rod with which I am not familiar.

The accompanying figure shows one

CRANK-PIN BOX WITH KEY ADJUSTMENT

type of rod in which adjustment is made with a key. It is plain that driving the key will draw the strap back on the rod. This may be continued until the box next to the key is worn in two or the key fills the space in the strap or rod.

Mr. Stewart's statement that a liner placed on the key side of the rod, that is, between the brass and the end of the rod, would have the same effect as driving the key, is incorrect for this is the best and simplest means of lengthening the rod.

I think that Mr. Stewart must have in mind a "wedge" instead of a key, but even then he is wrong in his assertion that an engine with a crank-pin key or adjusting wedge on the opposite side of the pin from the connecting rod, and the crosshead key next to the rod, has a tendency to keep the clearance equal, for a wedge has an effect opposite to that of a key.

Mease, Ky.

What Causes the Engine to Run?

Since Mr. Teer's puzzle appeared in the November 1 issue, I have been waiting for someone to solve it successfully.

Both Mr. Dunlap and Mr. Libby, in the January 3 issue, seem to have overlooked the fact that the bleeder is connected directly to the exhaust pipe. It does not look reasonable to me that the steam would turn three 90-degree angles and create a greater pressure in the end of the cylinder which is closed than it does in the exhaust unless the velocity which it attains in expanding into the exhaust pipe causes a partial vacuum, thereby creating an unbalanced condition of the piston having a partial vacuum on one side and a slight pressure from the cylinder drain on the other. In this case the vacuum created in the exhaust would have to be greater than the drain pipe which is connected to the end of the cylinder, which is open to the exhaust, would supply.

The Double Entasis

Referring to the article entitled "A Handsome Chimney," which was illustrated in the January 3 number, it is, perhaps, to be regretted that most industrial plants evidence so little of the "esthetic" or the beautiful in their construction, and, therefore, it may be that no word other than praise should be spoken of this present effort in the right direction. Still, it may be questioned whether or not a chimney top is just the place for a display of elaborate ornamentation. Do not too many frills around the mouth of a smoke vent jar upon one's sense of the eternal fitness of things, much as do the Ionic and Corinthian columns of some old-time engines and machines?

The top of a chimney seems to require some relief from straight-line severity, but the more simply its lines can be given a graceful termination the more correct will be the design. The base of such a structure being removed from the vicinity of the smoke offers a more fitting place for ornamentation than the top. Formerly, the smokestacks of most river steamboats were surmounted by a crown of pointed iron plates shaped like slender leaves of a plant; but latterly these "ornaments" are being relegated to the limbo of things that used to be, and the so called astragals which afford additional surface for the wind to blow against at the top of many steel smokestacks might well be made to follow them.

Whatever is right, looks right; therefore, anything in the nature of a sail on a chimney top must look wrong.

Wonderful people, those Greeks! And it does seem strange that after more than two thousand years we are not able to produce designs so entirely to our credit as their designs were to their credit. In the use of the double entasis the Greeks were right, as usual. In the case of a column supporting a superimposed load it is right and, of course, it looks right. But is not the building of a chimney a problem of another kind? A chimney, exposed to the wind, must act as a cantilever beam uniformly loaded, and such a beam, weaker at the point of support than at other points, is at once recognized as being faulty in design. In the trunk of a tree nature shows the proper form of structure to resist the wind; it spreads out at the base and is firmly secured to the earth upon which it stands.

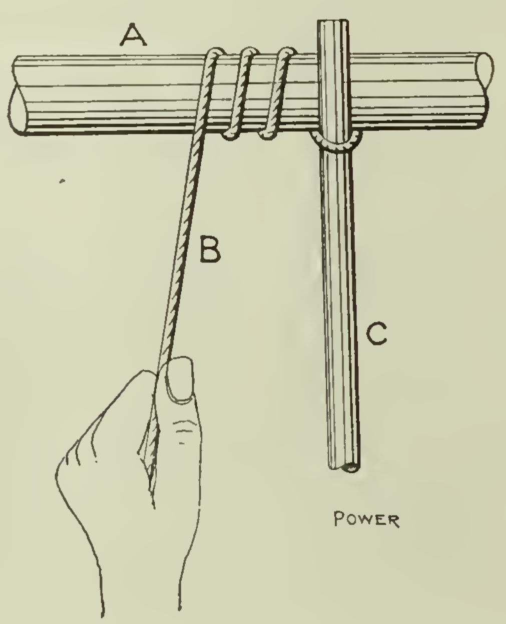
Pittsburg, Penn.

Piston Rod Clamp

In Power for January 3 I saw a suggestion for keeping a pump rod from turning while tightening or loosening the jamb nuts. I think that the set screw would have a tendency to mar the rod if not bend it.

The accompanying figure illustrates a method which I learned in California 30 years ago. The pipe or rod to be held or turned is represented at *A*; *B* is a rope and *C* is a lever. The rope has a loop at one end. The end with the loop is lapped around the pipe two or three times, or more, if need be, in the direction that the strain of the lever will be made and the end of the lever is passed through the loop as shown. The rope will grip the pipe without injuring it in any way. The fewer turns of rope there are the easier it will be to slack off to get a fresh bite with the lever. A piece of iron pipe or a hammer handle does for a lever. For polished brass or nickel-plated pipe, use webbing such as suspenders are made of or strong cloth instead of rope and a piece of cloth wrapped around the pipe where the lever touches.



Arrangement for Gripping Pipe

Causes of Boiler Explosions

A writer in a recent number of Power does not believe that a sudden reduction of pressure in a boiler will cause a lifting of the water with dire possibilities. He endeavors to substantiate his opinion by saying that boilers do not explode from a reduction of pressure due to the opening of the safety valve. I take exception to this statement. Anyone who will stop to think, will see that the opening of a safety valve does not reduce the pressure, except the amount of its pop, but prevents it from rising any higher. The safety valve allows the steam to escape only as fast as it is made, while a quickly opened stop valve lets it out faster than it is being made with a drop in pressure in the boiler if there is enough difference between the pressures of the boiler and the main. The greater the variation, the greater the danger.

I believe that the water-lifting action in a boiler under the above conditions has not reached the limit of study. I think it very possible that sheets and joints have been ruptured immediately upon the opening of a large valve, but I consider that more damage has been caused by a surging similar to that so often found in water pipes.

To understand what I mean, consider a possible case. Assume that we cut in a boiler whose pressure is 20 pounds above that of the main. The drop in pressure causes a lifting of the water. This in itself is serious. If the boiler holds, the pressure is soon equalized and the water is thrown down with greater force as it has the assistance of gravity. In this way there are produced a number of hard blows which may rupture sheets, joints or pipe connections or loosen the setting. A broken pipe connection of any considerable size would without doubt be the proverbial last straw, as it would produce a drop in pressure that could not be equalized with safety. A boiler might be "punished" by a water hammer of this nature many times before it let go or it might go the first time, depending on the severity of the "punishment" and the condition of the boiler.

New Bedford, Mass.

Trouble With Steam Radiator

The reason why E. L. Morris is having trouble with the heating system described in the January 17 number is probably because the feed pipe under the floor should be falling *from* the riser tee to the second radiator. At this point a tee should be used instead of an elbow, and a bleeder or drip connected into it. The drip could be run directly to the cellar and there connected into the boiler return, or it could be run back and connected into the return riser below the ceiling. I assume that the system is for low-pressure steam.

Another mistake in the work is that only one valve is used at each radiator. In all two-pipe systems two valves should be used at each radiator. An air cock should also be placed on each radiator.

JAMES E. NOBLE.

Toronto, Ont.

If E. L. Morris will put an air-vent valve on the outlet end of the cold radiator, the steam will circulate. The cause of the trouble is that the steam drives the air to the furthest end where it is held by the supply and return pressure.

As a rule, all outlet sections of radiators are tapped for a ⅛-inch air vent.

W. H. PLOWMAN.

Philadelphia, Penn.

I noticed Mr. Morris' letter in the January 17 issue concerning a cold radiator. In his diagram, which is reproduced herewith, it will be noticed that the tee at the top of the riser is put on "bull headed," as steamfitters express it. This tee should be put on in the vertical position, that is, as shown in Fig. 2 herewith. I made such an alteration in a system of which I had charge and overcame thereby a difficulty similar to that described by Mr. Morris.

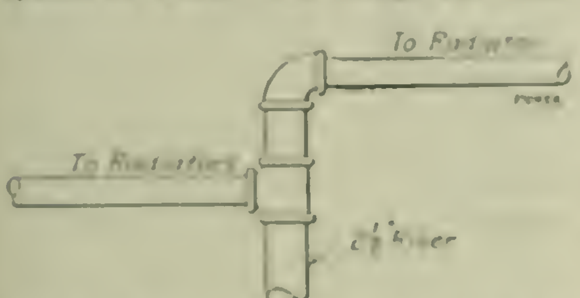

FIG. 2. REARRANGEMENT OF CONNECTIONS AT TOP OF RISER

FRANK MCCOTTIN.

Newport, Ky.

The trouble with E. L. Morris' heating system, as illustrated in the January 17 issue, is that the horizontal leads to the three radiators on the third floor are not large enough.

The central radiator evidently consumes the greater portion of the steam conveyed through the short 1¼-inch horizontal length leading thereto, while the remaining quantity, continuing along through the long lead to the left-hand radiator, condenses on the way and is practically all reduced to water by the time the valve is reached, the returning flow acting to cut down further the already insufficient capacity of the 1¼-inch horizontal pipe.

To make a serviceable job of this part of the system, both the supply and return horizontals should be run 2 inches from the 2" risers to the middle radiator, and thence 1½ inch to the left-hand radiator, with 1¼-inch vertical connecting branches to each radiator. Likewise, the leads from the risers to the right-hand radiator should be changed to 1½-inch size, with 1¼-inch branches to connect with the radiator.

A. J. DIXON.

Chicago, Ill.

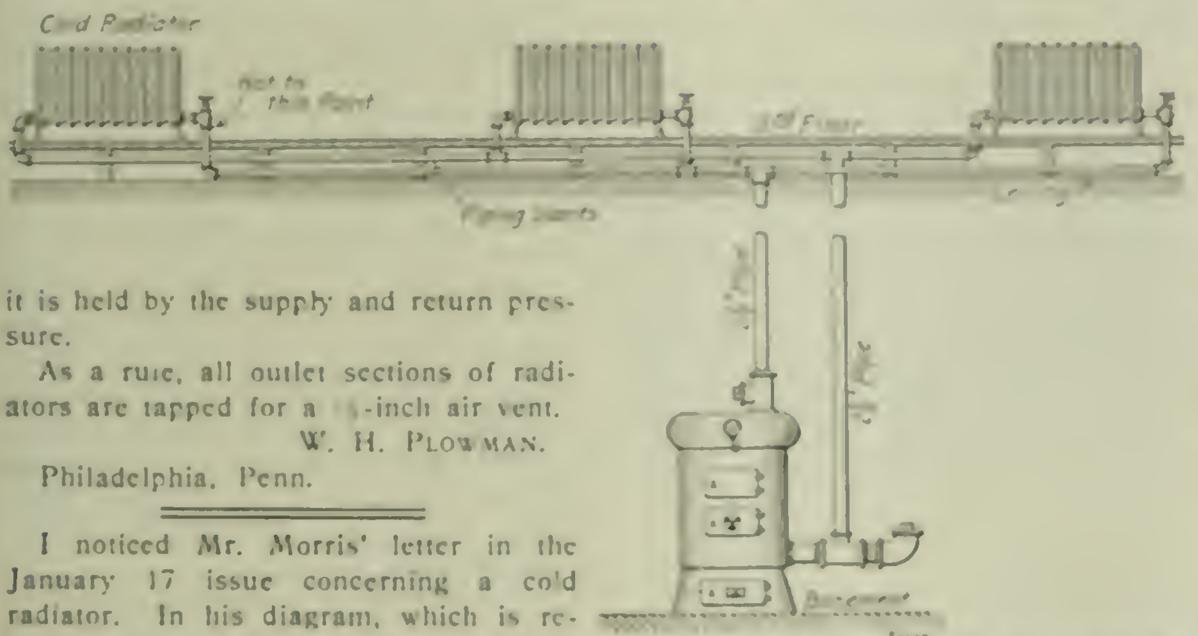

FIG. 1. REPRODUCTION OF MR. MORRIS' DIAGRAM

Cornell Fuel Economizer

I noticed the editorial in the January 17 issue regarding "Impossible Boiler Performances" supposed to have been brought about by means of a Cornell H_2O fuel economizer; and, as I have had some experience with this apparatus, I will recite some of it for the benefit of any engineer who may be curious about this device.

I once took charge of a large building having two 125-horsepower return-tubular boilers, both of which had been fitted with the Cornell apparatus just a little while before I took charge.

The apparatus was supposed to consume the smoke, giving smokeless combustion. All that it did in this line was to whiten the smoke a little by mixing steam with it. I made tests with the apparatus working and also when it was shut off and could see but little difference in the smoke from each fire.

We were instructed to stop or check the flow of steam through the jets. When we did this, condensation would gather and as soon as we opened up the jets again the jets or tuyeres would burst from the sudden rush of water. I tried draining the pipes but it did not help much. Then I removed them altogether from one boiler. We used each boiler alternate weeks. The one boiler used 200 pounds less coal in 24 hours than the one to which the "economizer" still remained, and we had no more smoke than when the apparatus was working, so I threw out the other set also. We then carried the full load, the same as before, on 200 pounds less coal per day. Hence we decided that the apparatus required 200 pounds of coal per day to supply the steam to operate it, besides the cost of renewing the tuyeres or jets, which was considerable.

ALLAN A. BLANCHARD.

Frostproof, Fla.

Fixing Receiver Pressure

I see a great many letters in POWER about receiver pressure. I have found it to be good practice to increase the receiver pressure until it causes the governor to start to drop. Then, to reduce the pressure so that the governor revolves in its highest position.

This rule is convenient for use by those who have not the use of a steam-engine indicator.

J. J. JACKSON.

Waynesburg, Penn.

Water Hammer and Boiler Explosions

I read with interest Mr. Clark's article on "Water Hammer and Boiler Explosions" in the January 10 issue.

I once had serious trouble with water hammer at a mill where there was an installation of four 60-inch by 16-foot return-tubular boilers.

The boilers were connected by a 10-inch header, out of the center of which a 4½-inch pipe led to the engine. This pipe connected into the bottom of the header, dropped about 2 feet and then ran 30 feet to the engine. Of course, this pipe drained the header and came near being the cause of wrecking the plant.

On going to the plant one morning, I found that the night watchman had closed the valve on the 4-inch header that connected into the pipe above the throttle. The pipe was cold and evidently full of water. The steam pressure was well up, ready for starting, but the safety valves were not blowing.

The first move of the header valve caused such a commotion that the fireman and one or two other persons in the plant ran out. Three or four times the violence of the surges and blows threw the safety valves off of their seats. Every time one of those heavy hammer blows came I could see the elbow on the pipe above the throttle move back and forth and quiver.

If a water hammer can cause a safety valve to rise and reset as these did, I believe it might easily cause a boiler explosion, to say nothing of pipe and fitting breakage.

Handling Men

We have been invited to give our views on handling men. There is nothing to it except giving them a square deal, a smile instead of a frown, when possible, maintaining discipline and firing shirks and grouches. I think that this covers the field or subject, though I could fill pages in elaboration of the above and still reserve the privilege of saying more.

J. O. BENEFIEL.

Anderson, Ind.

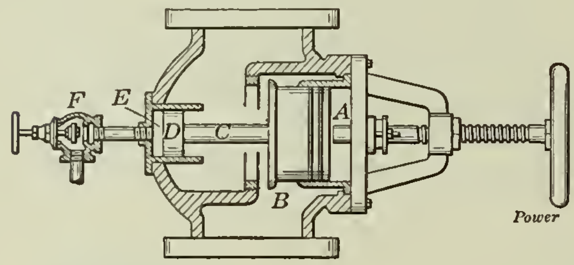
Safety Stops for Steam Engines

Under the above heading some time ago, Mr. Wakeman made some statements that according to his drawings were incorrect. For instance, he had the following to say concerning one of the numerous designs of valve described:

"Pressure acting on *B*, Fig. 3 (which is reproduced herewith), holds the valve open because the full area on the outer face is exposed to pressure, while the rod occupies a portion of the inner face, thus reducing the effective area. Etc."

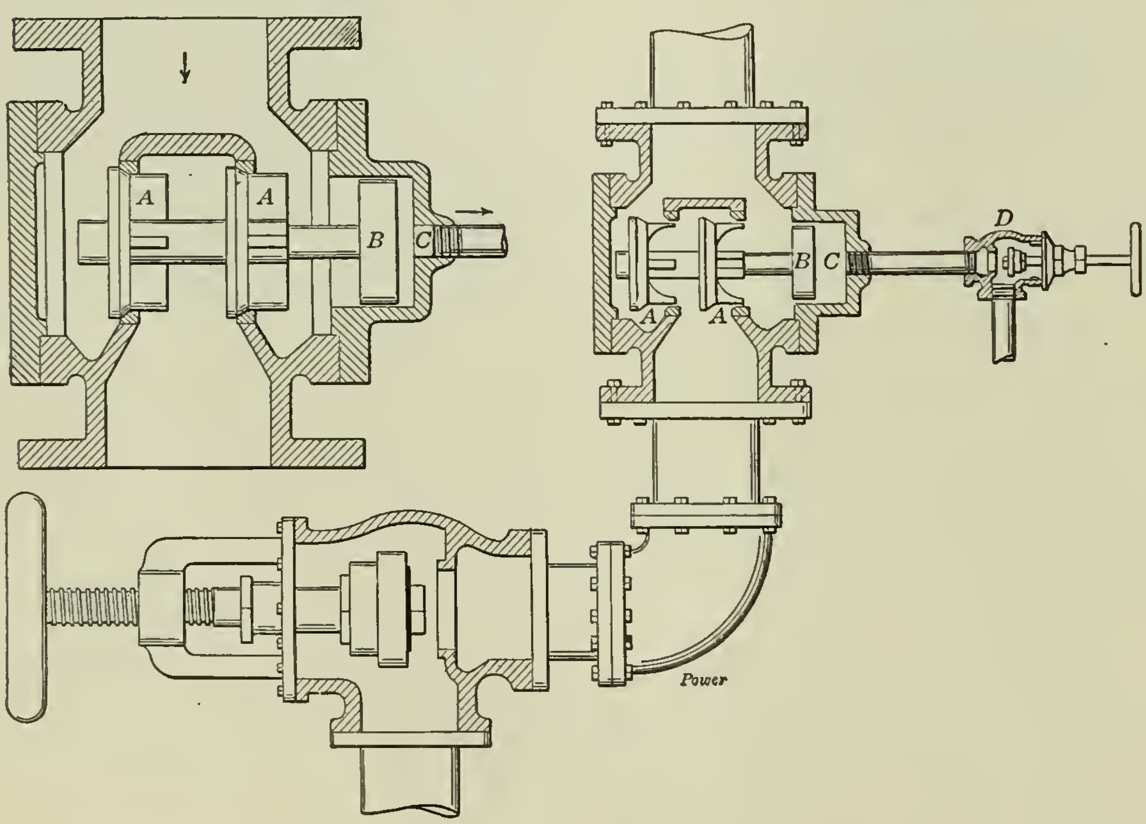
This would be the case if the stem of mechanical device has not been provided, the valve cannot be opened.

In the case of another device, shown in Fig. 7 (also reproduced herewith), he reverses the ideas worked out in Fig. 3. He says that piston *D* is in equilibrium, but the figure indicates that there is full pressure in *E* and that the stem terminates in the disk *B*, on the right side of which



REPRODUCTION OF FIG. 7.

there is no pressure at all. This arrangement gives a greater effective area at the left of *D*, than at the right. Suppose that the disk *B* is closed, pressure acts on it and *D* alike. But, as the area of *B* is greater than that of *D*, it (*B*) will follow the stem *A* to the right should the handwheel be turned from right to left. When the trip releases the pressure in *E*, the



REPRODUCTION OF FIG. 3 OF MR. WAKEMAN'S ARTICLE

the valve extended through the bonnet to the left, but the drawing shows it inclosed and therefore the end of the stem is subjected to the steam pressure. This would give equal pressure on both sides of the piston *B*, and as the main valve is balanced it would remain in any position so long as pressure was maintained in *C*. Should the electrical device act and release the pressure in *C*, the valve would close, but if there is no way of creating a greater pressure in *C* than there is in the steam main, or if some piston *D* is supposed to move to the left and close *B*.

But, as *B* is unbalanced and has to close against pressure, the piston *D* would have to be of greater area, while the figure shows that the opposite is the case and, therefore, the valve will not close. In the case of these two valves it would be interesting to hear from Mr. Wakeman as to whether the drawings or his explanation are at fault.

JOSEPH STEWART.

Hamilton, Ohio.

Weighing Small Parts Accurately

Mr. Kirlin, in the issue of January 17, describes a way of accurately weighing small parts without the use of a delicate balance. It certainly is simple and yet a method which one would be unlikely to originate himself in an emergency.

There are one or two places where I believe his method will stand simplification. In regard to the scale ratio, which is 100 to 1, I would like to ask Mr. Kirlin if he generally has his revolver handy to test the scales with. I hope not, for the sake of the poor man who might happen to dispute his weights. Also, does he generally carry a pound of tobacco around with him? Even had he the pound, or any other known weight of it with him, how many times would he find it unsampled, when he wanted to test his scales with it? I think I am safe in saying that all scale weights are marked with both their actual weight and the weight which they will balance on the scales. This, of course, gives the ratio and should be sufficient even if a man is "from Missouri." As an example, a 200-pound balance weight, with the above ratio, would have the numeral 2 under the 200 mark upon it.

With regard to weighing, assume that the ratio is 100 to 1. Suppose the article weighed approximately one pound. By Mr. Kirlin's method this would mean that we would have to hunt around for some thing or things which would weigh about 100 pounds to just balance the article. Quite a little work. And then we would still have the junk to get rid of when finished.

My method would be as follows: I would first step on the scales and find my own weight accurately, say it was 175 pounds. I would then place the article on the tray and repeat, finding my weight then to be, say, 90 pounds. Now, 175 minus 90 equals 85 pounds, which is the weight balancing my article. Then, 85 divided by the scale ratio gives me 85/100 pound as the weight of the article. Of course, if the article had been more than 1¾ pounds, my own weight would not have been enough and I would have had to have a helper or two on the platform with me.

The points I bring out are that it is not necessary to have an *exact* weight to balance the article, the balancing being done by the sliding weight on the arm, and that it is better to have a self-propelled balancing weight in these times of flying machines and automobiles.

JOHN BAILEY.

Milwaukee, Wis.

Cracking noises in steam pipes indicate that they contain water and that an explosion may occur at any moment. Such cases should be carefully inquired into.

POWER

The Pabst Boiler Explosion Decision

In the suit of the Pabst Brewing Company versus the Hartford Steam Boiler Inspection and Insurance Company, there are two important points at issue.

Does a company which undertakes insurance of apparatus, like boilers, flywheels, elevators, etc., incur liability in excess of that assumed in the controlling policy or contract, for damage from a defective condition which, it is afterward claimed, should have been discovered by the insurance company's inspector?

When several boilers explode at sensibly the same time, is it one explosion or several explosions?

The brewing company claimed that, relying upon the inspections of the insurance company, it had continued to run boilers which were defective until they exploded, and sought to collect from the insurance company, not only the damages resulting directly from such explosions, but such indirect damages as loss of business, increased cost of manufacture, etc.

Against this contention the insurance company urged that they had contracted to pay to the insured damages of specified kinds up to a certain amount, directly resulting from an explosion of one or more of the boilers covered by the policy. They had made no contract to inspect the boilers, were not obliged to inspect them, and if they did inspect them, it was only to protect their own risk, and they were not obliged to report the results of such inspection to the insured, nor liable beyond the terms of the policy for any damage resulting from their failure to make such inspections and report the results.

The court held that the liability of the underwriter was limited by the terms of the contract, or policy, and ruled out any claim based upon the alleged negligence of the company in the matter of inspections.

Any other decision would have thrown consternation into insurance companies of all kinds that maintain inspection service; for if a company making inspection of apparatus or buildings be liable, upon the establishment of negligence, for any damage which may result from the failure of such apparatus or the destruction of the buildings, one might with a $500 policy purchase immunity for any amount, and involve the entire capital of a strong underwriting corporation.

Many patrons of the boiler-insurance companies value the supervision of their boilers by the expert inspectors more than, or as much as, the guaranteed immunity from financial loss. The contention of the insurance company that it need not make such inspections unless it wants to, and is not obliged to report them to the insured, need cause no uneasiness in this respect. It was the logical reply to the contention of the plaintiff. But the only way that a boiler-insurance company can afford to take a risk is by diminishing by inspection the probability of explosion, and the insured are very sure to know the results of such inspection, especially if anything is discovered which is not just right.

The other question—what is "one explosion"—has not been so satisfactorily determined. The Pabst policy covered a battery of six Munoz boilers and was for $150,000 for three years. There had, however, been attached to the policy a "rider" or agreement, supplementary to the main form, providing that "the total liability of the company for loss or damage resulting from any one explosion shall not exceed the sum of $50,000, and in case of more than one explosion the entire liability of the company shall not exceed the sum insured by this company; viz., $150,000."

At the Pabst plant four Munoz boilers exploded at sensibly the same instant. Was it one explosion or four within the meaning of the policy?

The meaning of the policy is, or ought to be, the meaning which was attributed to it by the covenanting parties when it was drawn up and signed.

Did the man who accepted this policy for the Pabst Brewing Company understand at that time that the failure of each particular boiler constituted a separate explosion, notwithstanding a number of them should fail simultaneously and from a common cause? Do the many business men who hold policies containing this agreement (for it is by no means uncommon) consider that a single accident, involving more than one boiler, constitutes more than one explosion within the meaning of the policy?

If so, they had better have an understanding with the underwriters, for the underwriters' understanding of it is not that way.

The attachment of this rider, or agreement, to the policy very materially lessens the premium. The underwriter can take the risk for considerably less money when his liability for any one accident is limited to one-third the face of the policy. The probability of three destructive explosions within three years in the same plant is so remote that it is difficult to understand the attitude of a man who pays for such a chance, even at a reduced rate. If he is satisfied that $50,000 will cover any single loss, he would apparently be better off to take a straight policy for $50,000, and renew it, in the remote probability of his collecting it up, than to pay even a reduced premium on a $150,000 policy, upon which he can realize the face value only if he has, within the three-year period of the policy, say three to thirty explosions or tube ruptures in his battery of boilers, each causing direct damage of $5000 to $50,000 or more to persons or property. It was perhaps inability on the part of the jury to understand why a man should pay for such a policy, unless he understood the failure of each individual boiler to be a separate explosion, that led them to find for the plaintiff on this count. Notwithstanding their verdict, we think that the average disinterested engineer would regard the occurrence at the Pabst brewery as "a boiler explosion," that the underwriter has in mind in attaching the rider quoted, that he is limiting his liability for any one occurrence to the sum stipulated, and that the average business man in accepting this modified policy, at a materially reduced rate, recognizes that the stipulated sum fixes the limit of the loss which he can collect at any one time, or for any one occurrence.

Central Station Service in Public Buildings of New York City

The attitude of POWER in the strife between the central station and the isolated plant embraces neither antagonism nor sentiment; it accepts the facts purely upon an engineering basis, and as such recognizes that there is a field in which central-station service possesses advantages over the isolated plant. Nevertheless, when the agents of the former overstep the boundaries of this field and attempt to extend their business through misrepresentation of facts and juggling of figures, we feel it our duty to protest. The recent invasion of the central station upon the public buildings and plants of the city of New York calls for a careful investigation of the facts.

A consulting engineer, employed at a salary of seventy-five hundred dollars per year, to give the city expert advice, made a report—based presumably upon careful tests—relative to the cost of operating the isolated plant at the Harlem hospital. This report showed the plant to be operating uneconomically, and was accompanied by the recommendation that it be shut down and central-station service substituted. Fortunately, the report fell into the hands of those able to analyze power-plant costs and it was discovered that the consulting engineer, in his efforts to present an accurate statement of facts, had included the cost of two hundred and eighty thousand cubic feet of feed water, which, however, if based upon the amount of coal used, would have shown an evaporation of over fifty-five pounds of water per pound of coal, a rather startling figure. On the other hand, his coal consumption was estimated upon the abnormal basis of twelve and a half pounds of coal per kilowatt-hour. Needless to say, this particular recommendation was not heeded; but the fact remains that a number of other city plants have since been shut down upon the advice of this same engineer. That the city officials are beginning to awaken to this condition of affairs is shown by the resolution passed by the Board of Estimate on February 2; this was as follows:

"Resolved: That hereafter no contracts involving electric light or power equipment of any kind in the city of New York shall be advertised for or let by any branch of the city government unless the approval, in writing, of the Department of Water Supply, Gas and Electricity, of the plans and specifications for the work shall have been first obtained, and no alterations to the work as contracted for shall be ordered or approved without the written approval of said department.

"This resolution shall not, however, be deemed to authorize the commissioner of the Department of Water Supply, Gas and Electricity to prohibit or prevent the installation of generating or other electrical apparatus, provided the specifications therefor conform to the established requirements of the said department, nor shall this resolution confer upon the water commissioner any other right or power not specifiedly vested in him by the charter of the city of New York with respect to the use of electricity in any of the public buildings of the city of New York."

The Draft Gage

An instrument whose possibilities seem to have been greatly overlooked is the draft gage. Operating engineers and others who have to do with power-plant design and management will usually encourage the purchase of practically all kinds of instruments except those which will serve to make the fireman's work less a matter of guess work and judgment. And yet, beyond all other operations in the plant, the management of the boiler furnace depends on the personal element.

With a draft gage connected into the breeching at the base of the stack or beyond the damper and another connected with the furnace or first pass, and encouraged to watch the variations in the draft, the fireman should soon learn the importance of keeping the fires clean and the damper suitably adjusted.

Federal Inspection for Locomotive Boilers

The locomotive boiler-inspection bill, mentioned some time ago in these columns, has now passed both houses and will soon become a law.

The effect of the bill will be to put the inspection of locomotive boilers under the charge of the Interstate Commerce Commission. A chief inspector at $4000 a year, with two assistants at $3000 a year each, will have actual charge of the inspection service. Fifty inspectors will do the work of inspecting boilers in the field. Every locomotive boiler will be minutely and carefully examined at least once a year and also at such other times as is deemed advisable. The limit of cost of the service is fixed at $300,000 a year.

Another mysterious boiler explosion was avoided when the fireman of the boiler at the Empire laundry at Poughkeepsie, N. Y., discovered a dynamite bomb in a shovelful of coal which he was about to toss into the furnace. It consisted of a stick of dynamite wrapped in black paper with a percussion cap and fuse. If this was a gentle joke, the perpetrator ought to be dealt with under the impelling force of a conception of the possible results to the thirty-odd employees of the laundry, to say nothing of the neighbors and passers by.

There appears to be a change of policy with respect to the large gas engine. The Tennessee Coal and Iron Company, with a large amount of coke-oven gas available at its Ensley plant, has decided to burn the gas under boilers and use steam turbines rather than to use the gas in large gas engines; and the Cambria Steel Works is installing a 15,000-kilowatt turbine, the steam for which will be made in boilers fired with blast-furnace gas.

A few of us manage to carve our names on the tablet of fame, but some of us never carve them on anything more important than the plank siding of the coal bin.

Every small boy delights to blow a whistle, but that is no excuse for the engineer to play a rag-time tune every time he starts up or shuts down his engine.

"Whenever you see a head, hit it" is a good practice to follow in regard to the little leaks and irregularities in steam-plant operation.

Inquiries of General Interest

Questions are not answered unless accompanied by the name and address of the inquirer. This page is for you when stuck—use it

Safe Speed for Flywheel

How can I calculate the safe speed for a flywheel?

B. C. M.

The safe limit of rim speed of a well designed cast-iron wheel is 100 feet per second. The maximum diameter for a given number of revolutions is determined by the formula

$$D = \frac{1910}{R}$$

in which

D = Diameter in feet;
R = Revolutions per minute.

Conversely,

$$R = \frac{1910}{D}$$

High- and Low-pressure Pumps

What is the difference between a high-pressure and a low-pressure pump?

H. L. P.

A high-pressure pump is one that is used to pump against a pressure as high or higher than that of the boiler which furnishes the steam. A low-pressure or light-service pump, as it is sometimes called, is one designed for pumping against pressures below that in the boiler and the water cylinder is of a greater diameter than the steam cylinder.

Thickness of Cylinder Walls

Please give me a formula by which I can calculate the proper thickness of a steam-engine cylinder.

E. H. B.

For a good quality of cast iron

$$Thickness = 0.0004 \times Diameter \times Pressure + 0.3\ inch.$$

The 0.3 inch is added for reboring.

Hight of Suction Lift

In a well the water level is 25 feet below the surface. Will a 1½x2¾x4-inch duplex pump operate satisfactorily at this lift and discharge water 10 feet above the pump?

A. L. B.

With the pump in good working order there is no reason why the pump will not work well. The piston and the valves must be tight, as slight leaks past either will interfere with the operation. A foot valve should be placed at the lower end of the suction pipe to facilitate priming when it becomes necessary.

Compounding Separate Engines

Can two simple engines, each having the same length of stroke, running at the same speed, and both connected to the same line of shafting be run as a cross-compound engine?

C. S. E.

Yes. The cylinder diameters will, however, have a great influence on the practicability of the scheme.

Cause of Increased Receiver Pressure

In a cross-compound engine with a separate governor for each cylinder with a varying load the receiver pressure rises with a light load and falls with a heavy one. What is the cause of this and what is the remedy?

I. R. P.

The range of cutoff on the low-pressure cylinder is too long. The cutoff is too short on light loads and may be too long for heavy ones. The cutoff on the low-pressure cylinder should vary the same as that on the high. Then the receiver pressure will be constant and the load evenly distributed.

Evaporation from and at 212 Degrees

Please explain what is meant by the expression "from and at 212 degrees."

R. A. S.

When water is fed to the boiler at a temperature of 212 degrees and evaporated into steam at atmospheric pressure, the steam has a temperature of 212 degrees and the evaporation is said to have taken place from and at 212 degrees. As this requires a definite amount of heat, it has been adopted as a standard to which all boiler performances are referred when tests or comparisons are made.

Cutoff on Low-Pressure Cylinder

If the point of cutoff in the low-pressure cylinder makes no difference in the number of expansions, of what use is a cutoff on this cylinder?

L. C. O.

It is used for controlling the receiver pressure and distributing the work between the cylinders.

Effects of Bag on Boiler Safety

On the front sheet of a boiler over the fire a small bag about 2 inches deep has formed. Is it dangerous?

B. B. S.

It is not necessarily dangerous. The sheet at the thinnest part of the bag is probably stronger than the seam, and if kept free from scale or deposits of mud is not unsafe. However, the matter should be referred to an experienced boiler inspector.

Draft Regulation

What is considered the best practice to regulate the amount of air supplied to the furnace: by the damper or by opening and closing the draft doors?

H. E. H.

The draft should be regulated by the damper.

Air Receiver Explosion

I am using an old return-tubular boiler in a cellar as a receiver for compressed air at 100 pounds pressure. If it should explode, would the results be disastrous?

E. A. R.

Probably not. It would be a case of simple rupture, which, if it occurred at the side, would move the receiver a few feet from its position.

Water Hammer in Open Pipe

What is water hammer, and is it possible to get a water hammer in the exhaust pipe of a steam engine?

J. I. W.

Water hammer is the violent projection of a body of water against some part of the interior surface of the containing vessel or pipe. It is possible to get a water hammer in an open-ended exhaust pipe if there are water pockets.

Effect of Clearance

How is the ratio of expansion found when the clearance is known?

F. D. C.

The ratio of expansion is found by dividing the final volume by the initial, or volume at cutoff. When the clearance is considered, the percentage of piston displacement represented by the clearance is added to both the initial and final volumes. If the piston displacement be represented by 1, the final volume will be 1 + per cent. of clearance, and the ratio of expansion will be

$$\frac{1 + \text{clearance}}{\text{Cutoff} + \text{clearance}} = \text{Ratio of expansion}$$

Sizes of Turbine Steam and Exhaust Pipes

The accompanying curves were prepared by W. J. A. London, chief engineer, of the Terry Steam Turbine Company, Hartford, Conn., to save the necessity of working out the size of steam and exhaust piping for each individual calculation.

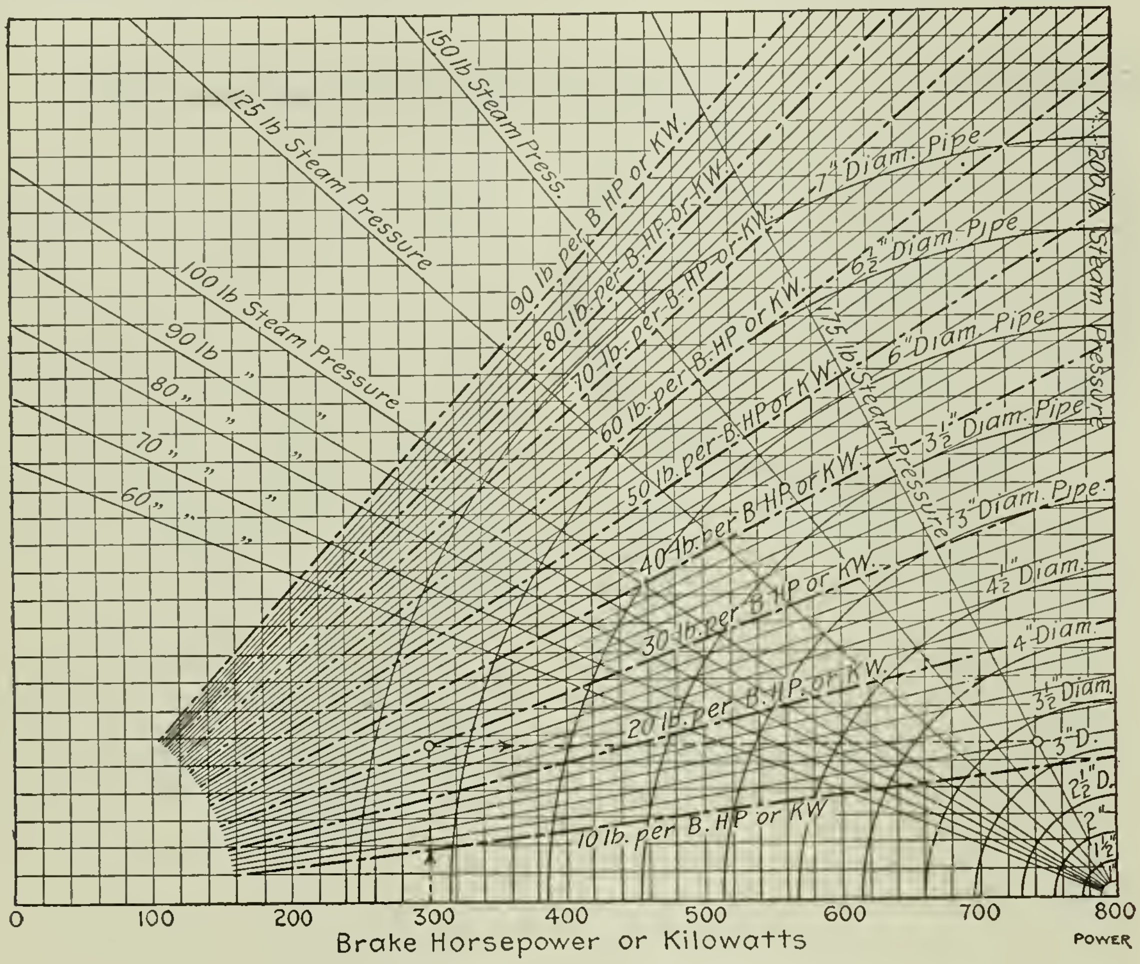

Fig. 1. Size of Steam Pipe to Turbine

Having given the power, water rate and steam pressure, the size of the steam pipe is obtained as shown in the example relating to Fig. 1. Thus: Assume 300 horsepower at 30 pounds water rate, with 175 pounds initial pressure. Follow up the 300 line to the 30 pounds water rate, and from the intersection run to the right to the initial-pressure line, and in the example this is between 3- and 3½-inch pipe, and will therefore take the larger size.

For determining the exhaust outlet when given the power, water rate and back pressure or vacuum, use Fig. 2 and in exactly the same way.

The steam-pipe sizes are based on the standard steam velocity of 100 feet per second or 6000 feet per minute, using dry saturated steam. The exhaust curves are based on a velocity of steam of 400 feet per second or 24,000 feet per minute for all vacuum curves; 100 feet per second, 6000 feet per minute, for the atmospheric-exhaust curve is allowed.

In all these curves steam has been taken as expanding from 150 pounds gage, and from Peabody's steam tables, which have been used throughout the calculation; this gives an entropy of 1.56. In cases where the initial pressure is different from that stated, a small correction should theoretically be made for the difference in moisture, but the percentage difference in ordinary work in expanding from 200 pounds to 1 pound absolute, and from 100 pounds to 1 pound absolute, is so small that the curves will be found sufficiently close for all practical purposes.

All pipe diameters given are based on net internal areas. As the net areas of extra-heavy pipe and double extra-heavy pipe are very often considerably less than the normal diameter of pipe, corresponding allowances should be made.

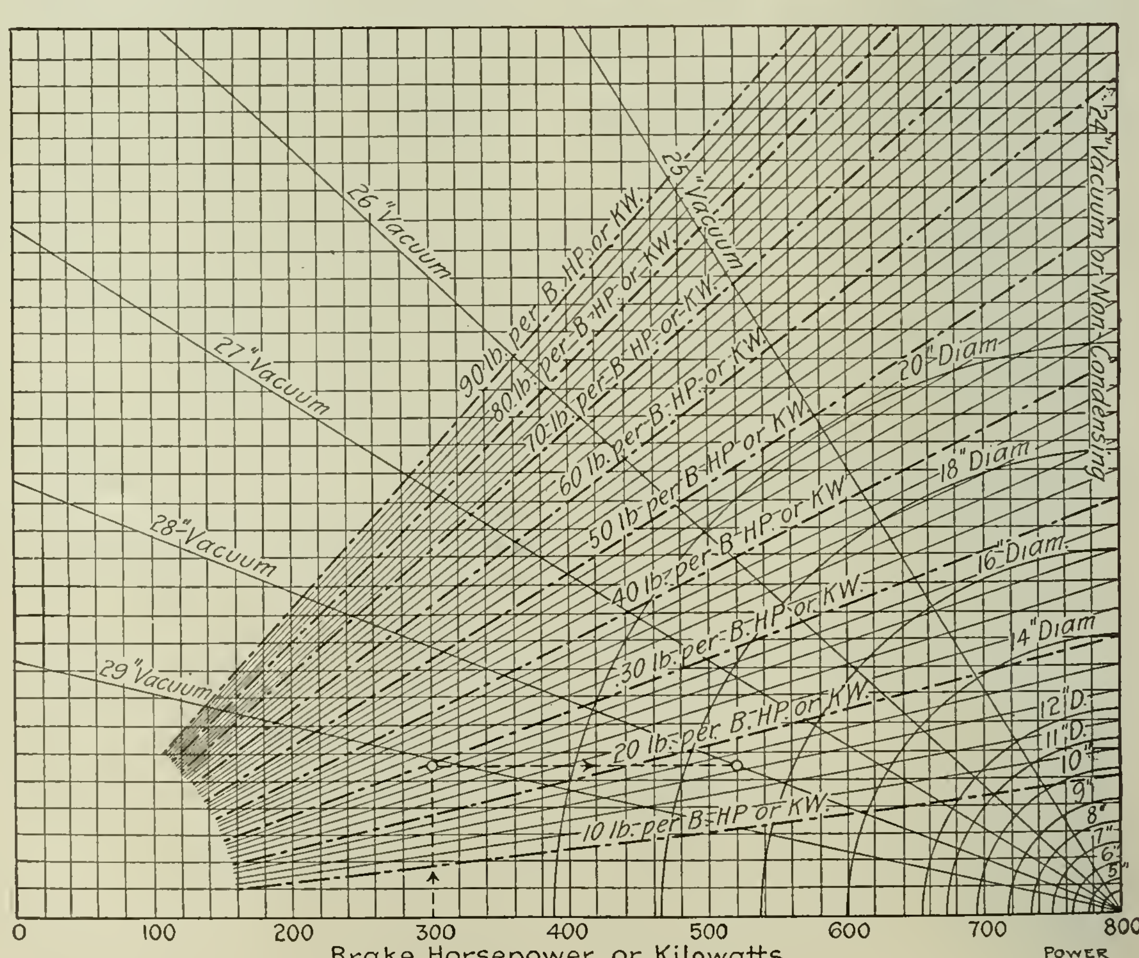

Fig. 2. Size of Exhaust Pipe

General Electric Centrifugal Air Compressors

A score of men connected with blast-furnace operation were the guests of the General Electric Company at the River Works, Lynn, Mass., on February 4, to inspect the design and construction of the three new turbine-driven, constant-volume centrifugal air compressors which are to be delivered to the Iroquois Iron Company at South Chicago, Ill.

One of these compressors is completed and erected on the testing floor; an actual demonstration of its operation was made.

These machines will constitute the third installation in the United States of this type of compressor. The first machine to be installed was that at the Oxford Furnace of the Empire Steel and Iron Company, Oxford Furnace, N. J.

The Cambridge Scientific Instrument Company showed several novel instruments at the recent exhibition held by the Physical Society of London. The first of these was the bi-meter carbon-dioxide recorder, which contains no glass nor liquid, the CO_2 being absorbed by lime and being recorded by the aid of a differential gearing between two cylinders, through which the flue gas is drawn. The second, the recalescence curve tracer of H. Brearley, of the Firth Laboratory, of Sheffield, gives recalescence curves on a very open scale of rectangular coordinates, connecting time and temperature with the aid of a thermo-couple and a galvanometer. One clock drives the whole mechanism. The observer has to turn a handwheel in such a way as to keep the pointer coincident with the light spot of the galvanometer mirror.—*Ex.*

New Power House Equipment

What the inventor and the manufacturer are doing to save time and money in the engine room and power house. Engine room news

Tools for Placing Baffle Brick

This set of two tools has been designed for the purpose of removing and replacing baffle walls of Babcock & Wilcox boilers.

Ordinarily when removing baffle bricks it is necessary to break them before they can be taken from between the tubes. When replacing new baffle walls, using old methods, it is necessary to chip the edges on two sides of each brick before it can be put in place between the tubes. With the new method the brick are put in place whole and set up snug against the tubes.

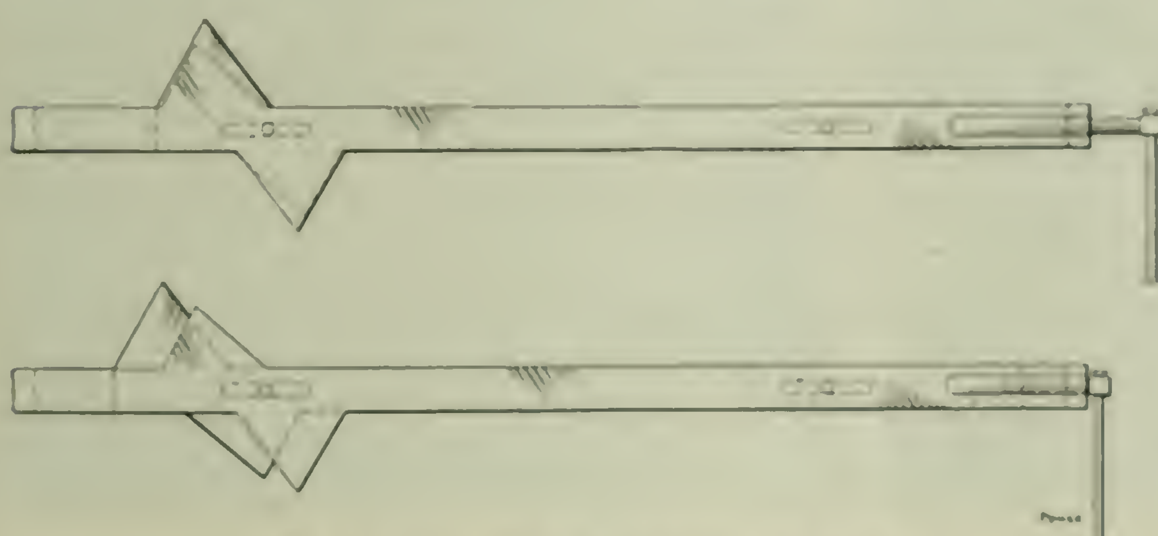

FIG. 1. TOOL USED FOR SPRINGING THE TUBES

In Fig. 1 is shown the tool used for springing the tubes. It is made with an adjustable spreader head. The movable part is operated by a threaded stem that screws into a nut on the inside of the handle, and is operated by the rod on the end. The upper view shows the tool in a contracted position; the lower view as it appears when the tubes are sprung.

By referring to Fig. 3 it will be seen that four tubes are sprung as the head is expanded; that is, tubes *A* and *B*, which bear against the stationary portion of the head are sprung away from the tubes *C* and *D* which bear against the movable part of the head. With the tubes sprung in this manner, it is a simple operation to remove an old baffle wall and replace it with new baffle bricks.

Fig. 2 illustrates the tool used for placing the baffle brick in position. The upper view shows the brick as it is placed in the tool; the lower view shows the brick gripped by the jaws of the tool. The gripping member is adjusted by a threaded rod which passes through a nut on the inside of the handle. The knurled end of the handle is turned, which tightens or loosens the jaws of the tool on the brick. The stationary member is so made that it fits the end of the baffle brick.

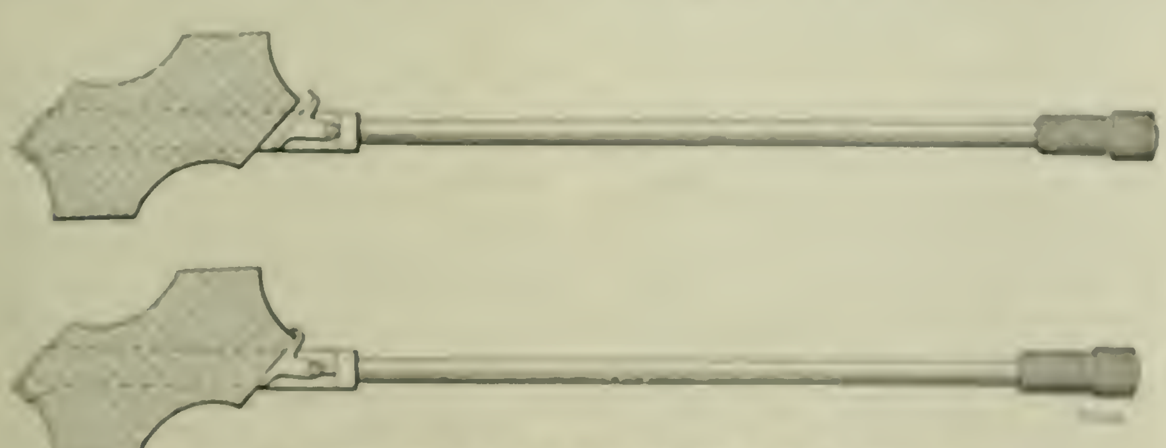

FIG. 2. TOOL FOR PLACING BAFFLE BRICK IN POSITION

With the brick gripped in the jaws, the tool is inserted between the boiler tubes and when in place the movable jaw is drawn back and the tool removed.

By using these instruments the baffle brick can be replaced whole and thus their efficiency is not impaired.

These tools are made by J. Keers, 224 Eighty-first street, Brooklyn, N. Y.

Albee Crude Oil Burner

This device has been designed for use in the furnace of steam boilers, forges or wherever crude oil can be utilized as a fuel.

It consists of a main body *A* which has an air and oil inlet and a discharge outlet. Oil is discharged into the burner through the plug *B*, in which is screwed a nozzle *C*. This plug has a wire screen *D* that is held in place by the cap *E*.

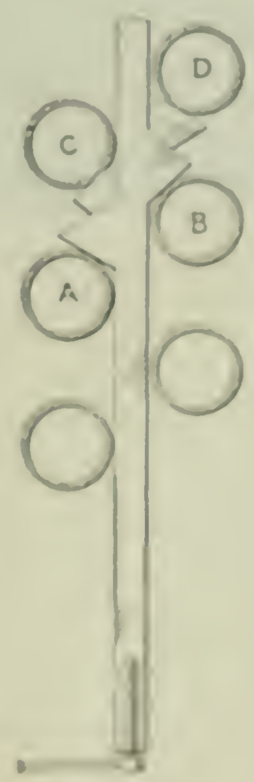

FIG. 3.

FIG. 4.

To the discharge end of the burner is screwed a cast-iron pipe having an outlet formed as shown in the illustration. This extension piece passes through the brick wall of the furnace front and is the only part of the burner that is exposed to the furnace heat. When it does become burned, it is easily renewed at a small cost.

When in operation the furnace works as follows: Oil is forced through a supply pipe to the inlet of the burner and out through the small discharge hole in the nozzle *C*. Air, under a three-pound pressure, is admitted to the body of the burner through the top opening and

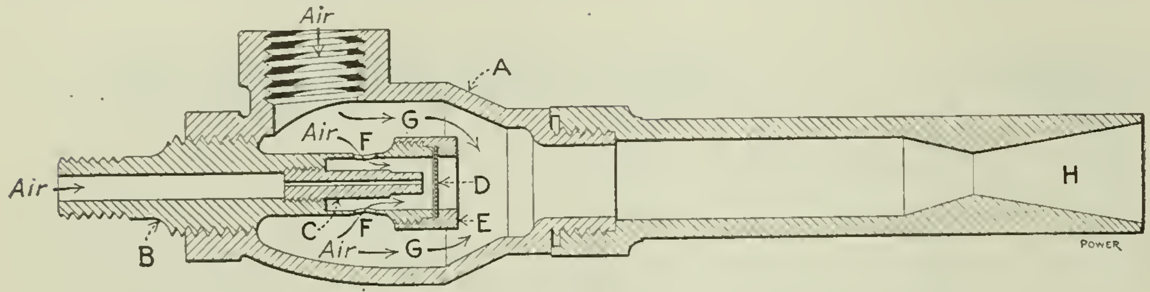

Fig. 1. Sectional View of the Albee Crude-oil Burner

travels along two paths before it is expelled at the discharge end. That is, a portion of the air supply passes to the interior of the plug *B* through a series of holes as shown at *F F*. This air mingles with the incoming oil from the nozzle *C*

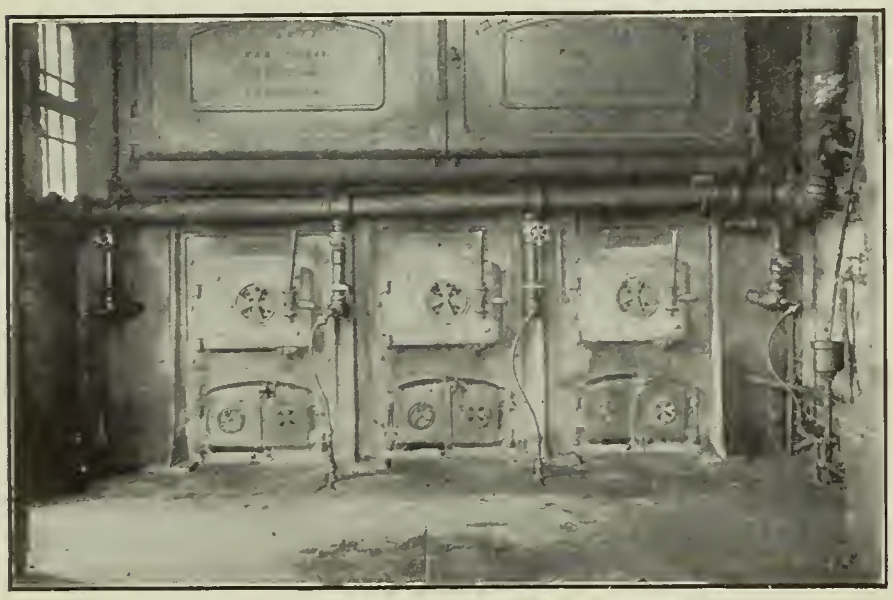

Fig. 2. Burner in Place Ready to Supply Oil as a Fuel

Fig. 3. Burner Pulled Out Ready to Burn Coal in the Furnace

and passes through the wire screen *D* in a partially atomized state, the current of air and oil passing diagonally from one side of the burner to the other from all points of the discharge cap *E*.

As this current of air, indicated by the arrows *G G*, strikes the oil and air being discharged through the cap *E*, the mixture is blown through the expanding tube and is discharged at the end *H* in a vapor, and is then ignited in the furnace of the boiler.

An oil connection is made to the supply pipe by means of a flexible hose, in order that the burner can easily be disengaged from the air line and withdrawn from the furnace. This is accomplished by a sliding coupling on the air connection. Fig. 3 shows the burner connected to and withdrawn from the supply pipe.

This arrangement permits of changing from coal to oil fuel, or *vice versa*, which makes it possible to burn oil during the day and coal during the night when the fires are banked.

This burner is manufactured by H. L. Albee, East Douglas, Mass.

First Monthly Meeting of the Institute

On Tuesday evening, February 9, the first of the series of regular monthly educational meetings inaugurated by the executive committeee of the Institute of Operating Engineers was held at the Engineering Societies' building, 29 West Thirty-ninth street, New York City.

Hubert E. Collins acted as chairman and after briefly outlining the objects of the institute and giving the reasons for holding the meetings, he introduced Prof. F. H. Sykes, director of Teachers College, Columbia University, who gave a half-hour talk on the necessity for industrial education as is exemplified by the scarcity of trained workers in all cases of modern industry.

Professor Sykes has made a careful study of the systems of industrial education in vogue in all the countries of Europe in which the industrial arts are most highly developed, and his address on this occasion was greatly enforced by statements of the changes in certain industries which in many cases have been wrought in a few years by the influence of the industrial schools, in some instances the school saving the industry from complete decline and the people who engaged in it from financial and industrial ruin.

He was followed by C. H. A. Bjerregaard, librarian of the Astor library, who dwelt on the ethical phases of the subject.

Mr. Jurgensen then presented a paper pointing out the weak spots in the present system of education for the engineering profession and outlining the institute's plans to provide him a balanced and competent system of professional education.

Professor Lorentzen, of New York University, in a few well chosen words emphasized what had been said by the preceding speakers.

He was followed briefly by F. L. Johnson, Timothy Healy and H. M. Elder, all of whom spoke of the significance to the operating engineer of industrial education as proposed by the institute.

San Francisco Exposition

San Francisco is to have the exposition to be held in 1915 in commemoration of the completion of the Panama canal. A joint resolution to this effect has already passed the House and is sure to pass Congress. California has promised $17,500,000 for the proposed exposition and no pecuniary aid has been asked of the national Government. New Orleans has put up a hard fight for the honor, but the location chosen will have the advantage of giving many of the visitors an opportunity to view the canal.

PERSONAL

Dr. F. R. Hutton, late of Columbia University and honorary secretary of the American Society of Mechanical Engineers, has been appointed consulting engineer of the Department of Water Supply, Gas and Electricity of New York City, vice George W. Birdsall, deceased.

On the evening of January 25, Melville W. Mix, president of the Dodge Manufacturing Company, celebrated the twenty-fifth anniversary of his connection with the company by giving a splendid nine-course dinner to stockholders and directors. At the close of the dinner, Mr. Mix was presented with a silver gold-lined loving cup by First Vice-president W. B. Hosford as a token of the company's esteem and confidence.

Mr. Mix began as office man and at one time was wrapper of *Power and Transmission*, the company's official organ. He became shipping clerk and also went to New Orleans, where he assisted in the Dodge exhibit at the exposition. In 1890 he went to Chicago, where he became Chicago manager of the company. In 1894 he was returned to Mishawaka and became general manager and in 1895 he was elected president and general manager, and has occupied that position since that time.

BOOKS RECEIVED

THE SLIDE RULE. By Frank C. Hinckley and William W. Ramsay. Engineering Text Book Company, Boston, Mass. Leather; 104 pages, 4x6¼ inches. Price, $1.75.

APPLIED THERMODYNAMICS FOR ENGINEERS. By Prof. William D. Ennis. D. Van Nostrand Company, New York. Cloth; 438 pages, 6x9¼ inches; 316 illustrations; indexed. Price, $4.50.

THE DOTINGTON MULTIPLE BOILER EXPLOSION AND OTHER MULTIPLE BOILER EXPLOSIONS. By Edward G. Hiller. Taylor, Garnett, Evans & Co., Ltd., Manchester, Eng.; 60 pages, 5½x8½ inches; illustrated; plates. Price, one shilling.

THE PRACTICAL ENGINEER ELECTRICAL POCKET BOOK. The Technical Publishing Company, London, Eng. Cloth; 567 pages, with diary additional, 3½x5¼ inches; illustrated; tables; indexed. Price, one shilling and sixpence.

Moments with the Ad. Editor

A department for subscribers edited by the advertising service department of Power

There was once a young Shepherd Boy who tended his sheep at the foot of a mountain near a dark forest. It was rather lonely for him all day, so he thought upon a plan by which he could get a little company and some excitement. He rushed down toward the village, calling out, "Wolf, Wolf!" and the villagers came out to meet him. This pleased the Boy so much that a few days afterward he tried the same trick, and again the villagers came to his help. But shortly after this a wolf actually did come out from the forest, and began to worry the sheep, and the Boy of course cried out, "Wolf, Wolf!" But this time the villagers, who had been fooled twice before, thought the Boy was again deceiving them, and nobody went to his aid. The wolf made a good meal off the Boy's flock and when the Boy complained, the wise man of the village said: "*A liar will not be believed, even when he speaks the truth.*"

While reading this one of Aesop's Fables, written some twenty-five centuries ago, we couldn't help wondering whether there was not advertising in some crude form even in those days.

The moral so exactly illustrates the reason why an advertiser who advertises regularly in reputable papers must back up his claims with bona fide goods!

And why an advertiser whose goods do not meet the claims made for them will not appear on the pages of reputable papers for any length of time.

We recently met a man who had been selling patent medicines. He told how in the last five years he had advertised and sold six different brands.

That is to say, *different* in name. The mixture was exactly the same each time, being advertised only as long as the new name and new claims would fool people into buying.

However, patent medicines and other articles which are put out to fool the public are now practically eliminated from the better grade weeklies and monthlies, and even the dailies are closing the door on them.

This change of attitude on the part of publishers is due to the ever increasing recognition of Advertising Ethics. That advertisers have come to a realization of their responsibility is shown by this report from one of our solicitors.

He says: "This concern is manufacturing a new design of gas engine. They are not yet in a position to advertise it because it has not been tested long enough to know whether it will 'stand up' or not. In fact, they refuse to make any sales until they are absolutely certain that it will be right in every particular."

In the same mail we get a letter from a subscriber, who, in renewing his subscription, says: "You may be interested to know that after reading the advertisements of the —————— Indicator, I bought one and found it to be all they claim for it."

This is the beginning and the ending of the story of modern advertising.

It begins with the advertiser who knows it will not pay him to advertise any but tested and proved machinery—

And ends with the buyer who finds the goods "all that is claimed for them."

Back of it is a conscientious publisher who will not insert the advertisement of the man trying to pull off something in the nature of a fake deal.

The publisher may be doing it from a sense of honesty, who knows? Give him credit for it, anyway.

In any event he knows it's poor business in the long run to do anything else.

The up-to-date buyer comes pretty close to knowing who's who and what's what.

And if he happens to be a power-plant man, he knows what supplies, equipment, money- or time-saving appliances he wants.

He *knows* because he reads the advertising pages of his technical paper and sees what goods are advertised regularly for which certain claims are made, backed up by convincing "reason why" copy.

The maker of a good article *can* advertise regularly and convincingly.

The maker of an inferior one can only raise the cry of "Wolf!" until the people get used to it and no longer answer the call.

POWER

NEW YORK, FEBRUARY 28, 1911

AN ancient allegory deals with certain six blind men who went once to "view" an elephant. After the manner of the blind, their "viewing" was done through the sense of touch.

It so happened that each came in contact with a different part of the pachyderm; one touched its trunk, one took hold of a tusk, one felt an ear, another touched a foreleg, another felt its side and the sixth caught hold of the elephant's tail.

When asked to give his "views" on elephants, the first man intimated that an elephant was long and round in form and coiled up toward the end, very similar to a huge snake.

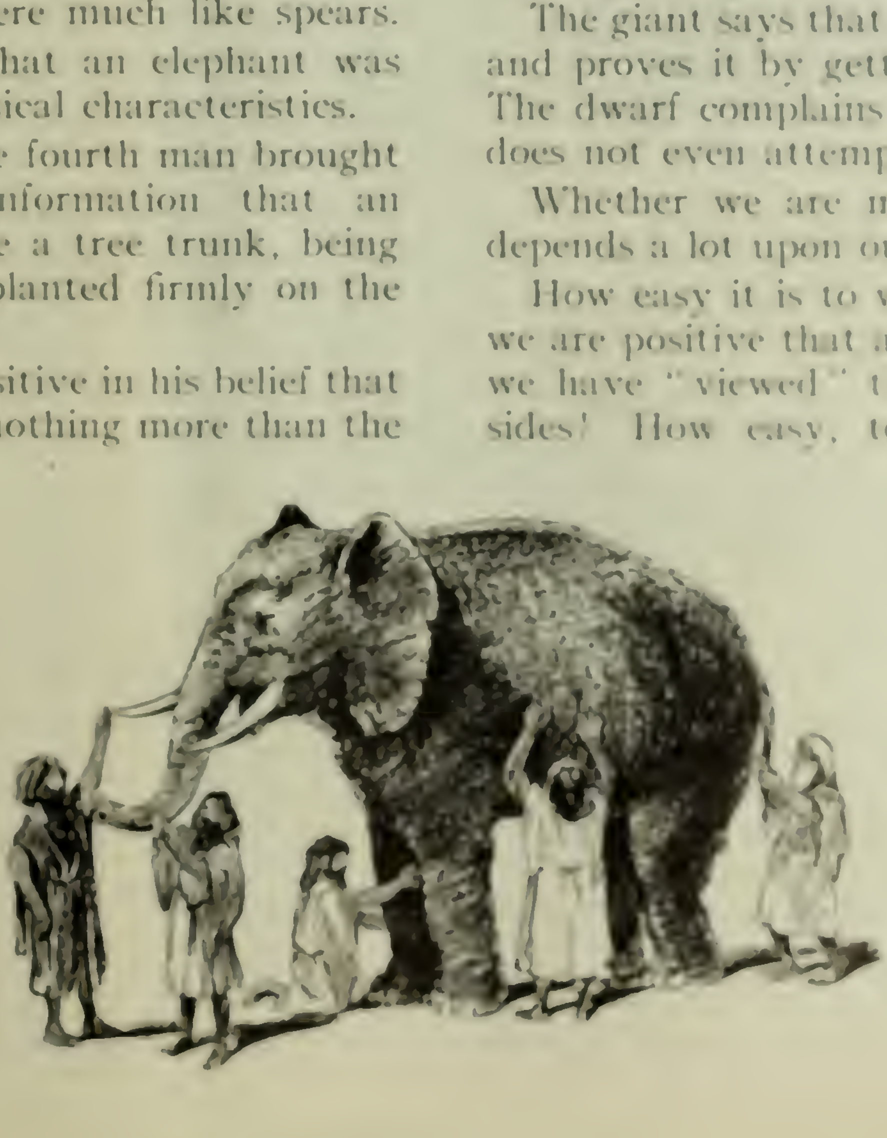
The second man went on record to the effect that elephants were much like spears.

The third thought that an elephant was much like a fan in physical characteristics.

An interview with the fourth man brought out the interesting information that an elephant was not unlike a tree trunk, being thick and strong and planted firmly on the ground.

The fifth man was positive in his belief that an elephant resembled nothing more than the side of a barn, being flat and broad.

While the sixth man did not wish to contradict anything which his companions had said, he felt justified in maintaining that an elephant was merely thin and long, just like a piece of ordinary rope.



Thus it was that the term "nature faker" came into vogue, although none of these blind men really was one, for the term faker implies deliberate deception while these men were entirely sincere in their misstatements.

*   *   *

The fable, a synopsis of which has just been given, was designed to show how easily a wrong opinion may be formed if limited observations are used as a basis.

All of us form wrong opinions; sometimes, because we form them too hastily, before all of the facts are in; sometimes, because the question is too large for us to view the whole of it at once and, like the blind men, we are led astray by our limited observations.

The giant says that the wall is easy to scale, and proves it by getting over in "jig time." The dwarf complains that it is too high and does not even attempt to climb it.

Whether we are mental giants or dwarfs depends a lot upon ourselves.

How easy it is to withhold judgment until we are positive that all the facts are in—that we have "viewed" the "elephant" from all sides! How easy, to measure our "wall" by true standards, not by self made, dwarfish units of measurement!

First, get the right point of view and, second, size things up at their true values.

Let's not underestimate our faults and overestimate our hardships.

Additions to Hartford Power Plant

By H. R. Callaway

The Dutch Point station, which carries the greater part of the lighting and power load for Hartford and the surrounding districts, has recently been equipped with two additional 1250-horsepower Bigelow-Hornsby boilers. These are served by the largest automatic stokers ever built.

The Dutch Point station of the Hartford Electric Light Company, at Hartford, Conn., has been a gradual growth from a small auxiliary to the water-power installations of this company to its present status as the main generating station of the Hartford system. When the company first began business its current output was the product of two small hydro-electric developments having a total output of not more than 2400 kilowatts. As the load became greater it became necessary to build a small steam station to serve as an auxiliary in the time of low water, and a location on what is known as Dutch point, on the Connecticut river, was chosen as the site. A small creek runs into the river at this spot, and the station is located on the point of land between the creek and the river, thus making it a handy site for the delivery of coal and other supplies.

As the load on the company's system increased, the development has been along the line of additional steam power, so that now the water powers furnish a rather insignificant proportion of the total electricity. So rapidly has the sale of electricity increased that the Dutch Point station has been added to several times, and the company has just recently completed the latest of these additions to the equipment.

FIG. 1. STOKER ASSEMBLED IN SHOP

The power-house building, including the recent additions, is about 250 feet long by 135 feet wide. It is of steel frame and brick construction throughout, with a brick dividing wall running lengthwise of the building and separating the boiler room from the turbine room. On the side of the building opposite the boiler house is an extra bay slightly lower than the rest of the building which houses the switchboard and the gallery containing the electrical equipment and the circulating pumps for the condensers.

The original boiler-house equipment consisted of six 550-horsepower Aultman-Taylor boilers. These are arranged in a single row with the horizontal firing aisle next to the building wall. Later it was decided to add 2500 boiler horsepower, and two 1250-horsepower Bigelow-Hornsby boilers were installed, these being set beyond the Aultman-Taylor boilers and transversely with the boiler house. The latest addition to the boiler equipment has been two more 1250-horsepower Bigelow-Hornsby boilers placed in an addition built onto the end of the boiler house next to that part occupied by the transverse boilers. The unusual size of the four latest additions to the boiler room is one of the notable features of this station, and not only are the boilers themselves of unprecedented size, but they are equipped with the largest automatic stokers ever built. These are fourteen retort Taylor gravity underfeed stokers, shown in Fig. 1. The first installation of these mammoth stokers was on the two latest of the Bigelow-Hornsby boilers. Afterward it was decided to change over the two original 1250-horsepower boilers from hand firing to automatic stoker firing, and these are now being equipped with Taylor stokers. The main reasons for using such large boiler units at this station were concentration of power, economy of floor space and increased economy in operation due to a smaller amount of radiation.

The Bigelow-Hornsby boilers which are shown in Fig. 2 measure 27 feet 6 inches across the front and stand 21 feet 6½ inches from the floor line to the center of the steam drum. The latter is 4 feet in diameter and extends the entire width of the top of the setting. This drum connects with forty sections of 3¼-inch water tubes, 21 tubes to a section, or in all 840 tubes, each section of water tubes terminating at either end in a cylindrical header. The front sections are inclined at a steep angle, while the rear sections are vertical. In this type of boiler the depth of the furnace is necessarily somewhat limited; therefore the extreme width of grate and a high rate of combustion are depended upon to develop the rated horsepower. All the boilers in the station are equipped with Foster superheaters. Three 10-foot steel stacks serve the various batteries, two of these discharging the gases from the Aultman-Taylor boilers and the two oldest Bigelow-Hornsby boilers, and the third, a new 50-foot stack, serving the two latest units. The stokers operate on about 4 inches draft, but as yet there is no information available as to the performance of these huge units. Tests, however, will be made before long, the results of which are awaited with interest, owing to their unusual size.

One of the principal reasons for the installation of automatic stokers in this station was economy in labor, 2500 horsepower of boilers being operated by three men per day of 24 hours. When this same battery of boilers was operated with hand firing it took 12 men per day for the same capacity.

FIG. 2. FRONT OF BOILERS SHOWING STOKER

There are in all six main units: one 3000-kilowatt, one 2000-kilowatt and two 1000-kilowatt Westinghouse turbo-generators and two 4000-kilowatt General Electric horizontal turbo-generators, the latter being the latest additions. The six machines all operate in parallel and generate two-phase, 60-cycle current at 2400 volts.

The turbines receive steam at 150 pounds pressure and 100 degrees superheat from a single 12-inch main running alongside the boiler-room wall and behind the batteries. The leads taken off to the various turbines are of 6-inch, 8-inch and 10-inch pipe; 6-inch to the two small units; 8-inch to the 2000-kilowatt Westinghouse turbine and to the new General Electric machines; and a 10-inch to the 3000-kilowatt machine.

Situated in the basement directly below their respective turbines are the condensers and their auxiliaries. The largest of the Westinghouse turbines exhausts into two condensers operated in parallel, each containing 6000 square feet of surface. By a suitable arrangement of valves this machine can operate singly on either condenser if required. Although the 12,000 square feet of surface available for this machine is much larger than is necessary, this arrangement enabled the company to make use of an old 6000-square foot condenser instead of scrapping it and buying a new one of 10,000 square feet. The two 1000-kilowatt turbines are served by a single 6000 square foot condenser and the 2000-kilowatt machine by one of 6000 square feet. The four Westinghouse units are all provided with similar circulating-pump installations, each pump being driven through a long vertical shaft by an induction motor situated in a gallery alongside the switchboard. Each pump is provided with a separate intake from the river, but the discharges of all are joined into one pipe line which ends at a point somewhat downstream from the intakes.

Very little condenser-tube trouble has developed at this station, due probably to the fact that there are few acids in the water of the Connecticut river. Instead of the pitting so often found in condenser tubes of large power stations, the main trouble here seems to be the wear at the ends of the tubes due to expansion and contraction in the heating and cooling of the condenser. Naturally this trouble is not as serious as is the case of poor water, the tubes merely becoming loose at the heads. A rather ingenious method is used for saving the tubes worn in this manner, by cutting them off just inside the condenser heads and inserting a short length of smaller tubing, which is extended just inside the cutoff ends and then sweated on. This method results in cutting down the area somewhat, which, however, matters very little in this particular case because the condensers are altogether too large for the turbines.

Each of the two new General Electric turbo-alternators is equipped with a 20,000-square foot condenser having 1-inch tubes. The auxiliaries for these machines are rather unique and exceedingly compact. They consist of a centrifugal pump for circulating water and another for the hotwell water placed on the same shaft, both pumps being driven direct by a steam turbine; these are shown in Fig. 3. The dry-air pumps for all the condensers are set on the turbine-room floor between the machines, and the vacuum maintained is unusually high, the average during the winter being 28.75 inches, based on a 30-inch barometer.

As already stated, the coal is usually received by water, it being brought up the river in barges and unloaded at the company's dock beside the power station. In addition to the facilities for receiving

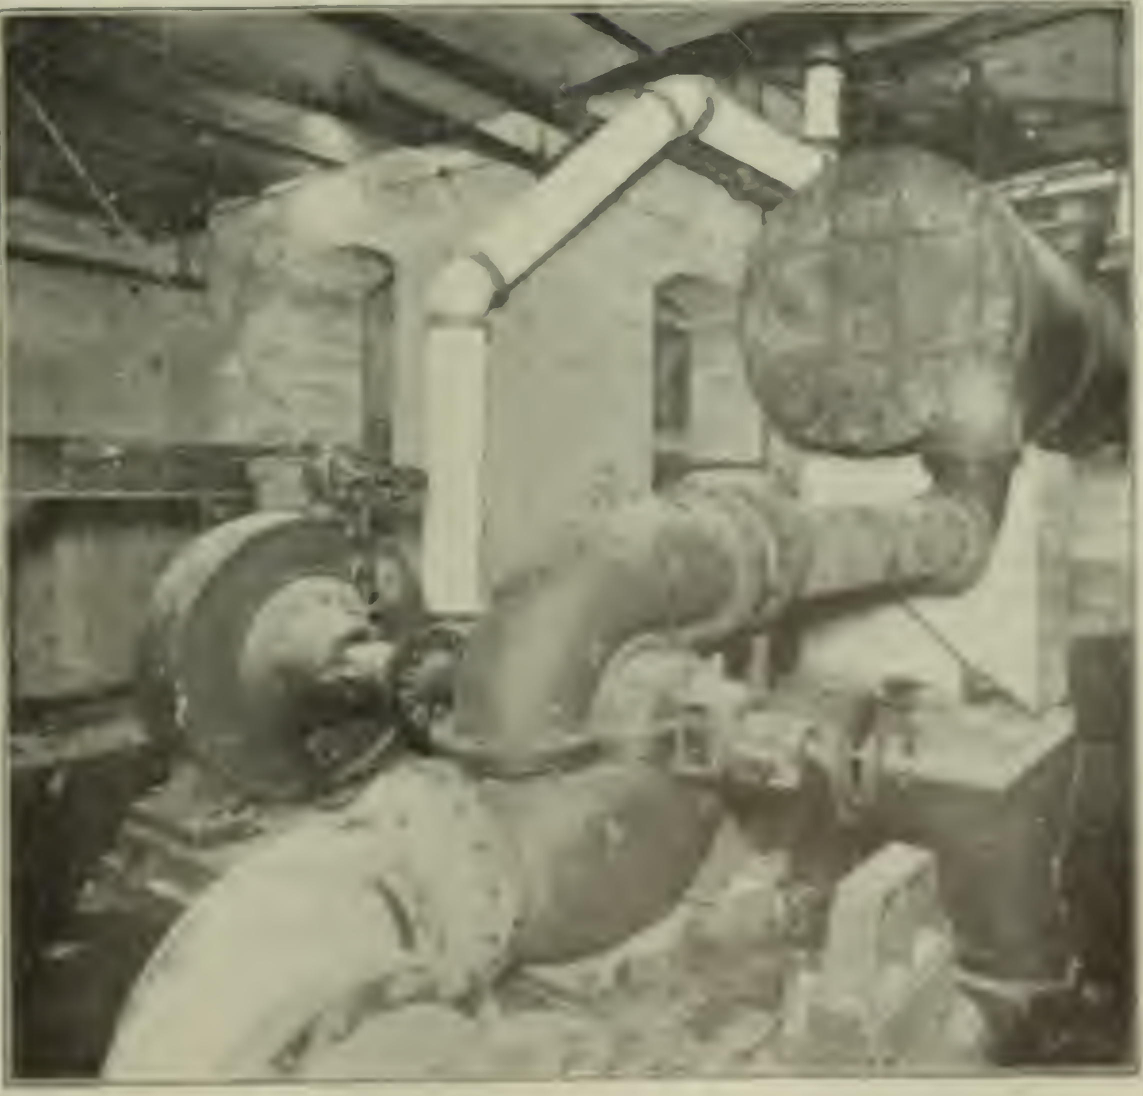


FIG. 3. CONDENSING OUTFIT

coal and other supplies by water, a spur track runs alongside the station on the boiler-room side. This is utilized for obtaining coal by rail during the winter months when the river is frozen and a sufficient supply has not been stored in the fall, although the 18,000-ton capacity of the storage bins usually proves adequate for this period. The approximate yearly coal consumption is 40,000 long tons.

The system of handling the coal is unusual. In addition to the spur track, already mentioned, which runs on the boiler-room side of the station, another spur runs on the river side along the unloading piers. Two derricks mounted on railroad trucks are used for unloading and loading the coal cars on these tracks. One derrick hoists coal from the barges and deposits it into the coal cars which are then shunted around onto the other track, and there unloaded into bins from which the coal falls by gravity to the boiler-room floor. In the case of the new stoker-fired boilers the coal goes from the bins into the hopper over the firing aisle, from which it is fed through chutes into the retorts of the stokers. Where the coal is brought by rail the cars are simply run in on the spur next to the storage bins and unloaded by means of the derrick hoists. It is said that 3 cents per long ton covers all unloading charges for coal. The hand-fired boilers burn a mixture of 75 per cent. No. 3 buckwheat and 25 per cent. bituminous coal. This mixture is the result of a large number of experiments on the most efficient and economical coal for use under the hand-fired boilers, and marks the point where the pounds of steam per unit cost is a maximum.

The Taylor stokers are supplied entirely with soft coal averaging about 14,600 B.t.u. per pound. The buckwheat averages 11,400 B.t.u. per pound. Although the mixture has proved to be the most economical fuel for average conditions on the hand-fired boilers, it has been found that under peak loads it is impossible to get sufficient capacity out of the boilers. Accordingly at the time of heaviest loads it is customary to burn straight soft coal on the hand-fired boilers as well as on the stokers. In the case of the former, this practice gives rise to considerable smoke and poor efficiency, which was another reason for the installation of the mechanical stokers under the new boilers.

The present system is to carry the steady load of the station on the stoker-fired boilers and handle the peak loads with the hand-fired boilers.

The ashes are dumped from hoppers under the boilers into ash cars in the basement. These discharge into a bucket hoist at one end of the boiler house, which dumps the ashes into carts. The ashes are then carted away by contractors who take all the ashes from the station without charge, so that the ash-disposal problem is very simple.

The station contains no fire pumps whatever; the construction being practically fireproof throughout and the coal-storage bins being outside the station walls, the chances of fire are exceedingly small. Located as it is on an isolated point between two bodies of water it would be impossible for a fire in the station to do harm outside the premises.

Buckwheat No. 3, delivered by water,

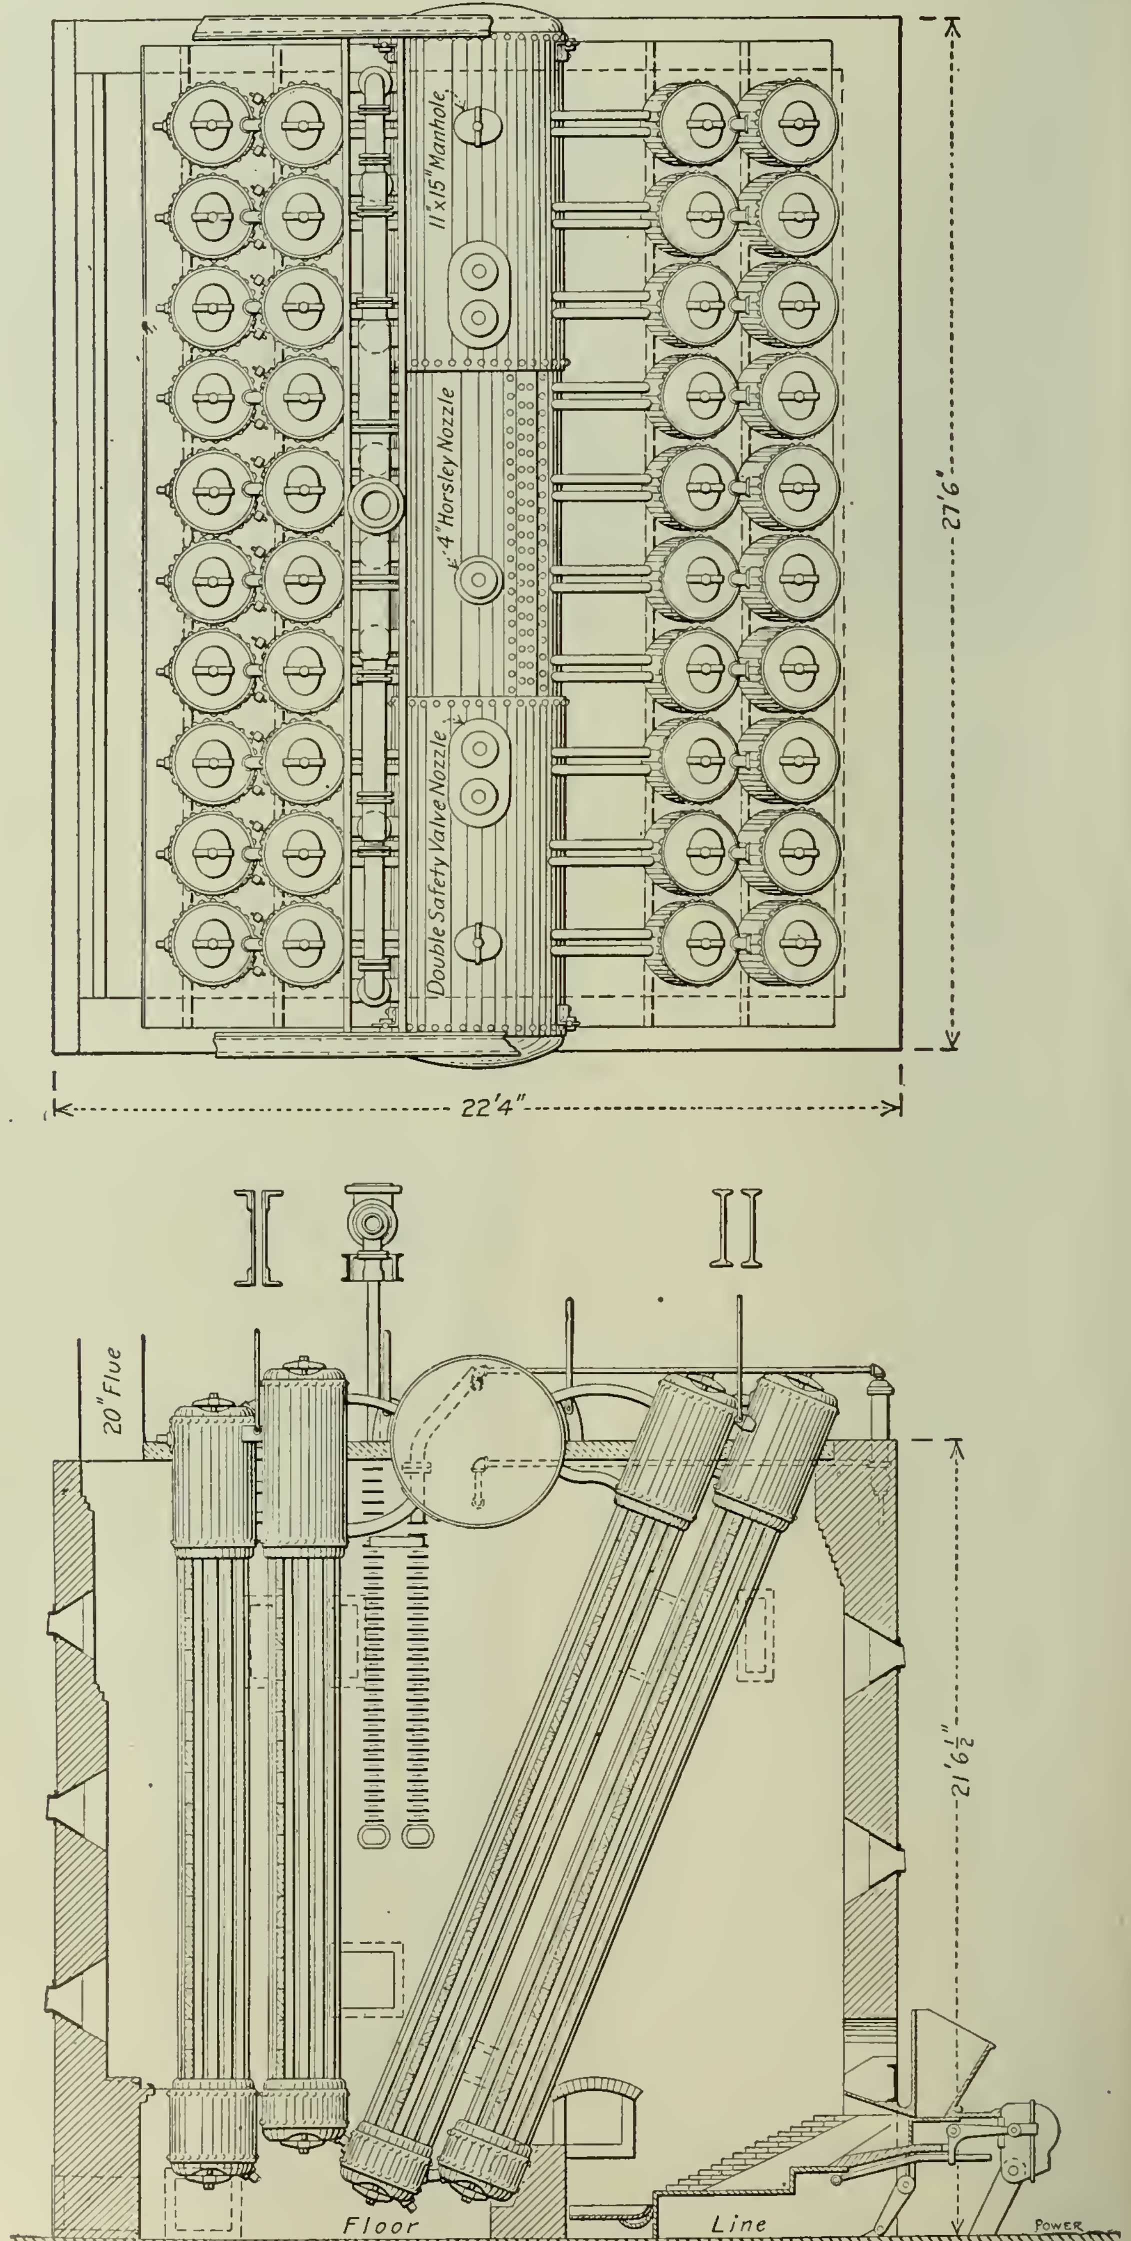

Fig. 4. Sectional Elevation and Plan of Bigelow-Hornsby Boiler

costs $2.05 per ton; by rail, $2.72. The bituminous coal costs $3.35 and $3.65 respectively.

The electrical distribution is divided up into two separate systems. For the city proper the current is not transformed but is transmitted at the generator voltage of 2400 to two substations, where it is stepped down to 220 volts and changed to direct current by means of rotary converters.

The lighting distribution from these two substations is on the Edison three-wire system, 220 volts outside and 110 volts between the outside and the grounded neutral. In the case of large power consumers, such as mills and factories, separate feeders go direct from the power house to transformers located on poles at the mill end of the feeders; this current is alternating.

There is a second system of distribution in use for the outlying districts; transformers located in the basement of the station step up the voltage from 2400 volts two-phase to 11,000 volts three-phase. In this system there are no converters, alternating current being distributed and stepped down by pole transformers.

The winter load on the system averages 140,000 kilowatt-hours per day and the load factor is unusually high for a lighting installation, approximating 65 per cent. Because of the large number of induction motors operating during the day in the various factories, the power factor during the day time is only 85 per cent. As soon as the motor load goes off in the evening the power factor rises to 95 per cent. It is understood, however, that rotary condensers are to be installed in order to counterbalance the lagging effect of the induction motors and to bring up the load factor during the day to somewhat near unity. It would not be necessary to operate them during the night.

The designing engineers of this plant, who also had charge of the erection, are Westinghouse, Church, Kerr & Co., of New York City.

Making, Use and Care of Belting

By Chas. A. Schieren, Jr.*

> *The tanning of hides for belt leather by the old, long-time, oak-bark process and the operations in making belts.*
>
> *Belt specifications fair to both buyer and seller, and belting factors that have been tested by long experience. How to get maximum belt service per dollar of investment.*

*Treasurer, Charles A. Schieren Company.

With the bark and the hides at hand the process of tanning to produce leather for belting may be taken up.

The hides are first soaked in pure spring water until all the dirt is thoroughly washed out of them. They are then placed in a vat of weak lime water, which is gradually strengthened until the sixth day, when the hair has been loosened sufficiently to allow the skin to be laid on a beam and the hair scraped off with a blunt knife.

The bare hides are then placed in an alkaline solution called the "bate," for the purpose of removing the lime which may have remained from the previous bath; this liming and "bating," done in a building known as the "beam house" or "lime house," is a very important step in the making of good, solid belt leather.

Cleansed from hair, flesh and lime, the hides are taken from the "bate" to the "handlers," where they receive their first bath of weak tanning liquor.

Preparing the Tanning Liquor

This liquor is prepared from oak bark. Ten years ago this bark was ground in something like an overgrown coffee mill, but our tannery has been equipped for five years past with an improved crushing machine which does the work quicker and more effectively, and as the crushed bark leaves this machine it is blown by means of a rotary fan through large metal pipes to the leach tubs.

These are 12 feet in diameter, eight feet deep, and hold fully eight tons of ground bark.

To this ground bark water is added by means of rotary brass sprinklers and filtering through the mass, takes up and carries downward the tannic acid.

There is a false bottom in each leaching tub, and the liquor is collected beneath it and pumped away to the storing and supply tanks for use when needed. It is from these tanks that the liquor is drawn for the handler vats in which the hides are put after the "liming" and "bating."

Tanning

The hides are placed in the handler vats across sticks side by side, packed as closely as possible, and are left here for about 10 or 12 days, during which the hide swells, opening the pores and increasing both in thickness and firmness.

When the hides are taken from these vats the bellies and heads are trimmed off and tanned separately for shoe purposes. The butt portions intended for belting are then stowed in vats called "lay-aways." Here they are laid flat, one on top of the other, about a hundred in each vat. Loose bark is spread between the layers, and they are covered with strong tanning liquor.

Hides intended for belting are given five successive layers or treatment of bark. The first layer remains 10 days, and the process is graded up to 40 days for the last layer.

In this way oak tanned belt leather is submitted to a tanning which takes 120 days for the attainment of the best results.

Drying and Finishing the Belt Centers

When the hides have thus been thoroughly tanned they are taken from the vats, washed, so as to remove every particle of tan bark, and then oiled on the grain side, hung up to dry in a darkened loft, where they are kept at an even temperature with very little heat, and gain a beautiful clear russet color. The leather, as such, is now completed, and each hide is cut into widths according to its grade and weight.

The bellies, shoulders and all flabby or imperfect parts are thrown out for shoe purposes, and the central portion or heart of the hide is reserved for belting.

This solid leather is carefully shaved on the flesh side in huge machines, operating somewhat on the principle of a milling machine, and is then scoured by other machinery. The object of this is to open up the pores for the reception of the stuffing of cod oil and pure beef tallow by which the leather is preserved and made suitable for the transmission of power.

Many hours are devoted to this stuffing, and the thoroughness with which it is done lends to belting one of its most prominent features—long life. When the stuffing is accomplished the leather is smoothed and stretched so that the fibers will be made uniform.

Nothing now remains to be done at the tanneries but to allow the leather to dry, brush it off, pack it in bundles and ship it to the belt factory.

The capacity of the Dixie Tannery, of Bristol, Tennessee, owned by the Charles A. Schieren Company, is [illegible] hides a year, and its equipment is used solely for tanning and finishing prime oak leather for belting.

The leather centers and sides, when they reach the belting factory, are from [illegible] feet to [illegible] feet long. At the facnery, after the leather is taken out of the vats, and before the currying process, the shoulders are removed from all of the hides, and each hide is measured four feet from the butt end of the tail to the shoulder, and the shoulder cut straight across so that no piece of shoulder or flanky leather is left on the hide.

After the severe stretching which these pieces undergo during the currying process and in the stretching frames the pieces elongate from four inches to six inches, making each piece four feet to four feet six inches in length, and all of the pieces solid leather.

Operations in Making a Leather Belt

The first process at the belting factory is to select the centers and sides for thickness and weight, and cut them up into various widths for which the stock is most suitable; this is one of the most important processes in the making of leather belting.

After the leather has been cut to width it is transfered to the matching tables, where the pieces are matched in pairs and marked for the scarfing machine; this machine scarfs the laps to a length already indicated by the matcher.

From the scarfer the stock is taken to the feathering-machine operator, who feathers the edges of the laps prior to their going to the pressman to be cemented. The cement used is either our improved belt cement for regular belts to run under dry conditions, or our waterproof cement for waterproof belting. Perfect joints can be and are made with no other fastening than cement, and in most cases riveting or sewing the laps is superfluous; joints that are cemented only have the advantage of running smoother and with less vibration than belts fastened in any other way.

The belt next goes to the finishing department, where it is inspected and where the edges are finished either round or square as the case may be. During the finishing of the edges the belt passes through a stretching device which eliminates all of the stretch or surplus elasticity that may be necessary for good running.

The belt is next turned over to the final finishing table, where the edges are burnished and the roll made up ready for shipment and sent to the shipping department.

Every center-made belt six inches in width and over takes the central portion of one steer hide for every four feet of length single ply, and two steer hides for every four feet of length double ply. A large main-drive belt made by us was 243 feet long and 72 inches wide, three ply thick. It took the best or central portion of the hides of a herd of 549 steers to make this belt. The average area of a steer hide when it reaches our tannery is 40 square feet. The head, shoulders and bellies are trimmed off and tanned separately for shoe purposes, and only 14 square feet, or the central back portion of each hide, is used for first-class belting. This indicates one reason why good belting is expensive.

Belt Specifications

It is hard to suggest a belt specification which would be acceptable to every buyer and every seller, and there is a great divergence of opinion regarding such specifications. From my standpoint the following is reasonable in all respects:

1. The belting shall be short lap, cut from centers of the best oak-bark tanned belting butts, tanned with oak bark by the old slow and long-time process.

2. No piece of leather in the belt shall be more than 54 inches in length, including laps. The leather shall be cut lengthwise from the extreme end of the butt, eliminating shoulder, and offal of every description. No piece of leather in the belt shall be cut from a portion of the hide further away than 18 inches from the side of the backbone of the animal which shows through the center of the butt.

3. The weights shall be as follows: Single belts, 1 to 2 inches in width, 14 ounces to the square foot. Two and one-fourth to 5½ inches in width, 15 ounces to the square foot. Six inches and over in width, 16 ounces to the square foot. Double belts, 1 to 2 inches in width, 28 ounces to the square foot. Two and one-fourth to 5½ inches in width, 30 ounces to the square foot. Six inches and over in width, 32 ounces to the square foot.

The above weights are for the very best brands of heavy oak-bark tanned leather belting. Of course, belts lighter than these weights can be made and are lower in price. The quality of the leather is just as good but the substance of the belt is thinner. A second weight would be one ounce per square foot under the weights above enumerated, and for a very light-weight solid-stock belt the weights would be two ounces less per square foot than the weights above enumerated.

4. Laps. In single leather belts six inches wide or less, no laps shall exceed seven inches in length, or be less than 3½ inches in length. On all wider sizes of single belts no laps shall exceed nine inches in length or be less than five inches in length. In double leather belts, no lap shall exceed six inches in length, nor be less than 3½ inches in length.

5. Cement. All laps of leather belting shall hold securely in every part, and when pulled apart the surfaces then exposed shall show no resinous, vitreous, oily, or watery condition.

6. Tests. Belts must show an elongation of not more than 15 per cent. for single belts, and not more than 13 per cent. for double belts when subjected to a stress of 1500 pounds per square inch; the elongation to be measured under stress. The breaking strain should be about 3200 to 3500 pounds per square inch of unstressed cross-section, both single and double ply.

Belting Factors

Regarding belting factors there are many rules and regulations that are published and talked about. In Europe they use single belts for everything, whereas in America most of our belts above five or six inches in width are double ply. They carry the single-belt theory to an extreme and use single belts a meter wide. Their idea is that a single belt runs better and will transmit much more power than the same amount of leather put into a double belt; this, however, is not true because the transverse strain on a wide single belt weakens it, and a double belt over eight inches is a good investment for any service and is really necessary as a reserve power. In general they figure too close on the power-transmission proposition in Europe and the belt gets the worst of it. Some of these ideas are coming more and more into vogue here. My opinion is that the old rules that have been used for the past 40 or 50 years are the best.

Regarding the length of belts, it is generally safe to figure that the minimum distance between centers should be three and one-half times the diameter of the largest or driving pulley.

A good transmission rule, and one that leaves sufficient reserve power in the belt, is to divide the number of feet that the belt travels per minute by 800; the result is the number of horsepower that a 1-inch single belt will transmit; in other words, if a belt travels 2400 feet per minute, according to this rule a 1-inch single belt under this condition would transmit three horsepower, a 10-inch belt 30 horsepower, and so on.

A good rule for double belts is to divide the number of feet that the belt runs per minute by 500; the result is the number of horsepower that a 1-inch double belt will transmit; in other words, a double belt 1-inch wide running 2500 feet per minute will transmit 5 horsepower, and wider belts in direct proportion.

These are both old rules but they are safe.

It is impossible to give a hard and fast rule in regard to shortening a new belt before it is placed on its pulleys, and in regard to taking up belts that are in use. The factors for such shortening would vary with the different tannages of the belt leather. The old long-time process of tanning gives a long-fibered leather with more elasticity, more life and more staying power than the shorter-tanned leather. A shorter-fibered leather does not stretch as much as the longer fiber, and while it may have a greater tensile strength in the beginning it lacks the durability of the old-style long-fibered oak-bark tannages.

Thus, while it is impossible to lay down an exact rule regarding how much shorter belts should be cut than the actual tape-line measurement around the pulleys, it is safe to say that the average leather belt in the market today should be cut two inches short for each 10 feet of tape-line measurement; thus a belt that is to be 30 feet long when in place on its pulleys should be cut 6 inches short and this 6 inches stretched out of the belt when it is put in place.

By following this method a belt properly selected for the work it is to do should not have to be taken up at frequent intervals.

In regard to a factor for shortening belts in use the same conditions confront us as regards the different tannages of leather as have been mentioned above, that is, the short-fibered leather stretches less and has less elasticity and a shorter life. Two per cent. of the length should be the maximum that a belt will stretch unless it is severely overstrained. Any belt that stretches over 2 per cent. of its length is overstrained, and is liable to break if stretched to a much greater degree.

Care of Belts in Service

Regarding the care of belts in service, belts which are subjected to extreme heat or dryness need a good belt dressing applied perhaps once every six months, in some cases oftener than this, but once every six months will harm no belt if it is properly done, and this treatment has a tendency to preserve the wearing quality of the belt.

For special service leather link belts are made for drives that have short centers, and are the only belts that we guarantee to run quarter turn; their usefulness, therefore, is limited.

Belt Efficiency

The most efficient belt can perhaps be defined as the one that will give the maximum number of horsepower-hours of service per dollar of belt investment. Sometimes engineers tell us that they wish to put in a temporary drive and that they do not expect the belt to last over three months or one year, or two years, as the case may be. On the other hand, we can point to belts that have been running day after day for some 28 or 30 years and they are still in good serviceable condition. It is evident that a larger belt investment is justified in the latter case than in the former, and such cases must be decided on their individual merits.

Perhaps a short rule for the purchaser to remember in order that he may select belts that will give him the maximum number of horsepower-hours of service per dollar of investment is to design the belts with plenty of reserve capacity.

If a belt is figured according to the ordinary rule given in a previous section of this article, there is a certain amount of reserve capacity, yet it is always safe to add to this another 10 or 15 per cent. for a long-life belt. The more reserve capacity the belt has, the longer will it last and the better will it withstand sudden and severe stresses.

However, all of this is a question of good judgment and common sense on the part of the engineer or mechanic who is putting in the drive. It should be remembered that the first cost of the belt is not the only consideration, neither can it be entirely ignored. For greatest economy, all the considerations must balance.

Leakage Past Various Types of Valve

By James Cannell

A resume of the available information upon valve leakage and deductions showing that this follows a provisional law for slide valves and piston valves.

In these days of strenuous attempts to obtain an engine of maximum efficiency, it is most unfortunate that there should be such a scarcity of reliable information regarding valve leakage. The valves in use at the present time may be classified into four groups: the slide valve, the piston valve, the Corliss valve and the drop valve. There are many varieties in each of the groups, but these variations do not affect them greatly as regards their ability to prevent steam leakage.

It appears that only the slide valve has been tested for steam leakage in a manner that can be accepted as reliable. This was done by Messrs. Callendar and Nicolson in a series of tests on a 10½ x 12-inch engine at McGill University, the report of which is to be found in the *Proceedings* of the Institution of Civil Engineers, Volume CXXXI.

Tests were first made to find the difference between the leakage with the valve as it was and the leakage after the valve had been carefully scraped and refitted. As a result of these tests it would appear that the leakage is not merely a question of such minute differences of fit as could be corrected by scraping. Trials were then made at different pressures in order to find the rate of leakage.

From tests with two other slide valves in addition to this, the investigators were able to formulate a provisional law for leakage, they having found that the leakage was independent of the speed and that the results were remarkably consistent. The formula is:

$$K = \frac{C P}{L}$$

where

K = Rate of leakage in pounds per hour per pound difference of pressure;

C = Coefficient depending upon the nature of the oil film; for slide valves, this varies from 0.20 to 0.22.

P = Perimeter of port;

L = Mean overlap.

During the tests it was seen that the rate of leakage appeared to increase slightly as the oil film was gradually dissipated. It is probably that this film of oil makes the valve steam tight when it is still, but as soon as it begins to move, the oil film becomes broken up and leakage occurs.

The only tests of leakage in a piston valve of which the writer has knowledge were made by Mr. Mitchell at the University of Pennsylvania and published in the October 11 issue of POWER. It is unfortunate, however, that these are presented in such a manner that an analysis of the tests gives only an approximately correct result, but it gives the data necessary for arriving at a formula for expressing the rate of leakage.

In these tests the leakage is shown to increase at the rate of three pounds per horsepower per hour. As the description appears to indicate that the engine was governed through varying the expansion, this leakage evidently occurred at a practically constant pressure difference. The length of the valve face was 1 ⅛ inches, the total length, therefore, being 2¼ inches, and the perimeter of the port was 17.3 inches. According to the foregoing experiments on leakage through a slide valve, the rate of leakage would be constant under the same conditions as that given for the piston valve, and it is not conceivable that it would be otherwise with a piston valve. Hence, taking the average leakage as given, 185 pounds at 100 pounds pressure, the law of slide-valve leakage can be applied to the piston valve and the value of the constant C can be found for piston valves.

$$C = \frac{L K}{100 P}$$

$$C = \frac{1\frac{15}{16} \times 185}{100 \times 17.3}$$

$$C = 0.207$$

From this it is seen that this test shows the coefficient *C* to be practically the same for piston and slide valves.

The following tests illustrate the practical use to which this knowledge of valve leakage can be applied. They were made on a 330-kilowatt high-speed engine fitted with piston valves and the experiments were carried out in order to improve the economy of the engines of this type.

They were first made at various loads with a standard engine which had valves without rings, and which had run for some days to give its bearings, piston rings, etc., time to get to a proper working fit. The engine was governed by the throttle. The curves, here shown, representing the total steam per hour, follow Willan's law.

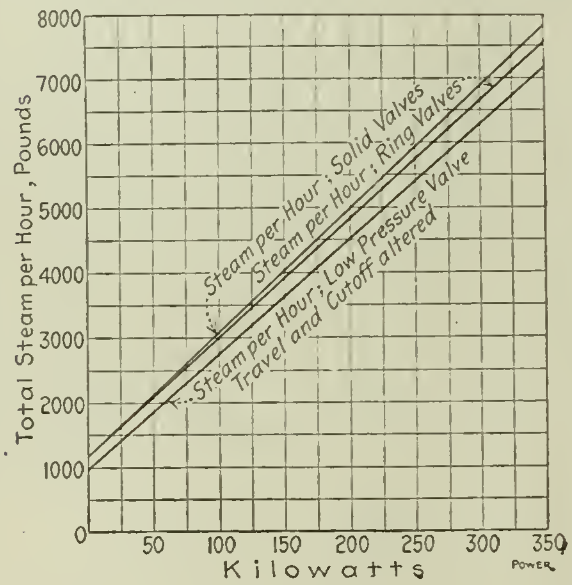
The curves show that the gain in economy with the ring valves is about 3 per cent. at full load, but at light loads there is practically no gain. This gain at full load was greater than was expected and the gain diminishing with the load is probably explained by the fact that the pressure is reduced with the load.

It was then decided to lengthen the travel of the low-pressure valve by fitting a new low-pressure eccentric; this permitted a greater length of valve face, and, as Messrs. Callendar and Nicolson found that the leakage of a slide valve was directly proportional to the length of the face, it was hoped that an appreciable saving would be effected in the economy of the engine. The travel of the valve was altered from 4½ to 6½ inches and at the same time it was arranged to cut off at 45 per cent. of the stroke instead of 60 per cent. This enabled a still greater length of valve face to be obtained. Altering the cutoff in the low-pressure cylinder does not affect the power of the engine but it slightly alters the distribution of the load between the cylinders. These alterations increased the length of the valve face from 4½ to 6 inches at the top end and from 4¼ to 5¾ inches at the bottom, giving a total difference of 34 per cent.

The results of tests at various loads with the longer travel low-pressure valve are shown by the bottom curve. Comparing these with the previous tests in which ring valves were used, it is seen that there is a gain by giving a longer travel to the low-pressure valve and having an earlier low-pressure cutoff of about 4.5 per cent. at full load and about 7 per cent. at half load. Also, the curves show that 350 pounds of steam per hour has been saved at full load but the saving gradually decreases as the load decreases.

It might be considered that altering the low-pressure cutoff improves the economy of the engine; however, it has been proved that this does not affect the economy in the slightest degree, both on piston-valve engines and on slide-valve engines.

As far as can be ascertained there are no published tests of the steam leakage of Corliss valves. It would seem probable that the leakage would follow a law somewhat similar to that of slide-valve leakage. However, it is shown by Messrs. Callendar and Nicolson that this should not be so in actual practice as with this type of valve both the live and exhaust steam do not pass through the same valve. They stated that the leakage probably occurred mainly in the form of water which was condensed on the valve faces, and then reëvaporated. As the result of their tests, they stated that this leakage might be greatly reduced by jacketing or otherwise heating the valve seat and thus minimizing the condensation; furthermore, that an engine with



LEAKAGE AT VARIOUS LOADS

separate steam and exhaust valves would possess advantages as regards steam leakage over a slide-valve engine, owing to the smaller condensation on the steam-valve face.

In the discussion on a paper read before the Institution of Mechanical Engineers in July, 1904, Mr. Longridge stated that superheating played an important part in reducing valve leakage. With fluids of small viscosity, such as steam and water at high pressure, the velocity of flow through a small orifice such as might be supposed to exist between a valve and its seat would depend almost entirely upon the difference of the pressure and would be practically equal under a given pressure whether the leaking fluid were steam or water. As the density of water is so much greater than that of steam, it is easily seen that the weight of water leakage would be very much greater than that of steam, and the effect of condensation is evident.

With drop valves the seats are either flat or conical. Experience has shown that flat seats are preferable provided the dashpot is of an efficient type; or if a positive gear is used, it might be considered that the leakage through these valves would be practically nil, for when steam is not being admitted the valves are on their seats and there is no clearance between the valve and its seat. This, however, is not true in practice, for even with the valves made to fit as perfectly as possible there is a slight leakage of steam, and if they be of large diameter this leakage becomes sufficient to run the engine if a high vacuum is maintained in the exhaust pipe and there is no load.

Tests showing the leakage of these valves have not been published, but in Volume CLXXIII of the *Proceedings* of the Institution of Civil Engineers, Mr. Preece shows that the leakage is less than with valves which have rubbing surfaces where a certain amount of clearance is necessary.

In actual practice with piston- or slide-valve engines the gain due to superheat is much greater than the gain with the same amount of superheat in drop-valve engines. This larger gain is maintained up to a certain degree of superheat, after which the gain due to increased temperature is practically the same for both types of engines, and this is correct whether the engines be expansion or throttle governed. This can be explained only by the fact that the condensation on the valve face of the slide or piston valve is decreased by the increasing temperature until the point has been reached at which the leakage of these types of valves becomes equal to that of the drop valve, the cylinder condensation and all other things affected by the superheat being the same with each type.

Warnings

The Manchester Steam Users' Association issues the following:

Don't overload the safety valves or tamper with them.

Don't let the water level sink out of sight.

Don't allow the cocks and valves to set fast.

Don't open the steam stop valves hurriedly.

Don't empty the boiler while steam is up.

Don't open manholes before easing safety valves.

Don't raise steam hurriedly.

Don't use unknown scale solvent or compositions.

Don't slake ashes against boiler fronts.

Old Hal Mossback, th' ingineer et th' ladies' rat factery, went t' sneeze tother day and his false teeth drapped out an' rolled inter th' flywheel. Hal wanted t' shet down an' get 'em out but th' boss told 'im the th' wimmin hed th' rat bizness rushed so dumd hard thet they didn't hev time t' stop. Hal sed he gessed thet et wuz up t' 'im ter live on soup th' rest uv th' week.

Cooling System for Condensing Water

By R. O. Warren

A homemade tower costing but $425 for material and labor lowers the temperature 50 degrees of all the circulating water used for 1500 horsepower of condensing engines.

A homemade cooling tower, costing but $425 for labor and material, is installed at the power plant of the Fitchburg & Leominster Street Railway Company, Fitchburg, Mass.

There is a made pond, having a natural bottom and concrete side walls, that contains the water used for condensing purposes. City water is used exclusively for boiler feed, which, when condensed, is discharged into this pond, the supply being more than sufficient to make up for the loss by evaporation. The pond is 70x70 feet, with a depth of 7 feet. Pond water is not used for boiler feeding, because it is contaminated to a considerable extent with dirt and oil.

The design of the cooling tower is shown in the accompanying illustrations. It is a structure 150 feet long and 10 feet wide, equipped with three cooling platforms, as shown in Fig. 1.

The platforms, all of which have a drop of 1 foot in 50, are made of 2-inch spruce planking and are supported by 6x6-inch timbers, each 8 feet long. The top cooling floor has baffle strips secured to the upper surface in the form of a V, which ruffles the water and causes some of it to fall over the edges of the platform, as shown in Fig. 2. There are four rows of side deflecting pieces, also shown in Fig. 2, the three top deflectors slanting toward the outside edge and downward; the lower one slants toward the bottom floor. This arrangement causes the water to drop from one deflector to the next one below, the bottom deflector catching the water and diverting it to the lower cooling platform.

The condensing water is discharged from a jet condenser through a 14-inch pipe which is capable of taking care of two of the largest engines in the plant. The second discharge pipe is 10 inches in diameter and is connected to a second jet condenser. Both of these pipes are fitted with a Y connection, so that by opening a valve in the bottom pipe, the condenser water can be discharged direct to the pond through the lower pipes, shown in Fig. 3, without passing over the platforms of the cooling tower. This is desirable when the water is at a high level in the pond due to heavy rains, for it is then cool enough for condensing purposes. The discharge from the lower platform is onto a float, as shown in Fig. 2. This causes the water to flow into the pond in a thin film from the four sides of the float.

The temperature of the circulating water, after passing over the cooling platforms is lowered 50 degrees Fahrenheit. The tower will easily handle the

Fig. 3. Arrangement of Discharge Pipes

Fig. 1. Showing Three Cooling Platforms

Fig. 2. Showing Deflecting Boards

condensing water for 1500 horsepower of engines and 2000 horsepower if necessary, although there would be less drop in temperature with the greater quantity.

The pond is connected to the suction well by a 24-inch pipe. In case it is necessary to clean the well, a gate is lowered over the end of the 24-inch pipe leading to the pond. The slides for the gates are made of railroad rails and the gate is raised by means of a handle passed through an extension rod.

Special Setting for Water Tube Boilers

By Edward J. Kunze

An outline of the fundamental principles of combustion and heat transmission, application of which is made in a special form of setting intended to eliminate smoke when using soft coal.

Viewed from the standpoint of smoke formation, one of the worst conditions where soft coal is used, is that of having the grate directly under the tubes in the first pass. In many plants, thus equipped, there is not enough space in front of the boilers to permit adding an extension furnace, and it is to meet this condition, particularly, that the setting here illustrated was designed. Before examining in detail the constructive features of this setting it might be well to consider the fundamental principles which underlie its use.

Among the agents that prevent the proper mixing of air and gas are the so called "neutrals" consisting mainly of carbon dioxide, nitrogen and water vapor. If enough neutral is added, combustion may be entirely prevented. For instance, if one part of carbon dioxide is mixed with seven parts of a combustible mixture of gas and air, ignition and combustion will not take place. Likewise, if one part of nitrogen is mixed with six parts of the combustible mixture, the power of combustion is nullified. Therefore, it is important that the neutrals be removed from the combustible matter as soon as they are formed. If the water vapor, formed by combustion, is allowed to mix with the heated gases, it may also become dissociated, taking up heat from the surrounding gases and cooling them.

The quantity of steam in a boiler produced does not depend upon the intensity of the fire, but upon the amount of heat absorbed by the water from the burnt gases which are the conveyer of the heat. According to Perry's theory, the rate of impartation to a boiler tube is for ordinary gases proportional to:

1. Temperature difference of the gases and the metallic surface.
2. Density of the gases.
3. Velocity of the gases parallel to the metallic surfaces.
4. Specific heat of the gases at constant pressure.

To these I should add:

5. Character of the metal surface.
6. Heat-conducting property of the metal.

Usually the first factor alone is considered. The second assumes that an increase in density causes the contact between the molecules of gas and the part to be heated, to be more intense. From the kinetic theory of gases the individual molecules of gas give up their heat by vibrating against the metal; the greater the number of molecular impacts per second against a unit area of the metal, the greater the amount of heat imparted to the metal. But the number of impacts is directly proportional to the density, which, in turn, at a constant pressure, is inversely proportional to the temperature. On this account there is a direct neutralization of gain when striving for high temperature; for, as the temperature is raised, the number of molecules in action against any portion of the heating surface is reduced.

Regarding the third factor, consider the molecules of the metal in a state of rapid vibration with spaces between them much larger than the molecules. Entangled among the outer molecules of the metal there would be comparatively stationary molecules of gas held close together in a dense film next to the metal. Farther out, normal gas is reached, where the molecules are widely scattered. These gaseous molecules would be in a state of rapid vibration, but those close to the metal would be more or less bound by the attraction of the metal, and serve as a poor conductor of heat. Hence, the hope of transmitting more heat lies in the dislodging of the slowly vibrating molecules and replacing them with rapidly vibrating or hot ones. The dislodging molecules fly back and forth perpendicularly to the surface, and this scrubbing effect on the layer adhering to the metal is proportional to the velocity of the gas parallel to the heating surface. This velocity, therefore, has an important influence upon the heat transmission.

The products of combustion at a high temperature take the shortest course and will not spread over the entire heating surface unless external means such as baffling are resorted to. In order to prevent the thinning out of the heat current or short-circuiting the flow, A. Bement advises increasing the number of passes. He gives, as a result of changing from the single to the double pass, an increase of 10 per cent. in efficiency and about 4 per cent. more horsepower than the regular design of boiler. The result of triple passing as compared with the single pass gave an increase in efficiency of about 20 per cent. and an increase in capacity of approximately 4 per cent. In other words, the increased capacity of this triple pass is the same as with the double pass, although the gain in efficiency is twice as great. With the double pass the draft at the fire was unaffected. With the triple pass, however, the resistance offered by the passages reduced the draft at the fire, so that less coal was burned than with the same boiler having a single pass; but this is not a serious objection, because more horsepower was produced. Since baffling of this character brings into use twice as much or more boiler surface than was formerly utilized, it justifies the realization of a much larger capacity and the use of higher draft.

In considering factor four, it is evident that since a given volume of any gas at any temperature and pressure contains the same number of molecules as the same volume of any other gas under the same conditions, and since various gases upon cooling give up various amounts of heat per degree of temperature drop, a given number of molecular impacts of different gases will give up more or less energy according as the specific heats of the gases are respectively higher or lower.

Regarding factor five, the nature of the metal surface, this affects the heat transference by its ability to more or less entangle the molecules of the gas.

The reversed setting here shown has been criticized because it requires a greater hight, of about 4½ feet, in both setting and boiler house, with a correspondingly larger investment and maintenance cost; also that the mud drum is over the ignition arch. It is claimed further that this arrangement is not as effective in producing complete combustion as one which pitches downward toward the back. The writer believes, however, that these objections are not well taken.

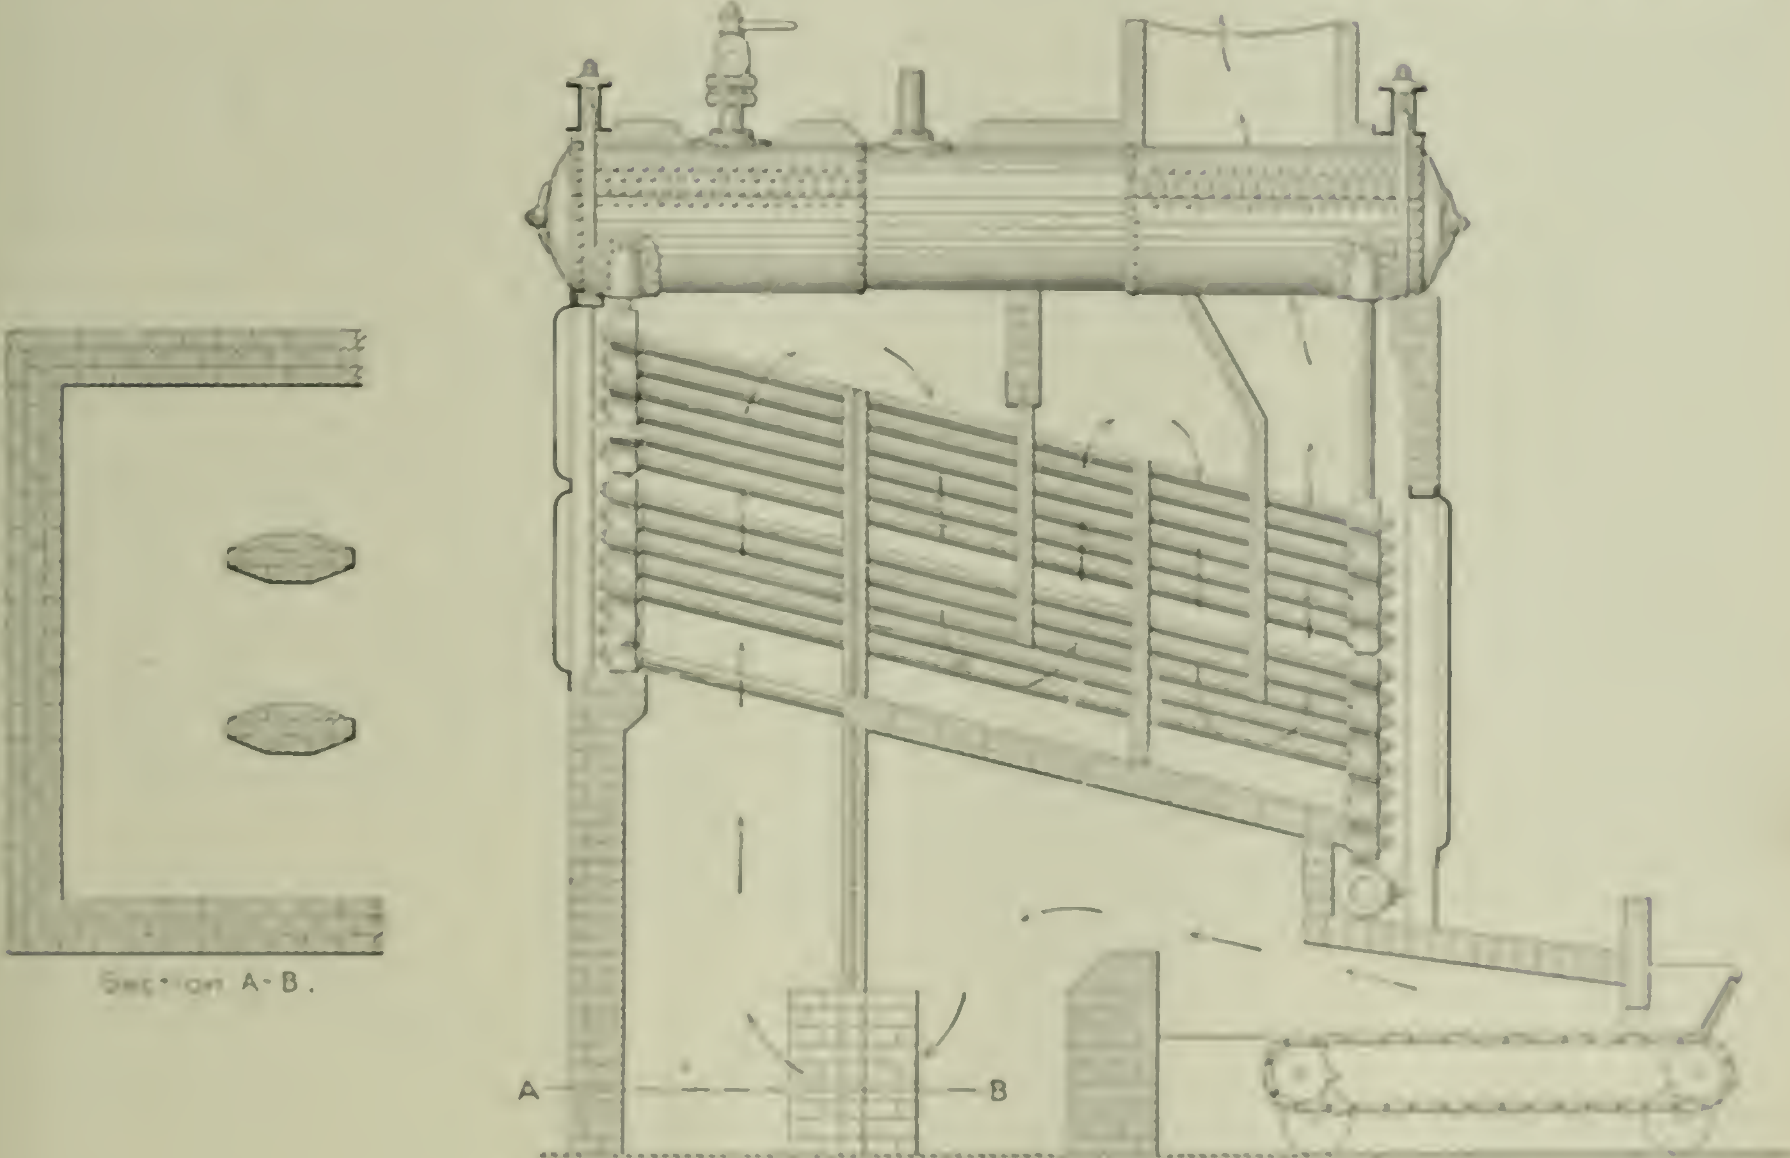
The advantages of a larger combustion chamber more than counterbalance the expense attendant upon a higher setting, and while it is admitted that the extra hight increases the cost of the building, it is more essential to decrease

*From a paper delivered at the annual meeting of the Michigan Engineering Society, January 11, 1911.

floor space which is more valuable, especially in plants already constructed. Floor space costs more than hight in large cities; also it is more necessary to keep the floor space in the boiler room reduced to a minimum than is the case with the engine room, so that corresponding units, especially in steam-turbine plants, may be as close as possible to each other. Regarding the mud drum, this is protected by hollow firebrick, and it would not be heated to as high a temperature as is the case where unprotected in the rear of the boiler, as is true of many settings now in operation.

The last objection may be answered by saying that in the design here shown the gases are diverted downward and pass through a more or less restricted area before rising to the tubes.

Another objection that has been raised to the reversed setting is that the radiation and unaccounted for losses would be increased. The fact is that in the majority of cases these losses amount to about 1 per cent. of the total heat available and most of this loss occurs through and around the doors, and is due to the necessity of opening the doors for feeding, slicing, poking, etc. In the case of well painted brickwork, it is often found necessary to heat the boiler room by some other means, not enough heat being radiated from the boilers.



Section through Boiler Setting

The advantages of the setting, as submitted here, may be summarized as follows:

1. Increased combustion-chamber volume without increased floor space.

2. Decreased velocity of the gases as they enter the combustion chamber, since there is a gradual increase in cross-sectional area. This permits better mixture between the combustible gases and the air, tending to avoid the formation of air shoots or impinging streams of cooler air with the accompanying tendency to effect an unequal heating of the tubes and cause unequal expansion of parts. The better mixture permits a reduction in the percentage of excess air required, hence there will be less cooling of the gases and better economy. Ordinarily the time required for the gases to pass from the grate to the heating surface of the boiler averages considerably less than a second, which is a very short time for the process of combustion to take place. If the passages are of large enough cross-section, a better opportunity is given for the neutral gases to separate from the burning gases; the latter, being hotter and lighter, will take the upper paths while the carbon-dioxide, water vapor and similar gases take the lower paths and avoid the detrimental action of preventing proper combustion. If the carbon dioxide generated on a thin fire is permitted to rise promptly from the fuel bed, as is the case when the space above the grate is large, there is less tendency for conversion into carbon monoxide. It is only when the carbon dioxide is passed through a thick bed of fuel or in close contact with an incandescent bed of fuel that this conversion takes place.

3. With the baffle in the rear, the gases are brought close together because of the restricted area just before rising to the tubes; therefore, there is a greater tendency toward complete combustion, and equal heating exists.

4. The large combustion chamber affords a large capacity for heat storage.

5. The larger cross-sectional area of the combustion chamber permits the introduction of firebrick baffles, without reducing the area of draft.

6. There will be a tendency for a body of air or cooler gas to collect under the roof. This body would not move as fast as that directly in the line of travel. As this line of travel is lowered by the baffle in the rear, there will be less injury to the furnace roof due to erosion than in the case of the downward sloped roof.

7. The boiler tubes can be readily removed or cleaned from the front of the boiler, thus avoiding the requirement for much room at the rear of the boiler for this purpose.

Indicator Diagrams and Calculations

By Frank S. Bunker

The steam-chest and the friction diagrams and what they show. The valve-rod diagram and how it is obtained. Method of plotting the combined diagram and the diagram of useful work. How to estimate the quality of the steam and the cylinder clearance from the diagram.

The taking of indicator diagrams from the cylinders of an engine and the subsequent examination, together with the time-worn formula,

$$HP. = P\,L\,A\ (2N) \div 33{,}000,$$

using the mean effective pressure estimated from the diagram to ascertain the indicated horsepower, form a part of every engineer's stock in trade.

The indicator diagram is, in reality, a graphic portrayal of the performance of the working medium (steam, gas, etc.), in whatever type of machine it may be necessary to inspect.

With favorable conditions and an equipment in proper shape, diagrams may be obtained which can be accepted as an infallible guide. Every precaution should be taken so that the sample of the working medium tested by the indicator will have the same physical and chemical qualities as those of the mass from which it is drawn. Care should be exercised so that the temperature, the degree of saturation or dryness fraction and the degree of superheat, if there be any, be unaltered. In other words, make the conditions in the indicator conform as closely as possible with those in the part under examination.

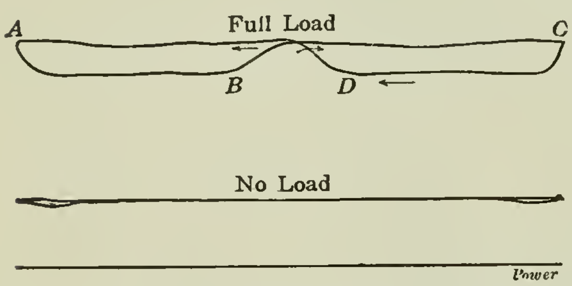


Fig. 1. Steam-chest Diagram at Full and No Load

Valve-chest Diagrams

Diagrams taken from the steam chest of an engine are always advisable as they show the fluctuation of pressure that takes place there and are thus a very good indication of the adequacy or the inadequacy of the carrying capacity of the steam-supply pipe which for many reasons may not supply the engine with the necessary number of B.t.u. An insufficient supply may be due to too small a supply pipe, a very crooked pipe offering an excess of friction or to an exceptionally long pipe improperly insulated, thereby causing excessive condensation.

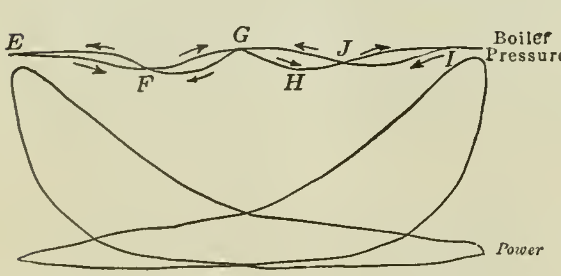

Fig. 2. Combined Steam-chest and Cylinder Diagrams

Fig. 1 shows diagrams taken from the steam chest of a high-speed engine under full load and under no load. The speed was 325 revolutions per minute and the cutoff, ⅖ of the stroke. As the valve opened at points *A* and *C*, the pressure dropped, thus showing the draining influence of the engine on the steam supply. When cutoff occurred at *B* and *D* the pressure rose to boiler pressure.

Fig. 2 shows combined steam-chest and cylinder diagrams from a twin-cylinder high-pressure launch engine with atmospheric exhaust. One steam chest supplied both cylinders with steam through two D-valves. The valve opened to steam at *E* and caused a drop in pressure until cutoff at *F*, after which the pressure rose to *G*, at which point the companion cylinder began to take steam and cause the drop in pressure to *H*. After cutoff the pressure again rose to boiler pressure until the end of stroke, when the opposite end of the first cylinder again took steam, causing a drop along the line *I J*, and thus the cycle was continued on back to the original point *E*.

Friction Diagrams

Another diagram of vast importance is the friction diagram. With its aid it is possible to estimate the amount of power necessary to overcome the friction of the engine. Such diagrams are taken in the usual manner with the engine running at full speed but with absolutely no outside load.

Fig. 3 shows a set of friction diagrams taken on a cross-compound automatic engine of 1200 horsepower capacity. The boiler pressure was only 37.5 pounds. The high-pressure diagram was taken with a 15-pound spring and the low-pressure with a 10-pound spring. The high-pressure diagram indicated 81.7 horsepower and the low-pressure indicated — 5.2 horsepower. This nets a total of,

$$81.7 - 5.2 = 76.5$$

indicated horsepower. It therefore required 76.5 horsepower to overcome the internal friction of this 1200-horsepower engine.

Friction diagrams are valuable for they give information which will oftentimes indicate trouble due to increased friction and consequently increased waste of power.

The Valve-rod Diagram

Although the valve-rod diagram is unique, very valuable information may be obtained from it. The indicator is placed on the cylinder of an engine having an inertia governor and consequently having a variable valve travel. The paper drum receives its motion from the travel of tho valve stem. The length of the diagram should be as near as possible some even fraction of the valve travel as ¾, ½ or ⅓, as this will greatly facilitate later computations. Having determined this fraction it will be necessary to open the valve chest and obtain the following data for use with the diagrams: width of steam port, steam lap and exhaust lap when the valve is in mid-position.

With these data as a guide, a valve model is constructed, as shown below the diagram in Fig. 4. The line *C L* being the mid-position, lay off from it equidistant on each side the distances *K* and *L* equal to the exhaust lap and the distance $K + M$ and $L + N$ equal to the steam lap. The distances *P* and *Q* are equal to the width of the steam ports and the total distance overall is the total valve travel. The diagram shown in Fig. 4 is a facsimile of a diagram obtained in the manner described, by giving the paper drum its motion from the valve travel.

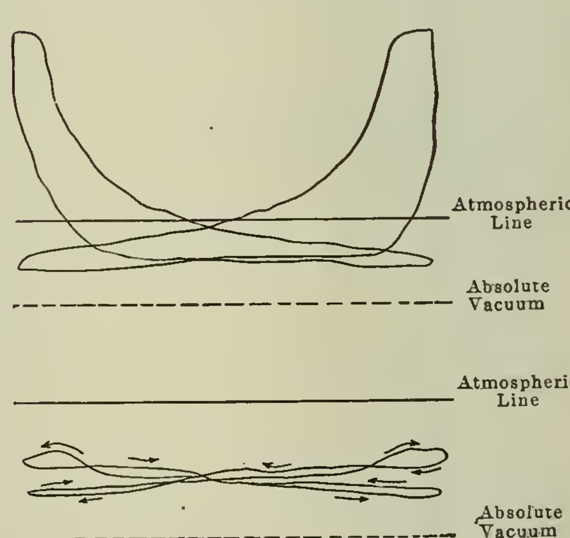

Fig. 3. Friction Diagrams from a 1200-horsepower Compound Engine

After dividing the total length of the diagram into two equal parts and marking the center as the mid-position, then by placing the valve model *mid-position* in line with this position and extending the various lines in it upward until they cut the diagram the perfect cycle of events is shown much more clearly than with diagrams of the ordinary kind. At *a*, exhaust has just closed and compression begins and when the valve has traveled the distance equivalent to *K* the valve is in mid-position. Compression continues until the distance $L + N$ has been traveled, when the valve opens to lead and the pencil rises along the steam-inlet line and continues on along the steam line to the end of the valve travel, getting slightly higher as the valve opening increases and slanting downward as the valve opening diminishes until the point *b* is reached. At this point the steam valve closes, cutoff is completed and expansion begins. During the expansion of the steam in the cylinder the valve must travel through the distance $N - L$ or the steam lap and through the distance *K* or the exhaust lap. At the point *d* the valve opens to exhaust and the pressure drops until forced to rise slightly by the forcing effect of the piston in purging the cylinder. The pressure continues thus until the exhaust closes at *a*. On no other type of diagram can the points of absolute cutoff and release be ascertained as accurately as on this type; and as the load changes and the valve travel increases or diminishes, the same events may be distinguished even though the travel becomes so short as not to allow the valve to uncover the steam ports.

A leaky piston may be indicated by this diagram as well as by any other, and in the case of leaky valves it will show the exact point in the valve travel at which the leak occurs.

The diagram may be taken from any engine having a piston or slide valve. It is exceptionally valuable with engines having inertia governors as it gives accurate information in regard to the action of the governor during operation when it is not possible to get data in any other way.

The Combined Diagram

It is often necessary to reconstruct the diagrams obtained from an engine the better to portray the performance of the machine. This is especially true of compound-, triple- and other multiple-expansion engines for which the diagrams are so reconstructed as to appear as if the steam had acted all the time upon the low-pressure piston only. In reconstructing diagrams of this type they are all plotted upon the same *volume* base, but with the respective pressures represented by ordinates whose lengths are directly proportional as the scales of springs used.

Fig. 5 shows indicator diagrams from the high- and low-pressure cylinders of a very poorly designed engine. The

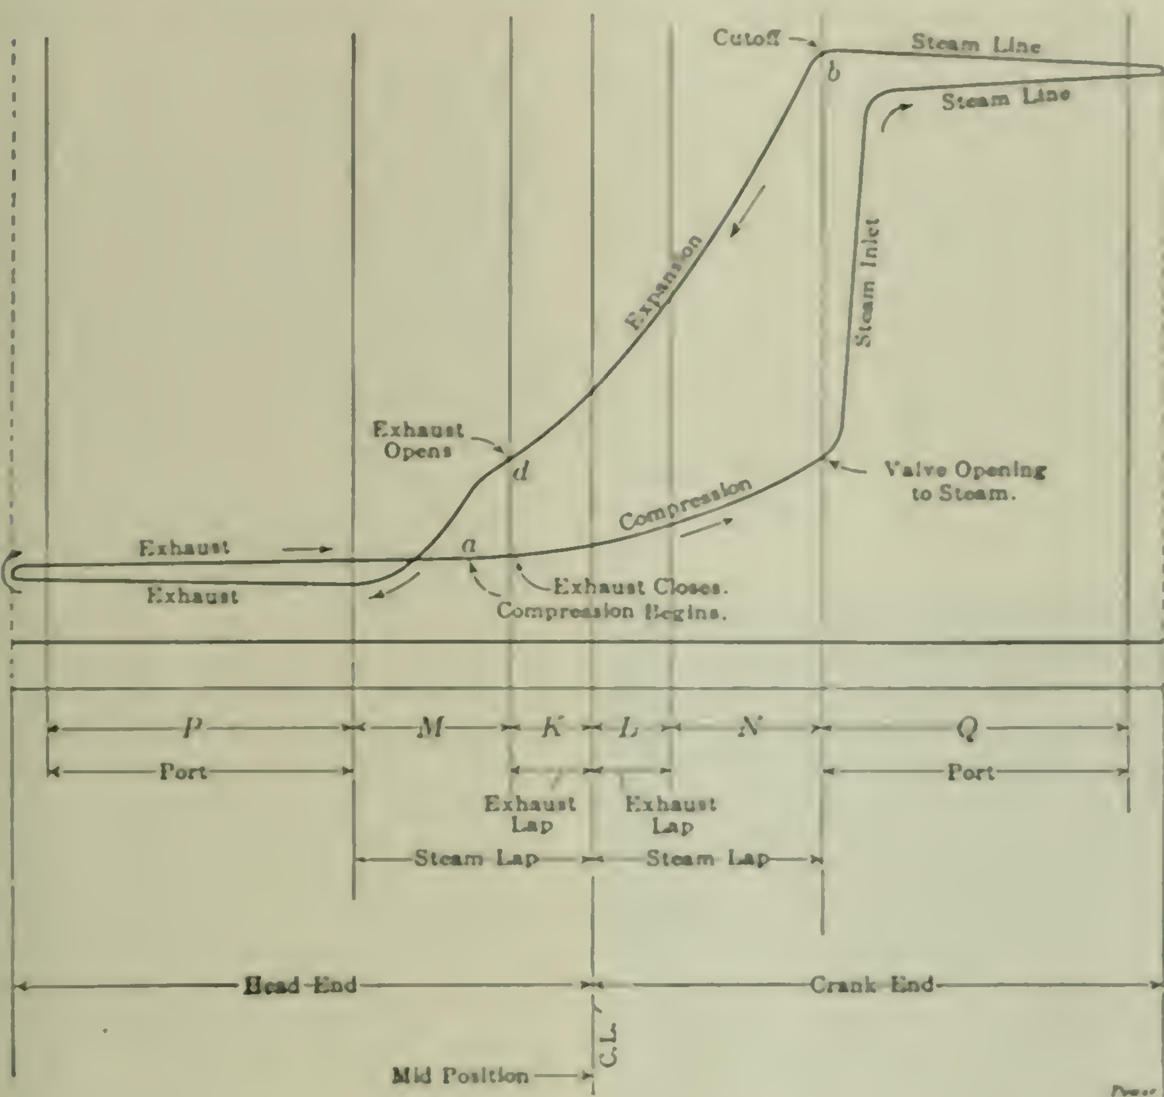

FIG. 4. VALVE-ROD DIAGRAM

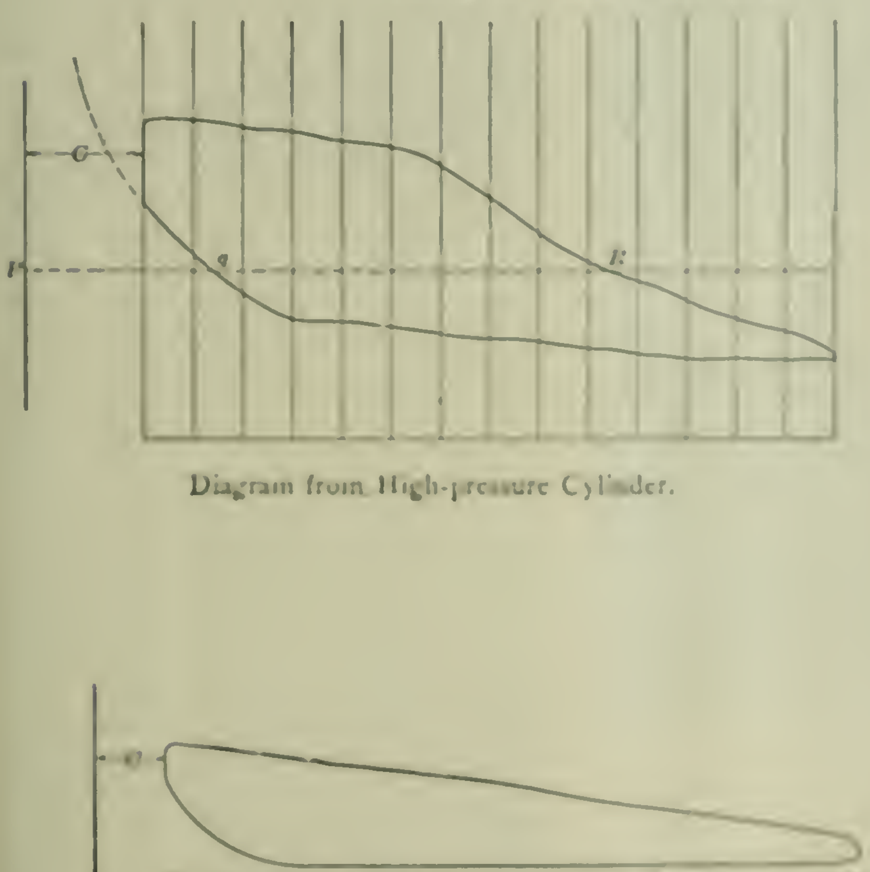

Diagram from High-pressure Cylinder.

Diagram from Low-pressure Cylinder.

FIG. 5. HIGH- AND LOW-PRESSURE CYLINDER DIAGRAMS

FIG. 6. THE COMBINED DIAGRAM

spring used for the high-pressure diagram was calibrated for 100 pounds; that for the low-pressure, 40 pounds. The cylinders were 20 and 30 inches in diameter, respectively.

In Fig. 6, *R S* is the atmospheric line and the vertical line *R T U* is the line of zero volume. The low-pressure diagram is here plotted with the clearance volume shown as *R V*. The horizontal line *W X* is the pressure line of the low-pressure diagram.

Returning now to the high-pressure diagram in Fig. 5, it is necessary to divide the diagram into a number of ordinates for future plotting. As the high-pressure spring was 100, and the low-pressure spring 40. in plotting the high-pressure diagram in the proper proportion it will be necessary to multiply each ordinate in Fig. 5 by $\frac{100}{40}$ or 2.50 before transferring to Fig. 6. Furthermore, the

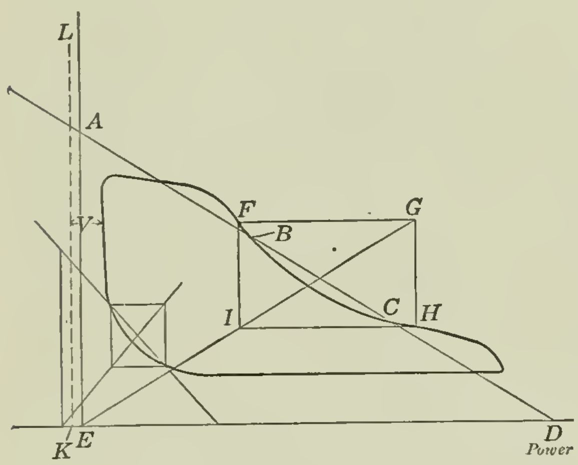

Fig. 7. Illustrating Method of Estimating Clearance

diagrams must be on the same volume base; and as the cylinders were 20 and 30 inches in diameter, the volumes swept through by the pistons vary as

$$20^2 : 30^2 \text{ or } 4 : 9 = 2.25.$$

Therefore, the horizontal length of the high-pressure diagram must be reduced by dividing its total length by 2.25. The reconstructed high-pressure cylinder appears in Fig. 6 in the upper half. In this diagram the work done in the high-pressure cylinder is represented on the same scale as is that done in the low-pressure cylinder.

The length *V S* represents the volume swept through by the piston and *R V* the clearance volume. At the pressure *R W* the actual volume of steam expanding in the cylinder is represented by *W X*. Of this total volume the amount *W Y* was trapped by the valve at the commencing of compression. Therefore, the volume represented by *Y X* is the steam which entered as new steam while the steam port was open and which will pass out during exhaust.

In the high-pressure part of the reconstructed diagram it will be seen that if the compression of the imprisoned steam had continued up to the initial pressure, the compression curve would be as *e f g* and the clearance volume would be quite full of steam at that pressure at the beginning of the stroke. All steam which then entered the cylinder would perform useful work while the compressed steam would act merely as a buffer and would exert as much work on the piston as was expended on it by the piston during compression. It therefore would neither contribute nor detract from the net useful work performed. When the cushion of steam is not compressed to boiler pressure, the incoming steam performs that function. The clearance volume represented by *U h* is filled with steam at the beginning of the stroke and the volume of the cushion steam at the same pressure is represented by *g h*. The difference or *U g* is, therefore, the volume of steam necessary to complete compression and the area *f g h* represents the amount of work lost thereby. This is replotted as *h j f* and this indicates the reduction of the area of useful work.

By referring now to a diagram of a rectangular hyperbola and placing the line of zero volume on the vertical axis *R U* and the line of zero pressure on the atmospheric line *R S*, the curve which most nearly corresponds to the expansion curve of the two diagrams may be plotted as *m n p*.

The area between the two diagrams represents the loss due to the poor construction of the engine and the faulty proportions of the design. The area between the hyperbolic curve and the diagram areas represents the losses due partially to this cause and partially to throttling, wiredrawing, radiation and condensation, and if an adiabatic curve is drawn in place of the hyperbola, the loss will show as due to condensation in the cylinders over and above what would have occurred with adiabatic expansion in cylinders which were nonconductive.

Steam Quality

The quality of the steam as it passes through an engine may be determined from the combined diagram. During the test determine the steam consumption and from this calculate the weight of steam used per stroke. Draw a horizontal line as *T e n r* so as to cut the expansion and compression curves. The line *T e* represents the cushion steam and *e n* the actual volume of steam passing through the engine per stroke. The line *t r u* is a saturation curve. Then *n r* must represent the volume of steam which has condensed and exists as moisture at that pressure.

If *n r* represents the moisture and *T n* the dry saturated steam in the cylinder and clearance space, then $\frac{T n}{T r}$ will represent the fraction of the whole which is dry saturated steam.

This is called the dryness fraction. To determine the location of the saturation curve on the diagram it is necessary to find the point *r*. The distance *e r* is laid off to represent the volume of steam used per stroke of the engine as spoken of previously.

As the same total weight of the steam and water mixture will exist throughout the stroke, it is only necessary (by reference to steam-saturation tables) to obtain the volume of that weight of dry-saturated steam at various pressures and to plot them at the right of the compression curve which, if too short, may be continued by reference to the rectangular hyperbola, as in the dotted line *f g*.

The same process is followed for the low-pressure cylinder and is necessary on account of the difference in the clearance space of each cylinder. The line *y z* is the saturation curve of the low-pressure diagram.

Estimating the Clearance

The clearance space of an engine is generally calculated from the working

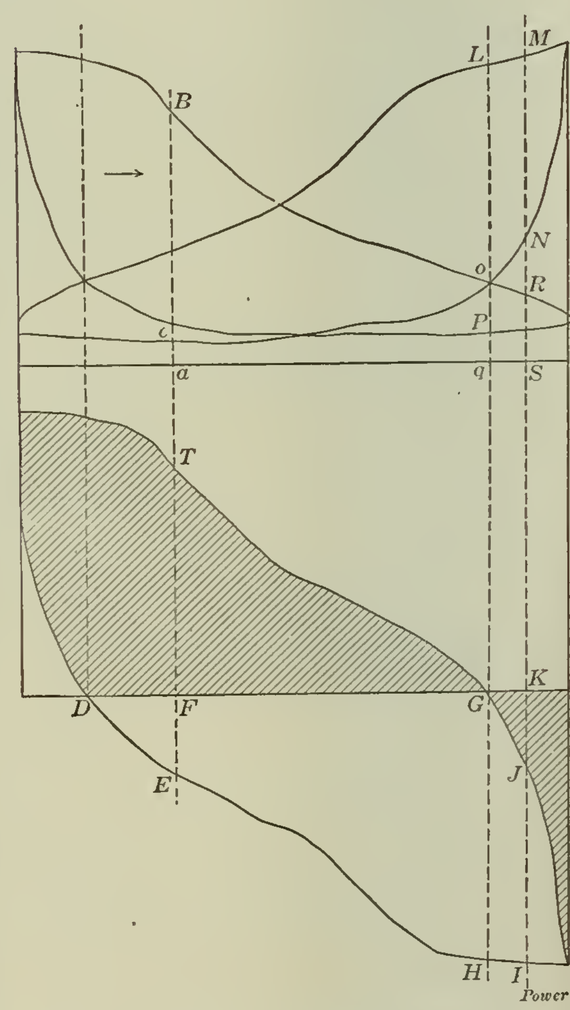

Fig. 8. Resultant-pressure Diagram

drawings of the engine. It may also be found by filling the cylinder and clearance space with water and in this way calculating the required volume. Fig. 7 serves to show the way to approximate the clearance volume from an engine diagram. Draw any line *A B C D* cutting the expansion line and lay off from *B* a distance *B A* which is equal to *C D*. Through *A* erect the perpendicular *A E* to the atmospheric line *E D*. Another method is to construct a rectangle as *F G H I F* parallel to the atmospheric line and with opposite corners on the expansion line *F H*. Then, the opposite diagonal is drawn and extended until it intersects the atmospheric line as at *E*. The same method may be followed with the compression curve and a general average taken of all the results as the dotted line KL which is then drawn. Its distance from the diagram area as V represents the approximate clearance volume of the particular cylinder under consideration.

Useful-work Diagram

It is often useful to reconstruct a set of diagrams to obtain the resultant of the positive and negative pressures acting on the piston. This is a graphic portrayal of the useful work done by the working medium. Such a diagram is shown in Fig. 8. At any point a in the stroke of an engine the pressure exerted for useful work is represented on the diagram by aB, and the pressure on the opposite side of the piston by ac.

The resultant effective pressure is therefore the differences between these two or cB. In plotting the resultant-pressure diagram, effective forward pressures are all plotted above a central line and effective pressures in the opposite direction are plotted below the line. Let $DFGK$ represent this central line. At F plot $FT = cB$. When the piston reaches q the forward pressure is qo, but the back pressure due to compression on the opposite side of the piston is also qo, so the effective forward pressure is zero and the resultant pressure line therefore crosses the base line at G.

With the piston at S and still moving in the same direction as the arrow the forward pressure is SR and the back pressure SN. The resultant is the difference or RN and is in the backward direction and therefore is plotted downward at KI. As the motion continues the same process is carried out. The cross-hatched section above the line represents the useful work done on the piston in the forward position by the steam and the shaded area below the line represents the negative work due to the purging action of the piston during exhaust and the compression. The same process may be followed for the return stroke and effective pressure plotted below the line and negative work above. The area between the two curves thus obtained would represent the net useful work performed during the two strokes or one revolution.

The resultant-pressure diagram is very necessary in the designing room and also very useful to the operative engineer.

The net area of useful work designated by the resultant pressure diagram should always equal the area of the indicated horsepower diagram.

In calculating the mechanical efficiency of an engine, it is necessary to subtract the frictional horsepower from the indicated horsepower and divide this result by the indicated horsepower, thus:

Indicated horsepower, 1200; frictional horsepower in high-pressure cylinder, 81.7; frictional horsepower in low-pressure cylinder, 5.2.

$$\frac{1200 - (81.7 + 5.2)}{1200} = \frac{1200 - 86.9}{1200} = 92\tfrac{3}{4}$$

per cent

The friction is greater at heavy loads than at light loads although not necessarily much greater. The probable mechanical efficiency of this particular engine at full economical load would be about 92 per cent., which is excellent.

Attractive Piping Job

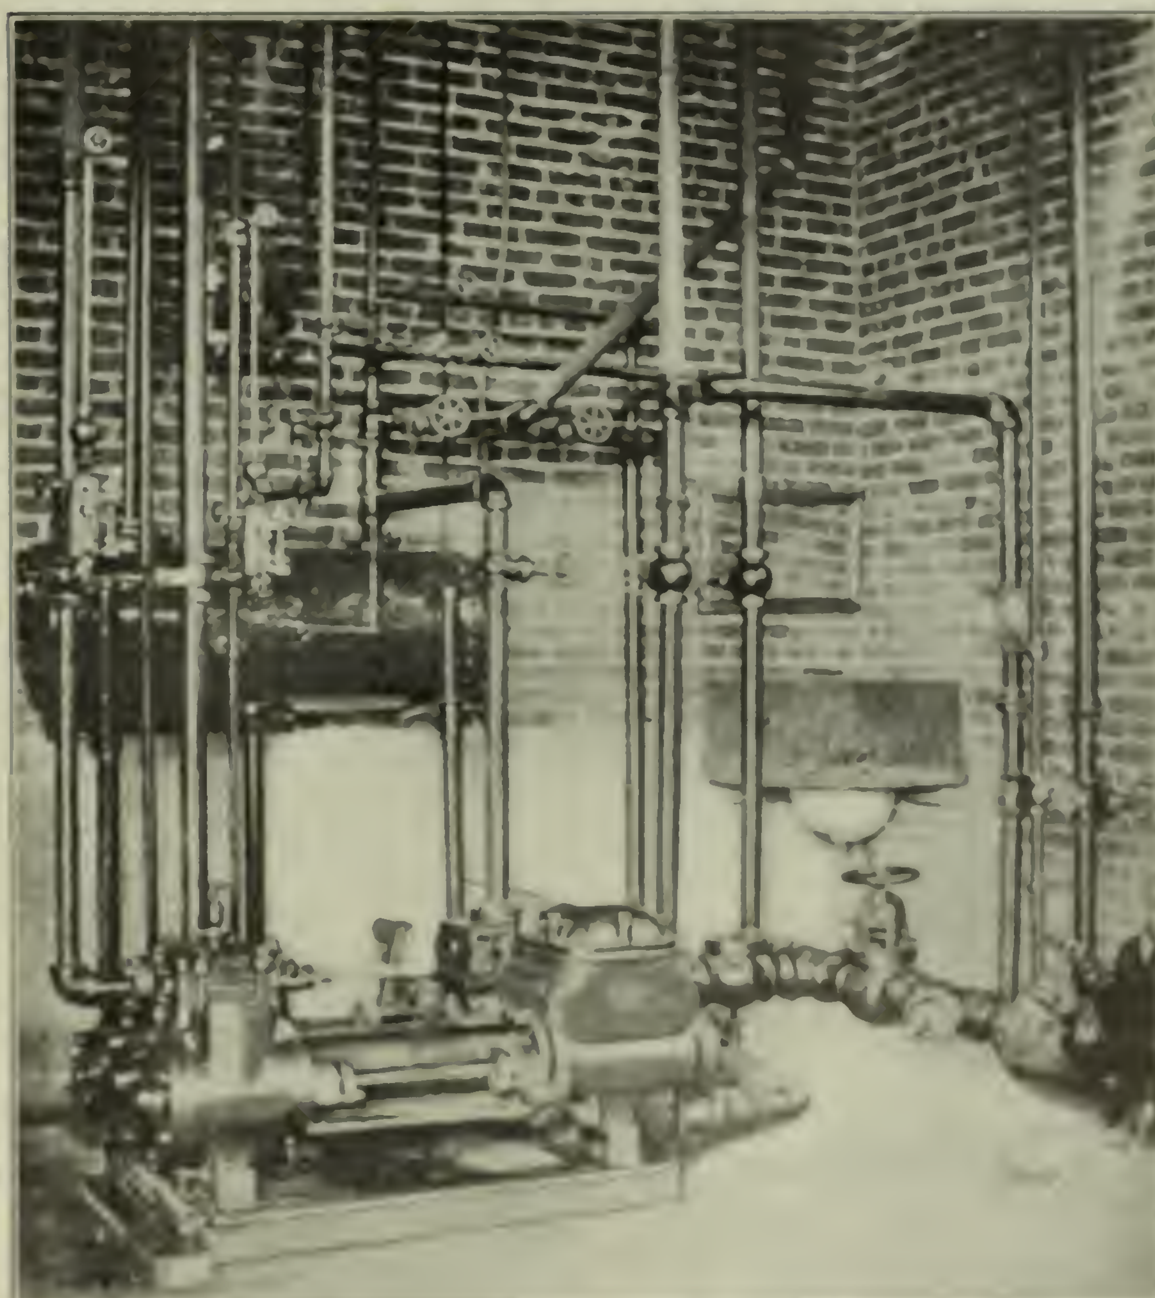
The accompanying illustration shows a neat layout of pumps, receiving tank and piping. The duplex pump is used for boiler feeding, the single pump for producing the vacuum on the heating system, and the small pump for house purposes. The receiving tank is piped to all of the returns leading from the factory. It is also connected to the city main and the make-up water is controlled by an automatic regulating float valve.

The construction of the stand supporting the tank is worthy of notice. It consists of two vertical pipes which are screwed into floor plates. A tee is screwed onto the top of each upright pipe and a horizontal pipe is screwed into the tee, the outer end fitting in a hole in the wall. The top end of each tee is fitted with an extension piece which is capped. This framework holds the tank clear of the floor and raises the float governor gear out of danger of being damaged.

The pumps are so connected that either one can draw from the receiving tank or from the city water main. An injector, not shown, can also be used as a boiler feeder.

The trap above the return tank handles all the returns from the shop in summer; the vacuum pump takes care of the heating system in winter.

The main feature is the neatness with which the piping has been put up. There is no leaning one way or the other. The upright pipes are vertical, and the horizontal pipes run true. It is an example of good pipe work.



Piping Job That Allows Freedom about the Pumps

There were imported into Russia during the first half of 1910, 1,751,000 tons of coal and 197,000 tons of coke. In the corresponding half of 1909 the imports of these fuels were 1,280,000 tons of coal and 102,000 tons of coke, which was a [illegible] over 1909 figures.

Electrical Department

Especially conducted to be of interest and service to the men in charge of the electrical equipment

Repairing Induction Motors

By R. H. Fenkhausen

Many articles describing the winding of induction motors have appeared from time to time in various technical journals, but most of these articles have been written by men connected with the large electrical manufacturing companies, and consequently have dealt with motor repairs from the manufacturing rather than from the operating point of view.

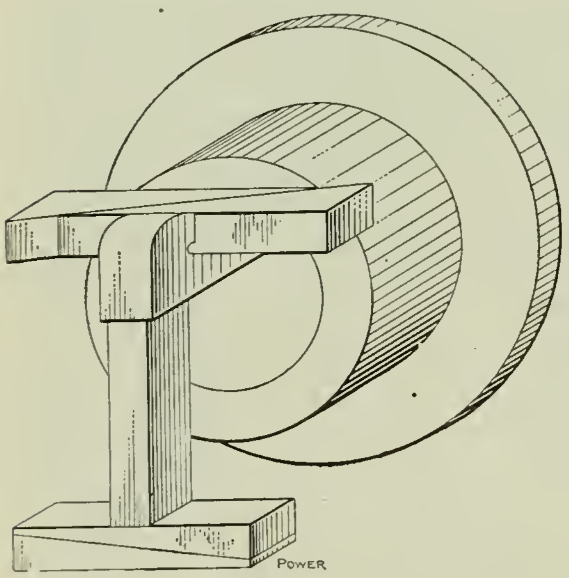


Fig. 1. Drawing a Key

It might appear at first thought that the winding of a motor at the factory and its rewinding in the field are identical operations, but besides the superior facilities available at the factory there are other advantages enjoyed by the factory winder which the field man must get along without. Take, for instance, the so called "basket" form of winding once so popular with all the motor builders, who claimed superior operating characteristics due to its use. This type of winding is largely used at the present time in partially closed slots, the coil being inserted in the slot opening one turn at a time, and the taping applied after the entire coil is in place.

No particular difficulty is encountered by the factory worker in placing these coils. He knows the exact shape required and the proper sequence of operations. The insulating materials are new and flexible and it is easy to bend the coils to make room for the operation of taping, and after the winding is complete the coils are easily shaped without danger of cracking the insulation.

The repair man in the field, on the other hand, is confronted with entirely different conditions. He handles all kinds of windings and does not become skilled in one kind like his factory brother. He must rely on his judgment as to the best way to proceed with an unfamiliar winding and, if he errs, valuable time is lost. The principal difficulty, however, is due to the brittleness of the insulation on the coils, which often defies all attempts at bending without damage. Several coats of varnish are baked on at the factory, and after being in service for a time the insulation of the coils becomes like glass and cracks as soon as any attempt to move the coil is made. The repairing of one coil damages adjacent coils, which must be also repaired, thus damaging still more. This often progresses until a large part of the winding is involved.

The foregoing remarks, though not covering all points of difference, will show that the viewpoint of the manufacturer is not that of the operator, and as evidence of this the type of winding referred to is being gradually abandoned by all motor manufacturers, except for the smallest sizes of machines, because of the difficulty experienced by operating men in making repairs.

In preparing the present article and those which are to follow, the writer has been careful to deal with his subject from the operating engineer's standpoint, and to describe only such processes as may be readily carried out with the tools and appliances available in any motor-driven plant. Many of the "kinks" described may appear simple, but it should not be forgotten that the simplest expedients are often most unfamiliar, and are only evolved from actual experience with far more intricate processes, which are gradually simplified.

Location of Trouble

The first indication of trouble with a motor is usually the appearance of a husky helper, who reports: "The motor in such a shop is burned up." This report need not cause alarm, as any motor trouble, from a blown fuse to a forgotten open switch, is usually diagnosed as a burned-out motor. Upon arriving at the scene of trouble the exact nature of the manifestation of trouble should be ascertained. If the motor was reported as smoking, it is, of course, due to overload or a short-circuit in the winding. If failure to start was the trouble, overload, blown fuses or bad contacts in the starting device should be looked for. The starter should be placed on the starting position and each phase tested for voltage by means of a test lamp.

If no trouble is found in the starter, the load should be removed from the motor by taking off the belt or pinion, and another attempt to start made. An open circuit in one phase will overload the remaining phase or phases and probably cause the motor to smoke. When the open circuit is corrected the motor should run all right. When a motor smokes from overload, it does not necessarily mean that the insulation is charred, because some insulations smoke at a comparatively low temperature and give a valuable danger signal which will save the motor from damage if heeded promptly. After the load has been removed, the motor should be allowed to run until

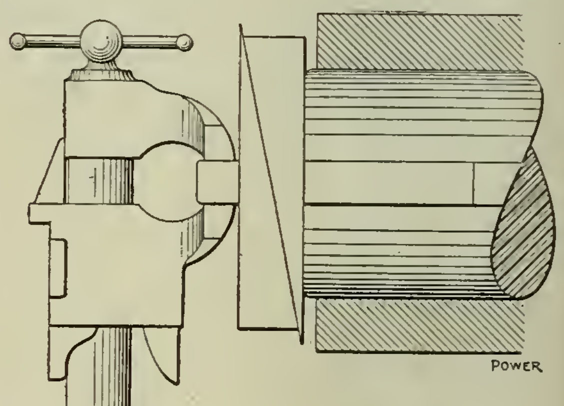

Fig. 2. Pulling a Tight Key

cooled down, as the fans on the rotor will draw cool air into the windings and cool it rapidly. As soon as it is cool the taping of one of the coils should be slit open with a sharp knife and the cotton covering of the wire inspected. If the cotton shows white or is only slightly discolored by the heat, the taping should be replaced and a patch pasted over the cut with shellac.

The earlier forms of induction motor were designed with lots of iron in the magnetic circuit and heating of the iron seldom occurred except as a result of overheated copper. An overload on one of these motors often charred the cotton covering of the wire until short-circuits resulted between turns, without any external appearance of trouble. The later forms of motors, however, use higher-grade steel and are run at high magnetic densities, so that abnormal conditions usually manifest themselves in excessive iron losses which heat the iron and char the outside insulation of the coils without even discoloring the cotton covering on the wire, so that the coils may be unharmed if the overload is of short duration.

If no overload exists, and the motor is receiving current in all phases, trouble must be sought in the windings. Test for grounds, open circuits and crossed

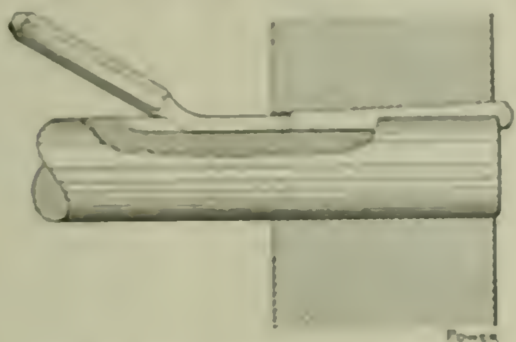

FIG. 3. "DRIFTING" A KEY OUT

phases with a magneto. In a three-phase motor the terminals of the three windings must be disconnected from each other before open or crossed phases can be detected.

WHERE TO MAKE REPAIRS

Every electrical installation should have a clean, well lighted place set aside for the electrical-repair force. A very small place will do, but it should be easily accessible so that motors can be taken there without excessive labor.

Motor winding is clean work and cannot be properly done in a dark and dirty place, so that the time spent in moving the motor to the shop will be more than saved during the winding operation. If forced to make extensive repairs to a motor in place, the repairman will usually do a poor job, and neither the appearance nor the insulation of magnet wire is improved by contact with the grease and dirt existing in some places where motors are necessarily located.

EQUIPMENT FOR HANDLING AND REPAIRING

A half-ton chain tackle hung under a convenient beam will answer most handling equipments, as motors weighing over 1000 pounds seldom give trouble, and when they do, it must usually be repaired in place.

A work bench with a couple of vises, and several pairs of horses complete the really necessary large equipment. A lamp bank, however, will prove very handy for testing, and a good type was described in POWER for May 17, 1910. Another handy piece of apparatus when rush work is to be done is an oven for drying coils. An electric oven which can be adjusted to maintain any one of three temperatures may be obtained for about $25.

The tools required are for the most part those usually owned by electrical workers, but what few special tools are needed can be easily made, and will be described in connection with the work requiring them.

The necessary supplies may be kept in the general store room and issued upon requisition signed by the proper person. The following list will cover most repair work:

Double cotton-covered magnet wire of various sizes;

Woven sleeving to fit magnet wire; two colors;

White muslin tape [illegible] and [illegible] inch wide for taping coils;

Leatheroid or fish paper 1/32 inch thick for coil cells;

Fiber 3/32 inch thick for slot wedges;

"Empire" linen 5 mils thick for cells (also called varnished cambric);

"Empire" linen tape, ¾ inch wide, cut bias;

White adhesive tape, wire solder and soldering paste;

Sheet copper about 1/64 inch thick for stub ends;

No. 22 annealed copper wire for binding joints, etc.;

Orange shellac (with denatured, not wood, alcohol);

Oil- and moisture-repelling varnish, air-drying or baking, depending on whether an oven is available or not.

These supplies represent very little investment, as only enough need be kept on hand to keep the repair force going until more can be obtained.

In case the plant is near a supply house, there is no necessity for keeping a stock on hand, except in large plants where the red tape incidental to getting an order through the purchasing department would cause delay. Even if a full stock of spare coils is carried, the foregoing list of materials is necessary for cells, connections, etc.

DISMANTLING

Upon arrival at the repair shop, the motor must be dismantled. In most cases the pulley or pinion must be removed before the heads can be taken off. If held by set screws, this is a simple matter, but if keyed it is often quite difficult, especially if no gib head is on the key. A gib-head key is usually removed easily by two wedges driven from opposite sides, as shown in Fig. 1, the end of the key being supported from beneath to prevent bending it downward. Very obstinate keys can often be removed by means of a vise from the bench, used to grip the end of the key firmly while wedges are driven between the vise and the pulley, as shown in Fig. 2.

If the key has no head it is sometimes possible to lay a short key in the keyway back of the key it is desired to remove; then, if the pulley can be driven further on the shaft, the key will be unable to follow it by reason of the short key behind it and it will remain stationary until the pulley is driven back far enough to allow the key to be gripped with the jaws of the vise.

In case there is room back of the pulley or pinion, a key drift may be inserted in the back end of the keyway and the key backed out as indicated in Fig. 3.

If none of the foregoing suggestions will start the key, it must be drilled out, but a gib-head key should always be used to replace it when the motor is reassembled.

After removing the key and pulley and taking off the journal brackets the rotor should be removed from the stator. Great care must be used in removing the rotor, because if the bolts are allowed to strike the stator coils, the insulation is liable to be damaged. The safest plan to follow with a rotor too heavy to be lifted by hand is to block up level with the bottom of the stator bore and slide the rotor out onto the blocking; very heavy rotors should be handled as shown in Fig. 4.

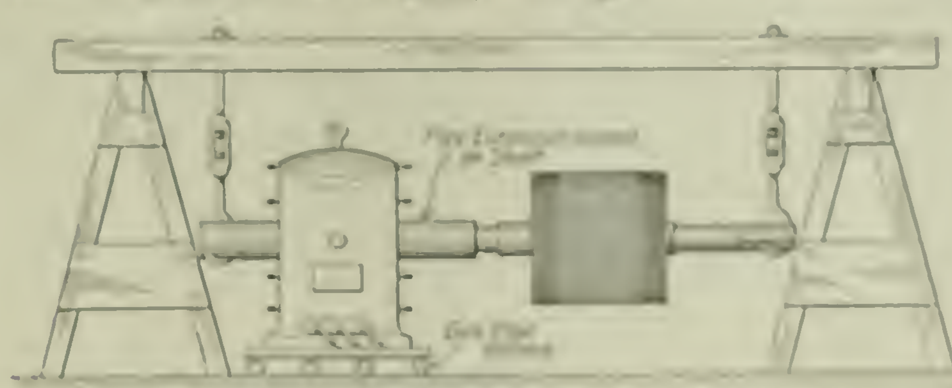

FIG. 4. REMOVING OR REPLACING AN ARMATURE

A helper should be set to work cleaning the stator and rotor thoroughly, first blowing out with an air blast and afterward washing with a rag soaked in gasolene. It is well known that gasolene attacks the varnish on the coils, but the oil and grease cannot be removed any other way, and as all coils should be given a coat of oil- and moisture-proof insulating varnish before the motor is replaced in service, the damage to the old varnish is unimportant.

SHAFT AND BEARINGS

The airgap of an induction motor is made very small as compared to that of a direct-current motor, in order to obtain satisfactory operating characteristics. Consequently, a small amount of wear will allow the rotor to come into contact with the stator, with disastrous results. It is, therefore, essential that the shaft and bearings be kept in good condition, and while the motor is in the shop advantage should be taken of the opportunity to inspect and overhaul them if necessary.

The shaft should be examined closely, and if scored or grooved it should be turned down to the next smaller thirty-second of an inch in diameter and a record kept of the size, as standard bearing sleeves can no longer be used to replace worn ones. In a large plant it often pays to renew the shaft rather than depart from the standard size. After some years it is sometimes necessary to reduce all shafts, but, of course, a new standard could then be adopted and each motor that comes in for repairs can be changed to the new standard shaft size. If the shaft appears to be all right, its truth should be verified by a test on centers if possible.

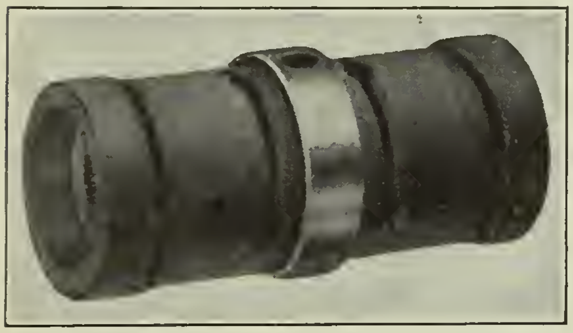

Fig. 5. Solid Journal Sleeve

The journal boxes should be removed from the heads and the sleeves tried on the shaft, all oil having previously been wiped off so that it will not form a cushion and prevent the detection of slight looseness between the shaft and the sleeve. This method is preferable to calipering, because it gives a closer indication than the average person can obtain with calipers, unless thoroughly experienced in their use. If the sleeve has more than a very slight amount of play it must be renewed, as it will grow rapidly worse because of the unbalanced magnetic pull in the airgap.

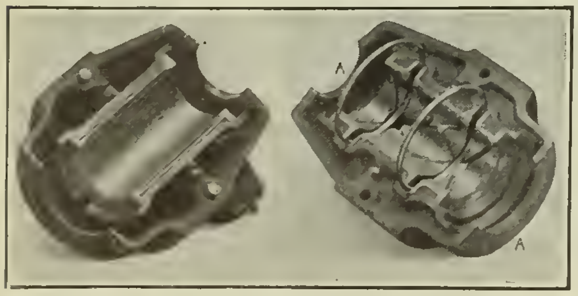

Fig. 6. Split Journal Boxes

Motors of 5 horsepower and smaller usually have solid bronze journal sleeves which must be renewed completely, although in some cases it is possible to reduce them with a bronze bushing kept from turning by a dowel pin. In motors of more than 5 horsepower, cast-iron bearing shells lined with babbitt are commonly used. These are of two types, shown in Figs. 5 and 6.

The plain sleeve type shown in Fig. 5 can be bought complete, with all oil grooves cut and ready to install, for less than the babbitt can be poured by a repairman. For example, the sleeve for a 10-horsepower motor costs but $1.65, while to babbitt the old shell, bore and cut oil grooves in the lining would cost $4 or $5 in most shops, besides the loss of time. Another advantage of buying standard bearings is the interchangeability secured. Many makers bore their bearings several thousandths small and size them by forcing a hardened-steel mandrel through them in a hydraulic press. When the journal on the shaft has been reduced, however, it is impossible to use standard bearings, and the old shells must be relined. Sleeves of the split type, as illustrated in Fig. 6, are many times as expensive as the solid sleeve type and it therefore always pays to reline old shells of this type.

Babbitting Shells

The proper grade of metal must always be used for relining bearings. The manufacturers of the motor will usually supply metal suited to its bearings, as it is to their interest to have their motors stand up well in service. The old metal must first be melted or chipped out, and remelted with a little new metal added. It is essential, however, that the two lots of metal shall be of the same composition. If any doubt exists on this point, the old metal should be discarded and all new metal used, because it frequently happens that two metals, each satisfactory for a given service, will run hot when mixed and ruin a shaft.

Fig. 7 shows how to set up for babbitting a solid sleeve of the type shown in Fig. 5. A mandrel is obtained, of a diameter from ⅛ to ¼ inch smaller than the required bore of the sleeve. This should be tapered if possible to make removal easy, but if freely coated with white lead it should give no trouble. The mandrel should be set up in a vertical position in a hole bored in a board and the sleeve slipped over it. Four wooden blocks should be spaced around the lower end of the mandrel to hold the sleeve concentric with the mandrel. Clay may be filled around blocks to keep babbitt out of the counterbore and the oil-ring grooves filled with thin wood or asbestos, cut out to fit half way around the shaft, as indicated in Fig. 7. This is not essential, but it saves cutting out the grooves in the finished lining and is well worth the trouble. The entire rig should next be heated with a gasolene torch until too hot to touch, in order to avoid chilling the metal before it reaches all parts of the shell, and also to expel any moisture. A very small amount of moisture will generate steam enough to cause a violent explosion when the hot babbitt is poured in.

While the shell is being prepared, a helper should be melting the babbitt in a ladle over a wood fire or a gasolene furnace. When the metal is hot enough to char a pine stick, a few pinches of sal ammoniac should be thrown in. This will cause all the dirt to rise to the top, where it can be skimmed off with a small ladle. Great care must be used to make sure that the metal is not overheated, as its anti-friction properties are liable to be seriously impaired.

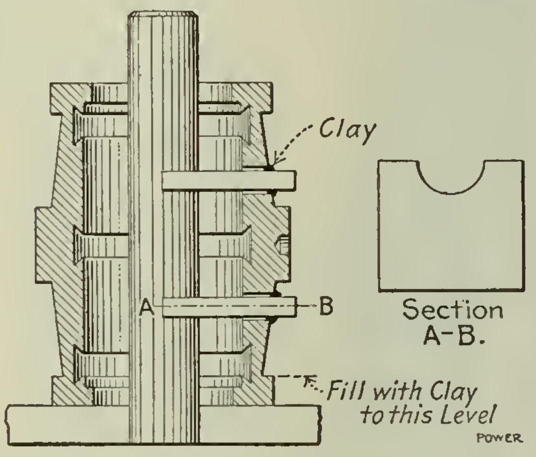

Fig. 7. Preparation for Babbitting

The metal should be slowly poured into the shell to avoid entrained air and consequent "blow holes" in the casting, and a close watch kept for leaks, which should be promptly plugged with soft fire clay. As it is obviously impossible to peen the metal in a solid sleeve, the worker must take pains in pouring to insure a tight joint with the iron. It is a good idea to tamp the metal into place with a stick while it is still in a plastic state, in order to prevent porosity and looseness of fit in the shell.

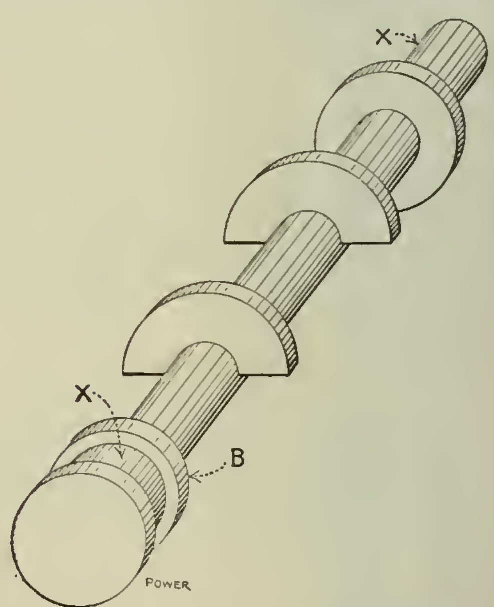

Fig. 8. Babbitting Mandrel

Split shells, such as shown in Fig. 6, are babbitted one-half at a time in the horizontal position. They are quite difficult to pour, owing to the number of grooves and shoulders that must be cast, but by means of a special mandrel like Fig. 8, which forms all grooves and shoulders without setting up, split bearings are very easy to reline. If the mandrel is made a good fit at the points *X X*, it may be used to babbitt the sleeve to exact size, because the bores *A A*, Fig. 6, are supposed to be concentric with the shaft, and to serve as guides for the accurate location of the mandrel. The shoulder *B* serves to locate the mandrel longitudinally and govern the end play of the motor shaft. The oil-groove collars embrace only one-half of the circumference of the mandrel; therefore, the lower half of the bearing is cast with the collar side of the mandrel on top. If a lathe is available, it is better to make the mandrel ¼ inch smaller than the shaft and after the metal has set, it may be peened until all pores in the metal are closed up.

The surplus babbitt must then be chipped off the seam face of the shell, care being used to chip *toward* the iron in order that the metal may not be loosened from the shell. The edges of the babbitt lining should be filed down flush with the iron; the two half shells may then be put together and bored out in a lathe.

As it is rather difficult to true up a

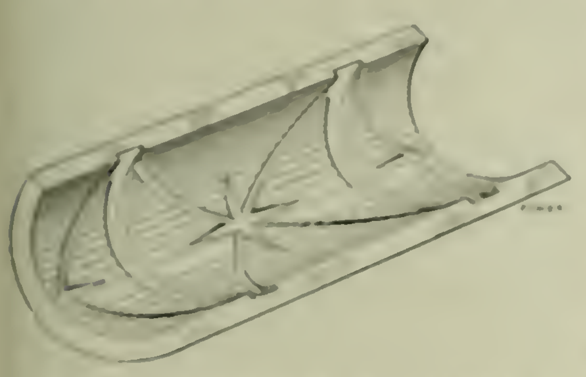

Fig. 9. Ineffective Oil Grooves

sleeve of this type, owing to the short length of turned surface exposed when the sleeve is clamped in the lathe chuck, it is better to bolt the sleeve in place in the journal bracket of the motor and chuck the bracket in the lathe. The face of the bracket may be bolted against the faceplate and trued up with the counterbore. If no lathe large enough to swing the bracket is available, it will save time and improve the accuracy of the work if a piece of cast iron from the scrap heap be bored out to fit the outside of the sleeve and the latter held in it by a set screw while being bored. Only a straight bore is required, as all grooves and both faces were formed by the mandrel.

Oil Grooves

Too much attention cannot be given to the cutting of the oil grooves, as the distribution of the oil and consequently the running temperature of the shaft and bearings are determined by the oil grooves. If the original pattern is not invisible, due to melted babbitt, it should be followed, a sketch of it being made before the old babbitt is removed.

If the old pattern has been obliterated, it should be remembered that oil, like water, does not naturally tend to flow up hill, and the grooving should be designed accordingly. Grooves cut as shown in Fig. 9 are useless; but many "mechanics" will cut grooves in this way. The grooves should start at the ring slot, on the top of the shaft, and curve down

Fig. 10. Oil-groove Chisel

toward the horizontal center line of the bearing. They should not extend to the end of the sleeve but stop about ⅛ inch from the end, to prevent the oil from flowing out at the end of the sleeve. A narrow, round-nose chisel, bent to the curvature of the bearing, as shown in Fig. 10, should be used. Oil grooves should not be cut in the lower half of a sleeve, as it reduces the bearing surface too much; the grooves in the upper half should not be cut any wider than necessary, for the same reason.

A good pattern for the oil grooves of motor bearings equipped with two oil rings each is shown in Fig. 11. It will be noticed that the grooves from opposite rings cross each other; therefore, even if one ring should fail to work, the remaining ring can supply oil to the entire bearing.

After chipping the grooves, the bearing should be carefully scraped with a half-round scraper, to remove any burs formed by the grooving chisel.

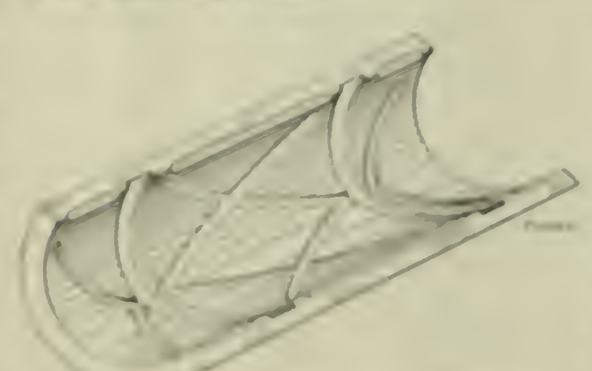

Fig. 11. Effective Oil Grooves

Before reassembling the journal brackets the oil rings should be carefully examined as they often are bent and twisted accidentally when the bearings are removed.

If the motor is a new one and the bearings have worn out without any apparent cause after a short run, it may be that the condition illustrated in Fig. 12 is responsible. At the factory a superficial examination is made to see that the rings revolve freely, but owing to slight irregularities, unavoidable in a rough casting, it occasionally happens that the rings barely clear the sharp edges *E E* by a hair's breadth. As soon as the bearing wears the least bit—as much as might occur in one day's run—the rings "hang up" on the edges *E E* and the bearing melts out from lack of oil. The remedy is to chamfer off the sharp edges at those points with a file or chisel. This will allow the rings to drop farther into the bore, as shown by the dotted lines. (The drop is exaggerated for clearness.)

When replacing the journal brackets on the motor, turn them upside down before slipping the bearings over the shaft. This will allow the rings to drop clear of the bore and avoid the necessity of lifting them with a bent wire while inserting the shaft. After the end of the shaft has passed the rings, the bracket may be turned half a revolution and shoved into position on the motor frame.

The nuts should be uniformly tightened all around the circumference of the bracket ring. If one side is tightened

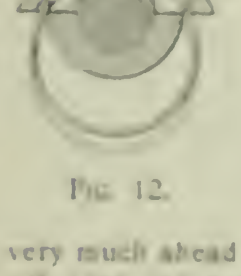

Fig. 12.

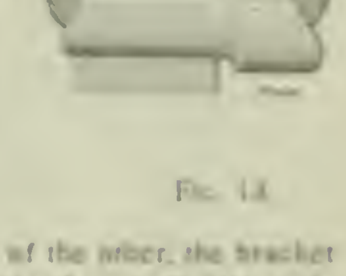

Fig. 13.

very much ahead of the other, the bracket will bind and cannot be drawn into position. The best method is to tighten all the nuts by hand until the bracket is just starting to enter the counterbore all the way around. Two opposite nuts should then be alternately tightened two flats at a time until the bracket is in place. With very large brackets and those which fit very tightly, four nuts should be worked up to avoid springing the bracket. The remaining nuts may then be run up by hand and all nuts given a final turn with the wrench.

After the brackets are in place, the rotor should be tried, and if it does not rotate freely, the brackets should be loosened and the rotor tried again. If it turns freely, the trouble is due either to poor alinement or lack of end play. Poor alinement seldom occurs, as self-alining seats are used on most bearing sleeves. Lack of end play may be corrected by moving the bearing shells outward in the housing, if means for adjustment is provided. Where no adjustment is possible, the sleeve must be faced off. End play of the motor shaft is often prevented by the entrance to the bore of the bearing sleeve not being flared enough to take the fillet on the shaft; Fig. 13 illustrates this condition.

Gas Power Department

Everything worth while in the gas engine and producer industry will be treated here in a way that can be of use to practical men

Splash Lubrication

By James H. Beattie

A great deal of difficulty is experienced by operators of small vertical gas engines depending on splash lubrication, due to heating of the crank shafts and wrist-pin bearings. The trouble in nearly all cases is due to the lack of sufficient care in renewing the crank-case oil from time to time. It is not sufficient merely to add to the oil in the crank case as it is used up; the old oil must be removed and the crank case cleaned thoroughly and refilled with new oil. The frequency with which this should be done varies with conditions, but in no case should it be allowed to go more than a few weeks without attention. Any engine depending on splash lubrication is subject to this trouble, but the smaller sizes, ranging from about 2 to 10 or 12 horsepower, suffer particularly, as these sizes are commonly used by farmers and contractors under conditions where the amount of attention given is very small.

It has always seemed to the writer that splash lubrication is wrong in principle. The oil is used over and over again, gradually becoming mixed with particles of metal from the bearings and other forms of grit. It has been my experience that bearings lubricated in this manner wear much faster than bearings supplied by sight-feed lubricators feeding pure oil.

One of the most alluring points claimed for splash lubrication is that it is absolutely automatic and requires very little attention. On the contrary, it is rather uncertain and requires very careful and systematic attention in order to prevent serious trouble, as just pointed out. The following experience is a typical one: In cleaning the crank case of a splash-lubricated engine, a small piece of waste was accidentally left in the oil reservoir. The oil hook on the connecting rod picked it up and soon stirred up so much grit by sweeping the bottom of the reservoir at each revolution of the crank that a hot bearing resulted.

What is even worse than the excessive wear on the bearings is the excessive wear imposed on the cylinder and piston through lubrication with grit-laden oil. Another and a very serious objection to splash lubrication is the fact that it is almost impossible to keep the oil in the crank case from working out through the bearings, spreading over the frame and flywheels and making a mess of the whole engine. The writer has never yet had the pleasure of seeing an engine depending on splash lubrication which was entirely free from this fault.

It seems evident that it would be vastly better to equip the cylinder and bearings with sight-feed oilers than to depend on splash feed. The advantages are so obvious that it is not necessary to mention them all, but the chief one is that the oil after passing once through the bearings is filtered before being used in them again, or else used for other and less important purposes.

What Caused the Freak Diagrams?

By S. W. Rushmore

The three indicator diagrams reproduced here were taken a few minutes apart from my 140-horsepower single-

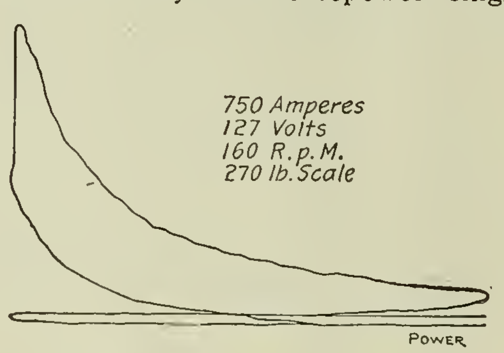

Fig. 1. Normal Diagram

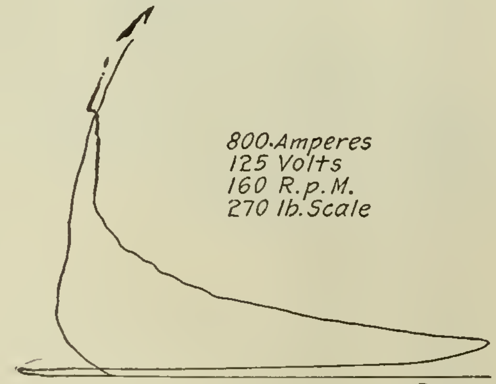

Fig. 2. First Freak

cylinder producer-gas engine. Immediately after taking the normal card, at the full rated load of the engine, the engine began to behave badly, and, while maintaining the full dynamo load of about 750 amperes, we got the two freak diagrams shown in Figs. 2 and 3.

Although the engine was carrying practically full load at the instant diagram No. 3 was taken, it is evident that the power was supplied chiefly by the flywheel. Perhaps some of the readers

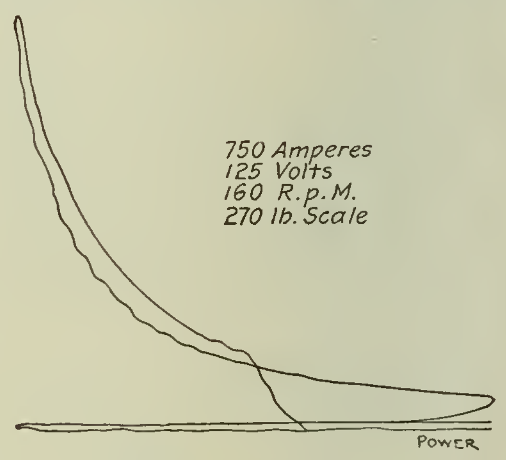

Fig. 3. Second Freak

of Power can explain the freak diagrams, in the taking of which the indicator was handled in exactly the same manner as when taking the normal diagram of Fig. 1.

Gas Poisoning

By J. O. Benefiel

In the issue of January 24 there was an interesting account of an engineer's experience with carbon-monoxide poisoning. I have had some experience along that line, being in charge of a scrubbed-gas plant of 4000 horsepower capacity.

We have had quite a number of the men overcome with the gas, but none fatally; they usually have a severe headache the rest of the day, but otherwise there do not seem to be any ill effects. Of course, the results would be fatal if the man were exposed to the gas long enough.

The gas does not seem to act gradually; apparently, one may get loaded with it before it begins to act, then the loss of consciousness seems to take place almost instantaneously. A man seldom gets a heavy charge of it the second time; in fact, we have had no one get a stronger dose the second time than he could walk away with.

The symptoms are a slightly increased rate of breathing and heart action, which will pass unnoticed by the inexperienced. Stepping into the cold air will cause it to take effect instantly.

One does not realize that one is losing consciousness, and this makes it very dangerous, especially when the workman is overhead. I had one man lose consciousness just as he was starting down a 25-foot ladder. Fortunately, two men were working together and the man on the platform dragged the poisoned man back just in time to prevent him from having a bad fall. In another case a man was working on a ladder when his senses left him, but there was a man just below him who carried him down.

The gas does not seem so effective before being cleaned. The generator men are exposed to it all day long on the charging floor and they suffer from nausea only; it is often so bad as to cause vomiting, but not dizziness or loss of the senses. It does not seem to affect the general health; some of the men have been doing this kind of work two years and are in good health.

When a workman is overcome by producer gas he should be carried to a place where the air is pure and *warm;* exposure to cold is to be avoided. There should be an oxygen outfit at hand and the oxygen should be administered at the earliest possible moment. The efforts of a physician are feeble as compared with the oxygen treatment. An oxygen outfit is not expensive; we keep two tanks on hand to avoid the liability to run short in case more than one man should be affected at the same time. A stiff drink of whisky is beneficial after the patient has regained consciousness, and he should not be allowed to go out of doors or to start home alone until he has fully recovered. We always have a doctor to attend a man who has been gas-poisoned, chiefly because the man might have a bad heart which would need the attention of a physician. Incidentally, it would clear the management of any charge of neglect in case of serious results.

Sometimes artificial respiration should be resorted to if the patient's breathing seems to be weak.

In the two years we have been using producer gas we have had only six men get knocked out, though we have had the men get a light dose often. Two pipefitters were working overhead on a plank runway one night and both of them got so weak and dizzy they could not get down; they had to lie on the runway until they recovered, there being no one else about.

LETTERS

Is This Speed Practical?

I shall appreciate expressions of opinion from POWER readers on the following question.

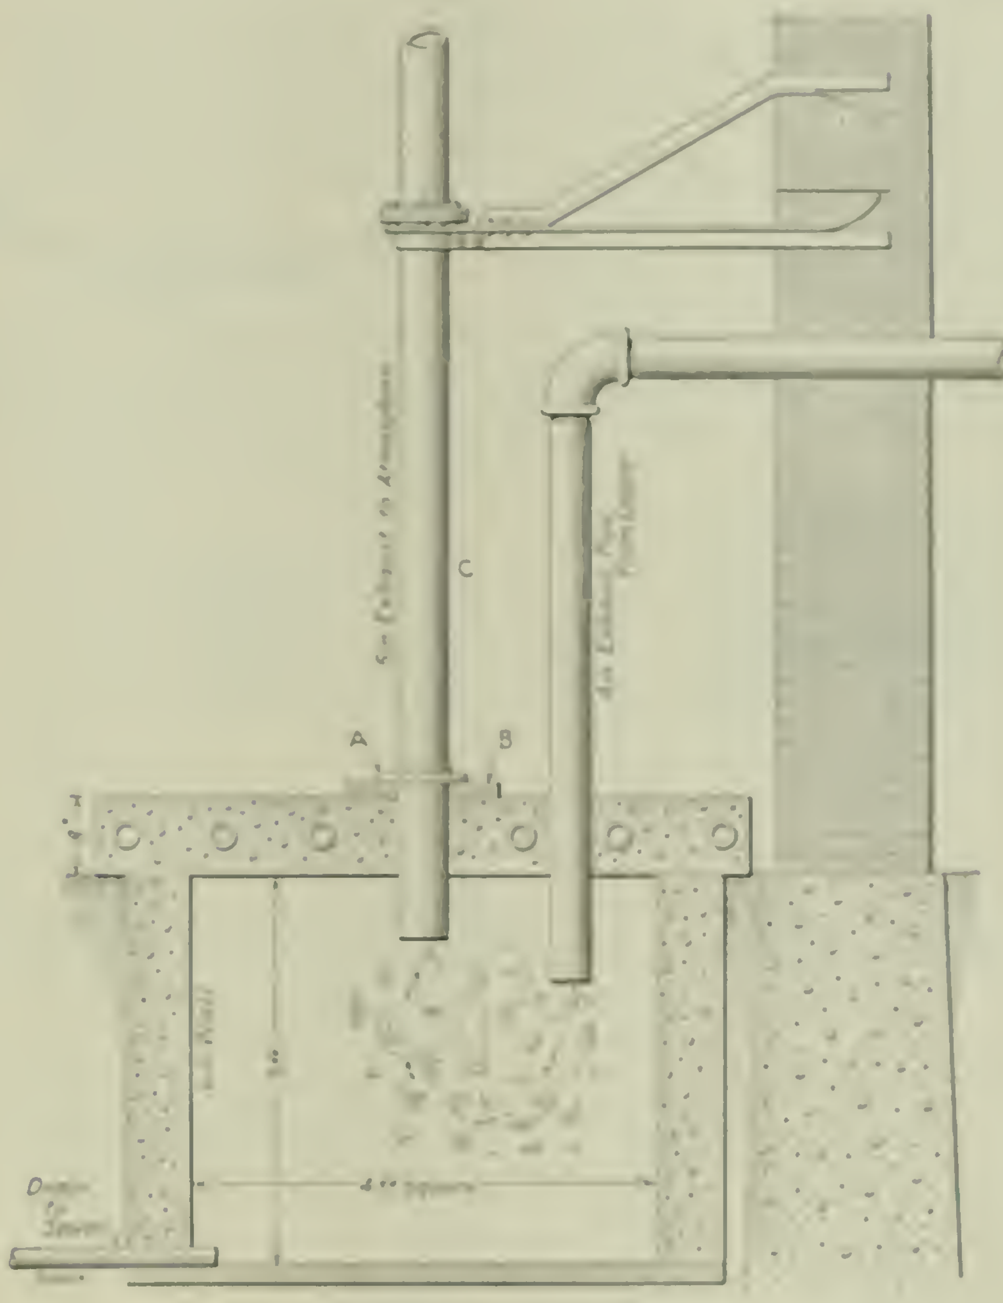
Is a rate of speed of 300 revolutions per minute too high for a vertical engine of 9½ inches bore and 12 inches stroke, with a connecting rod 30 inches long? The engine is single-acting but is built with a crosshead instead of the usual trunk piston and gudgeon pin. It is lubricated by splash from the crank case.

O. J. BARKER.

Cameron, W. Va.

A Homemade Muffling Box

The accompanying sketch shows the construction of a muffling pit which we have found very satisfactory. The pit is just outside of the engine-room wall and is 3 feet deep and 4 feet square. The walls are of concrete, 6 inches thick, and the cover is 8 inches thick and reinforced with old boiler tubes to stiffen it up. The pipe carrying the exhaust gases away from the pit is 5 inches nominal diameter; a 1-inch collar is shrunk on the pipe at *A* and this rests on a 15-inch plate *B*. The pipe *C* is braced to the building wall, as shown. When pouring the cover we put short pieces of pipe in place of the intake and outlet pipes and left them there until the cement had dried.



A CONCRETE MUFFLING BOX

This has muffled the exhaust so that the report is not as loud as that of a noncondensing steam engine exhausting to the atmosphere; in fact, it can hardly be heard when standing near the pipe.

The engine is a three-cylinder, vertical, with cylinders 12x12, rated at 100 horsepower when running at 275 revolutions per minute on natural gas of about 950 B.t.u. per cubic foot.

The first muffler was put in over a year ago and has given such thorough satisfaction that the other engines were provided with mufflers of the same construction. Of course, several engines can exhaust into the same pit if the pit be made larger; the one here illustrated is about the right size for an engine of 125 horsepower.

M. W. OTT.

Minster, O.

The briquetting industry in several European countries has made rapid advances within the past few years, the production last year in Germany alone amounting to eighteen million tons. This is due partly to the fact that the coal in these countries runs in thinner veins, limiting the supply of the larger sizes, and also that cheap labor makes it possible to use dust which would otherwise be discarded. The popularity of this form of fuel is shown by the fact that thirty per cent. of the total coal consumed in Berlin is in the form of briquets.

Readers with Something to Say

Practical information from the man on the job. A letter good enough to print here will be paid for. Ideas, not mere words wanted

Repairing a Wrecked Engine

A short time ago I had a repair job on a 20 and 36 by 48-inch cross-compound engine. The low-pressure cylinder took water on the head end and forced the front of the pillow block off, as shown in Fig. 1, also breaking the cap, and before the engine could be stopped the shaft had been thrown out of alinement so that the 50-inch belt ran off the pulley so far that it got up against the foundations and ripped one edge open about 3 inches, for its entire length. The belt was taken off and repaired, and in the meantime four 1¼-inch holes were drilled and tapped in the broken pillow block, and clearance holes drilled in the broken piece, which was fastened to the main casting by means of bolts, as shown. An 8x8 timber was placed from the wall to the pillow block and in place of the cap two 2½x1-inch wrought-iron straps were used to further strengthen the block. Then the low-pressure side was disconnected and the engine ran a part of the plant until a new pillow block arrived.

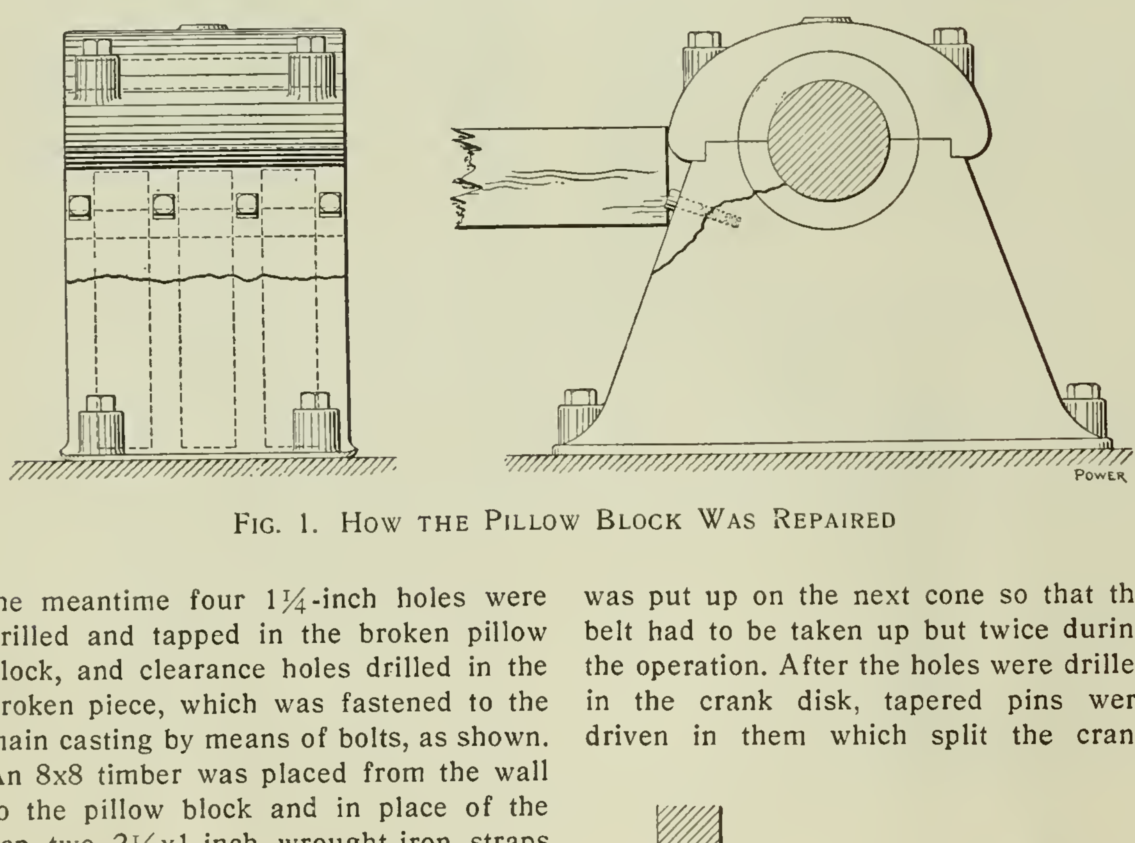


Fig. 1. How the Pillow Block Was Repaired

The shock received by the crank sheared the key about 1/16 inch on the shaft so that it had an offset, making it advisable to take off the crank and put in another. When the new crank arrived, the engine builders sent a man to assist in taking off the old crank and to put the new one on. He intended to work all night, with a ratchet, drilling holes in the crank to break it off. I suggested taking a headstock from one of the lathes in the machine shop and blocking it up level with the center of the crank shaft, and with a drill chuck in place and a jack screw between the wall and the headstock for a feed, using a small 6-horsepower engine to drive the same. It took 90 minutes to remove the crank, which was 7 inches thick. Fig. 2 shows the method of drilling the crank. A 12-inch face driving pulley was used, and as the lathe head was moved nearer the driving engine, the belt was put up on the next cone so that the belt had to be taken up but twice during the operation. After the holes were drilled in the crank disk, tapered pins were driven in them which split the crank disk along the row of holes, when the new crank was put in place. The new pillow block was then made secure, and after adjustment the job was completed.

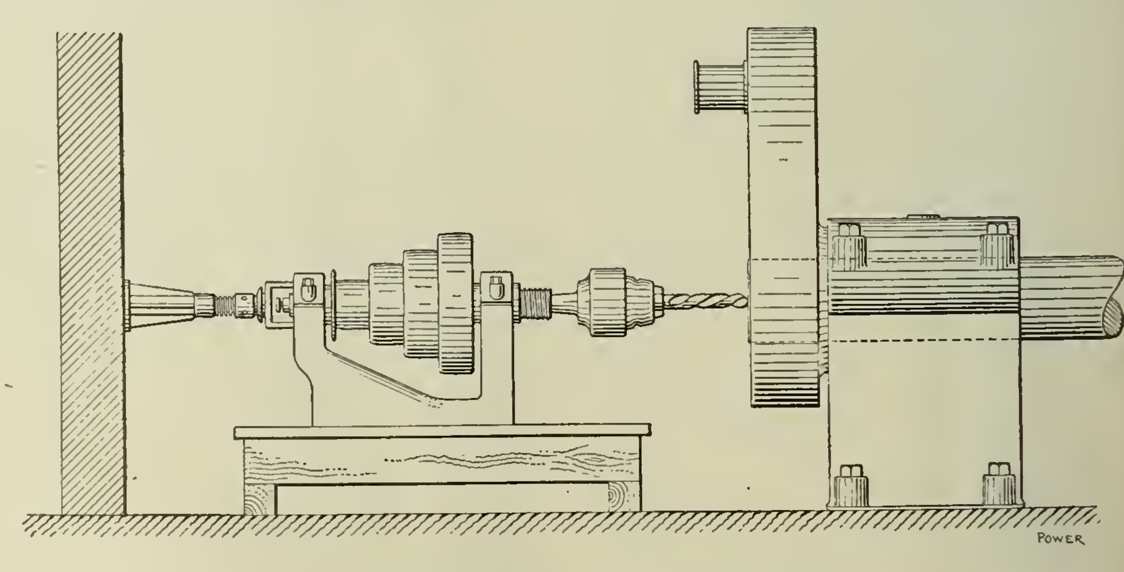

Fig. 2. Method Used in Drilling Crank

All preparations were made, such as getting the drilling apparatus, engine and lathe headstock ready during the day while the plant was running, so that no time was lost in getting to work after shutting down.

L. R. Corm.

Boston, Mass.

Slipping Latch Blocks

In a certain power station, considerable trouble and annoyance were experienced with the latch block slipping or failing to open the valve. This caused the engine to take steam on but one end, causing surges and cross currents between the alternators, which affected the most distant substation. Sometimes the slipping would be so bad that the engine would have to be cut out of service until the latch block could be changed.

As a remedy it was decided to make some latch plates of Novo steel, a very fine, hard grade of tool steel. The first effort was a failure, owing to the fact that the plates were not hardened sufficiently in tempering.

A second trial, however, produced plates that have been in continuous service for five months without being disturbed and still show no sign of wear, and have not once failed to open the valve. This steel must be annealed before working, which is done as follows: Cut it into pieces of approximately the size of the plates. The pieces should be buried in lime in a length of iron pipe, of sufficient size to hold them, and the ends capped. A hole should be drilled in one cap to let out moisture, etc. The whole is then placed in a slow fire and gradually heated until the pipe begins to take on a welding heat. The fire should then be covered with coal and left undisturbed until the steel has cooled, after which it may be worked into the desired shape for the plates. After finishing, the plates must be tempered by heating to a *bright red* and plunged into oil. This steel is expensive, costing about one dollar per pound, but considering the wear secured the cost is trifling.

By buying the steel in bars of the proper width and thickness it is a comparatively easy matter to make any ordinary latch plate. The steel may be bought annealed but it may still be too hard to work well.

Gage Pipe Froze

The night breezes without registered a temperature of 20 degrees Fahrenheit and everything was lovely, so to speak. No. 3 was working connected with Nos. 1 and 2 boilers, all being 125 horsepower and of the horizontal return-tubular type. Suddenly, No. 3 gage registered a pressure of 135 pounds, but Nos. 1 and 2 gages remained normal at 90 pounds per square inch.

I began investigating, and the safety valve convinced me that the gage, and not the boiler was at fault. I soon found that the ¼-inch line to the gage had frozen, due to some person neglecting to close a window nearby, and the expansion of ice, together with the noncompressibility of water, caused an increase of 45 pounds pressure on the gage over that carried on the boiler.

This incident demonstrated three important facts; first, the incompressibility of water; second, the expansive force of ice, and third, pressure created by freezing water will release itself along the lines of least resistance.

I am none the worse for my experience, although the first discovery of the increased gage pressure gave me a "jolt" for a moment.

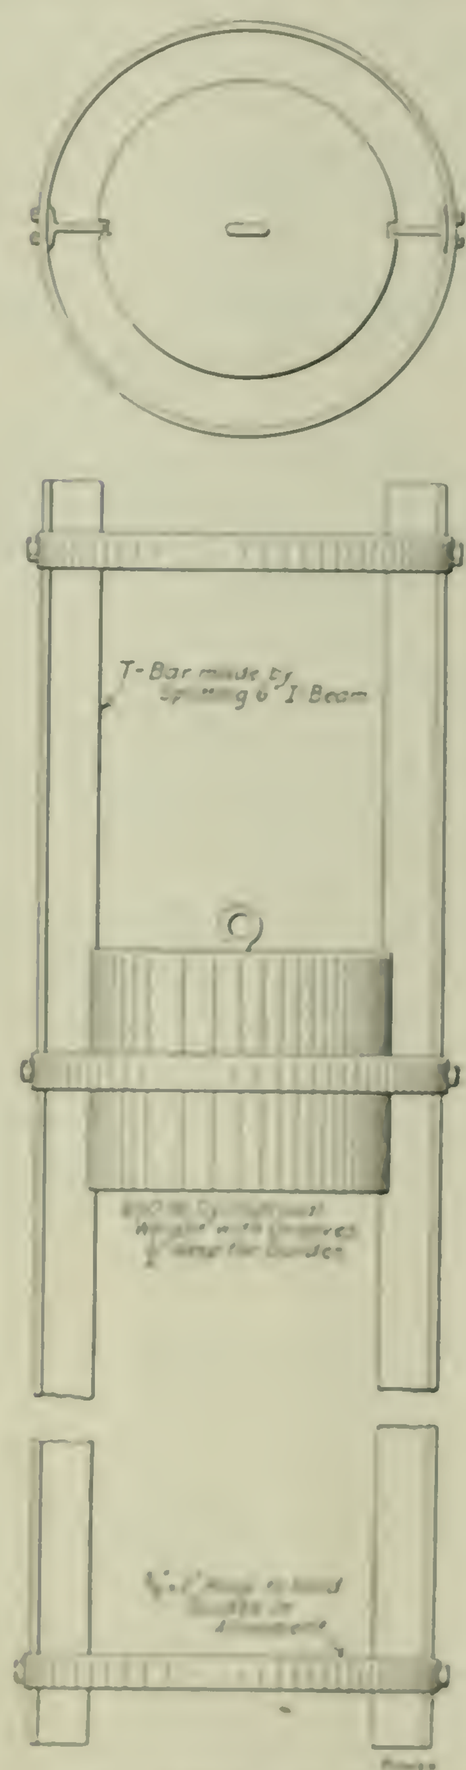
L. E. Kenney.

New York City.

Removing a Piston Rod

The accompanying illustration shows a device used to force the piston rod out of the piston of an old blowing engine.

One of the valves in the top cylinder head of the air tub broke and a piece fell into the clearance space. The result was that the piston rod was jammed



How Hammer Was Used

¼ inch through the piston. The question then was how to remove the rod. It was suggested that the piston be blocked up and a weight dropped on the protruding portion of the rod.

A pair of guides for the falling weight were made from a 6-inch I-beam, 15 feet long, which was mounted on a planer and cut into two T-bars by splitting it down the middle with a cutting-off tool. The guides were held in proper alignment by hoops made of 1½x2-inch flat bar iron, as shown in the sketch.

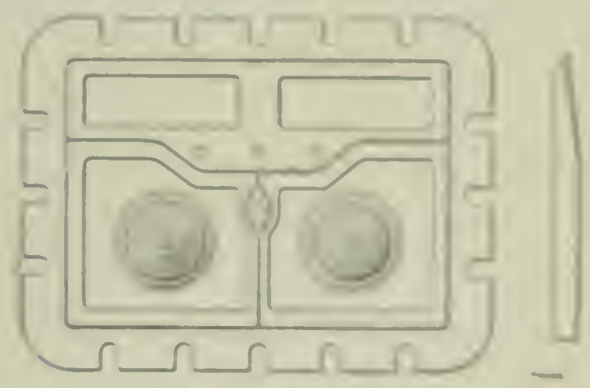
This rig was bolted into place and lashed in position. The piston was blocked up on four blocks set so as to bring the stress of the blow on the four legs of the A frames. The rod was disconnected and the crosshead moved down. The weight was hoisted 10 feet and one blow did the work.

J. J. O'Brien.

Buffalo, N. Y.

Lead Fuse Gasket

I have had a great deal of trouble keeping sheet packing between the suction valve plate and the discharge valve plate of an old tank pump. When a soft sheet packing was used it would blow out, and if it was stiff and strong enough to withstand being blown out, the water



Grooved Plate

and air would be forced between the gasket and casting.

After experimenting with several styles of sheet packing, I had a grooving chisel made as shown in the sketch, which would make a groove with about 1/32-inch radius.

The plate was grooved as shown. Then I got some electricians' lead fuse, which was the only kind available, and made an endless gasket by soldering all ends, and this lead-wire gasket was a success.

B. T. Hawley.

Starkville, Colo.

Crosshead Pound

A disagreeable knock at the crosshead of an 18x36-inch Corliss engine puzzled me for some time until I discovered that it was caused by a sidewise movement of the rod brasses on the crosshead pin. There was but little clearance between the brasses and the crosshead, yet there was enough to allow it to slap at the end of the stroke.

Efforts to remedy the trouble by means of washers, etc., were unsuccessful, but I finally gave one side of the brasses a thin coat of solder and dressed it down with a file until it made an easy fit in the crosshead. The knock then disappeared.

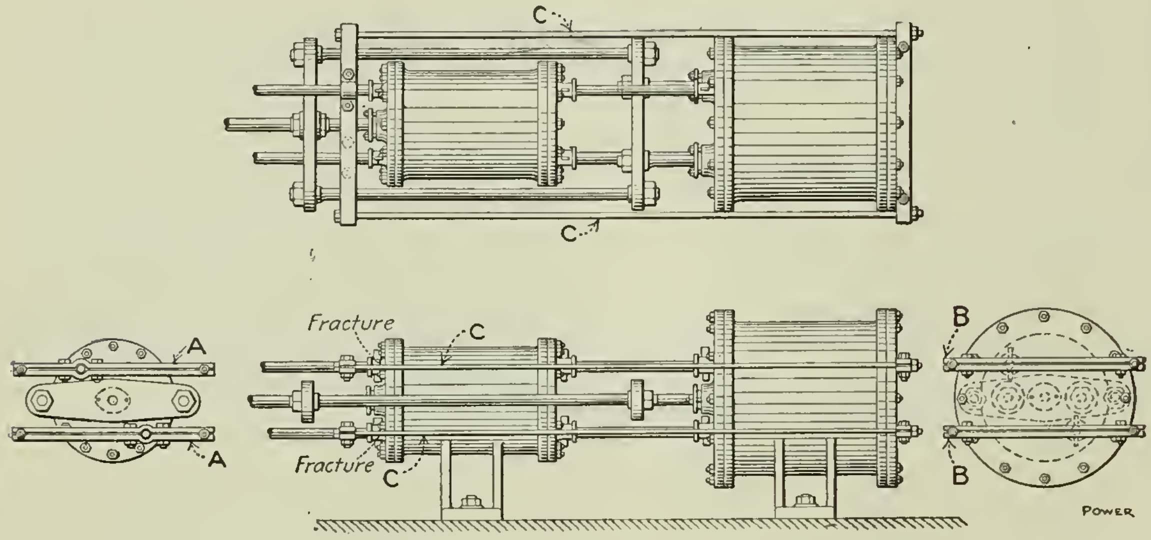
Ware, Mass.

Wrecked Steam Pump

During a recent visit to the steam plant of a friend, he showed me one of the large duplex tandem-compound pumps which had clamps and rods applied to hold the steam and water ends together, as shown in the figure. The low-pressure piston had two piston rods which ran along the high-pressure cylinder, one on each side diametrically opposite, and were fastened to a crosshead on the high-pressure piston rod which was also the plunger rod for the water end, as the steam piston rod and the plunger rod were one piece, carrying on one end the steam pistons and on the other end the plunger, with a crosshead in the center of the rod between the steam and water ends. One of the piston rods in the low-pressure cylinder became disengaged on the forward stroke, but the other remained fast. This tipped the piston in such a manner that when the pump started on the back stroke the low-pressure piston moved in jerks. Several of these jerks were enough to tear the steam end from the stayrods between the water and steam ends, the fracture occurring in the sockets on the high-pressure cylinder, into which the ends of the stayrods were keyed, as shown in the upper view. The piston rods, bell crank on the vacuum pumps, and the valve rod were twisted, bent or broken when the steam end started to back off from its foundation. The water ends only are anchored to their foundations as the steam ends ride on iron plates laid on foundations to allow for a slight movement of the steam end to adjust itself to the strain on the rods between the steam and water ends.

The engineer had two clamps made as shown at *A* and two as shown at *B*. The first set were clamped to the stayrods between the steam and water ends, snug up against the parts of the sockets which remained on the rods with the keys left in place. Long bolts with a head on one end and a long thread and heavy nuts on the other end were inserted through the set of clamps on the stayrods and through another set of clamps across the low-pressure cylinder head, as shown at *C*. Nuts were then run on and all drawn up even until the fractures closed tight. The bolts on the side of the greatest strain were made of heavier rods. The strain on the bolt in the clamp on the upper left stayrod is greater than on the bolt in the other end of the same clamp. The same applies *vice versa* on the lower clamp in the same figure. The pump handles just as much water now as it did before the breakdown, but its appearance is spoiled.



Details of Pump Repair

This breakdown was caused by an engineer with a "pull" and illustrates how such an engineer can be an expensive man. There certainly must have been a warning sound before the breakdown occurred, which an engineer of real merit would have heeded and have stopped the pump in time to prevent the accident. At the time the pump was running about twenty strokes per minute.

Pueblo, Colo.

Dynamite in the Coal

I am in charge of a battery of seven water-tube boilers equipped with mechanical stokers. A few days ago one of the firemen brought me a piece of dynamite about 4 inches long that the coal wheeler had found in the coal. Instructions were given to be very particular and examine every shovelful of coal, and it was not long before he found two more pieces of dynamite, one about 3 inches and another about 1¼ inches long. The dynamite was frozen when found, but if it had got into the fire, there would have been an explosion, and a good many people would naturally have said the boilers were dry, or this, that and the other thing.

I have had charge of boilers for about twelve years and have always been very careful to avoid accidents, but that would not have amounted to anything if the dynamite had got into the furnace. I have wondered a good many times since if any of the boiler explosions that occur from no apparent reason have been caused by dynamite. I have found caps in the coal several times, but I have never found dynamite before.

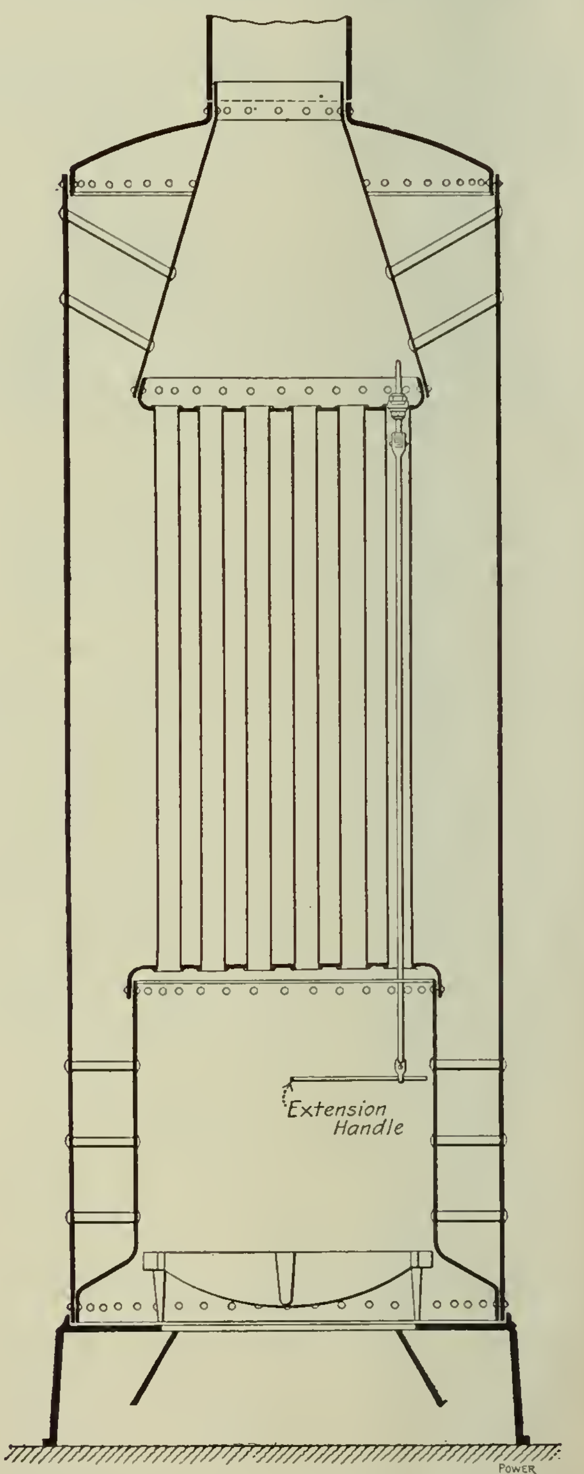
Peace Dale, R. I.

Using a Tube Expander

Recently, while putting new tubes in an upright submerged-flue boiler, I had to devise some means of rolling the outside tubes on the top end, as the pitch of the cone was such as to make it impossible to put the roller in that end.

The accompanying illustration shows



Expander in Tube

the roller slipped in from the bottom end after that part of the roller which rests against the outside of sheet had been removed. This did the job very nicely and very little difficulty was experienced in keeping the roller in place and turning the extension rod from below.

Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

Exhaust Steam in Low Pressure Turbines

In the January 31 issue, Mr. Fenno, while attempting to prove that the statements in a certain turbine catalog are misleading, neglected to take into account an important factor in the steam-engine cycle—that of reëvaporation—and by so doing rendered his analysis more misleading than the original which he was trying to disprove.

The original statement was to the effect that a pound of dry steam expanding adiabatically from 150 pounds gage to atmospheric pressure, gives up, in work done, approximately the same number of heat units as a pound of dry steam expanding from atmospheric pressure to 28 inches of vacuum, the inference from this being that an exhaust-steam turbine working between the lower pressures would do as much work as a reciprocating engine working between the upper pressures. Mr. Fenno showed that dry steam expanding adiabatically from 150 pounds gage to atmospheric pressure would have a final quality of 85.7 per cent., which in actual practice would be further decreased by cylinder condensation and radiation; hence, the low-pressure turbine would not receive dry steam, but instead steam only 85.7 per cent. dry, at the most. If a separator were used between the engine and the turbine this would mean that the latter would use only 0.857 pound of dry steam for every pound used by the former.

Theoretically, this is true, but practically it is not. Condensation will take place in the early part of the stroke, but at some point between cutoff and release the temperature corresponding to the pressure of the steam will fall below that of the cylinder walls and reëvaporation will set in. This, although not very large at first, is greatest near the end of the stroke; but the instant the exhaust port opens there is a considerable drop in pressure (with a corresponding drop in temperature) accompanied by a rapid reëvaporation, and the exhaust steam will leave the engine very nearly dry. The application of Hirns' analysis to an engine test will show this plainly. The heat regained during the reëvaporation adds little to the work done in the cylinder but it would be available in a low-pressure turbine, and the original statements are not so misleading after all.

A. de Groot.

New York City.

Changing the Throttle

Speaking about the best position of the throttle valve, why not change it if the position in which the erecting engineer left it does not suit? Why continue from year to year to leave it in front of the cylinder, flywheel, governor or valve gear, when you know that on the other side, upstairs or below the floor would be better? Several times you have

Diagram Showing Change in Position of Throttle

ducked from the firing line, wished for better things and let it go at that.

I am reminded of a case where the engineer of a plant in a large department store reversed the throttle as a temporary expedient and became so tickled with the handiness of the new location that he made the change permanent. He also changed the throttle on the duplicate unit, for if one was good, two were better.

There came an emergency call one day for special lighting in a neighboring building where the steam plant had a breakdown. A small generator was borrowed and belted from the flywheel. The only thing that could be done was to fasten the generator to the floor near the head end of the cylinder, thus running the belt across the throttle wheel, as indicated at *A* in the accompanying diagram. This made the symptoms of trouble so acute that a decision was made to reverse the throttle instanter. The pipe flanges being symmetrical, the trick proved so easy that the engineer wondered why he had not made the change before. His memory also carried him back through the long years spent in other plants where throttles and other things made operation unhandy, not to mention occasional flashes of unsafety. The erecting fellow had happened to put things together so and so, and it had never occurred to him as operating engineer to make any changes.

F. Webster.

Scranton, Penn.

Liquid Discharging Device

Mr. Seibert's article in the January 10 issue seems to imply that I have made use of his idea in the design of my device and also that the device in itself is a dangerous one to use.

In answer I would say that the device is entirely my own idea, and while Mr. Seibert may have had the same idea, he failed to protect it with a patent.

The principle on which the device works is old and not patentable, but the combination is new and I hold the patent.

I do not recommend the use of over 20 pounds pressure, and every purchaser is cautioned against anything in excess of this in wooden barrels, unless the heads are clamped.

It is immaterial to me how this pressure is obtained, whether by maintaining a receiver or boiler pressure of only 20 pounds or by using a reducing valve to step down from a higher pressure. I can do the trick nicely with no other apparatus than a common globe valve between the high-pressure line and the device and anyone else can do the same by using a little judgment.

While an opening 1/16 of an inch in diameter, as Mr. Seibert used, might not maintain an overpressure in the barrel with 80 pounds primary pressure and a light grade of oil, it can easily be seen that it would and did give an overpressure while discharging a heavier grade of oil.

If anyone has any liquids so gummy that 20 pounds will not push out, I think that such liquids are approaching the state of solids and that it might be best to knock in the head of the barrel and use a paddle or a spade.

Mr. Seibert's experience proves that the device was not at fault, but the operator.

EARL PAGETT.

Coffeyville, Kan.

Beading Boiler Flues

In reply to L. Earle Brown's inquiry in the December 13 issue about beading flues, the following is submitted from experience gained in practical work as a boilermaker in marine, locomotive and stationary work:

The beading should be put down close to the head until the sheet is nearly nicked by the beading tool. The flues will hold better and last longer because there is less metal exposed to the hot gases and, being tight against the head, there will be less difference in temperature between the sheet and the head and in consequence less difference in expansion and contraction. It is this difference in expansion that causes the flues to leak.

I would like to add a few words here about renewing and repairing flues that are leaking, especially about the use of expanders. It would surprise anyone who had not had years of experience to learn how little expanding is needed to make a tight job and a lasting one.

The majority of engineers always instruct the repair men to expand the flues well, and if he is a boilermaker from a contract shop he will follow instructions with the result that the flues are rolled so thin that the next thing in order is a new set of flues and the contract shop has another order on hand.

When the flues leak, the beading tool only should be used, as it will do all the expanding necessary and not split the bead. If the flue is loose in the head, of course the expander will have to be used.

WILLIAM BEATON.

Gold Roads, Ariz.

Treatment of Subordinates

A great deal has been said recently in the columns of POWER concerning the manner of treating subordinates and I desire to give my views on the matter.

I can heartily indorse Mr. McGahey's letter in the January 24 issue, for I know him personally and have worked for him and his brothers for six or seven years. He practises what he preaches.

I have been a chief engineer for the last four years. I find that by giving fair treatment I can get better results from my assistants than otherwise.

Rightly educated and treated, an assistant can and will save his superior much trouble and annoyance.

I find that the man who must be continually hammered at and driven is practically worthless. The sooner such a man is weeded out, the better for all concerned.

DAVID M. GROVE.

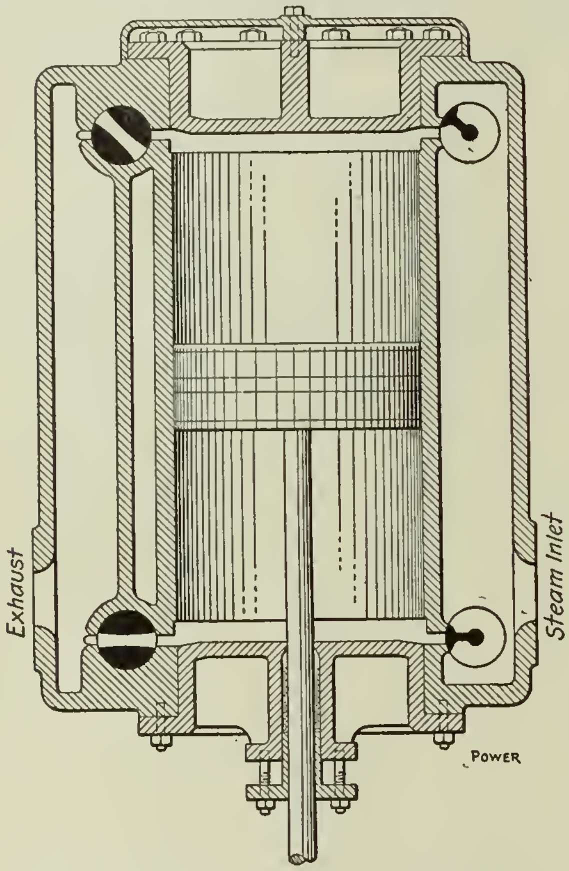
Covington, Ky.

Water Wrecked Cylinder

In the January 17 issue, Mr. Sheehan tells of the wreck of an 18 and 36 by 36-inch compound-condensing Corliss engine.

The cause given is that the valve failed to open on account of the hook blocks being worn, the valve remaining closed long enough for the steam chest to fill with water. When the valve was made to open, this water passed into the cylinder and caused the wreck.

If this statement is correct, it behooves all engineers in charge of vertical Corliss



CHANGE IN LOCATION OF STEAM AND EXHAUST OPENINGS

engines to take notice, for they all might meet with the same trouble.

Why, if there is danger of wrecking an engine in the manner stated by Mr. Sheehan, do not builders design the steam and exhaust connections as shown in the accompanying figure?

A. W. GRISWOLD.

Adams, Mass.

Federal Laws

In the issue of January 10 is an article on Federal license laws by A. A. Blanchard. I believe this article to be a good one and indorse Mr. Blanchard in trying to expand a good thing by which every engineer in the United States would be benefited. I am with him in this great movement and will do all that I can and use my influence with others to help in this great cause; the protection and conservation of life and property.

But stop—and think! Are we getting good results with the present license law in Ohio?

Do you know it to be a fact that politics plays a great part with this law and its enforcement?

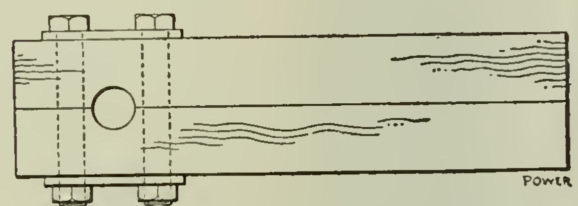
Study your law! Watch its enforcement. The robe of the license examiner is too precious a garment to hand out to any political machine or system. What we need and want is efficiency from the men who secure license. And we *must* have it or else we decay. The examiners themselves should be examined as to their ability in order that when they get a violation they may not always be outgeneraled or defeated to the carelessly concealed mirth of the violators.

ORRIN C. WERNER.

Kent, O.

Piston Rod Clamp

In the Jan. 3 issue, Alfred Woolcock described a piston-rod clamp. I have used the one shown herewith for a number of years; I think it is superior and easier to make.



HARDWOOD CLAMP FOR PISTON ROD

Take two pieces of hard wood 2 inches square by 12 to 16 inches long and bolt them together as shown, using either washers or a plate under the heads and nuts. Then drill a hole the size of the rod, or a trifle smaller, through the wood. Should the hole be too large, so as not to clamp tightly, a thickness of paper may be wrapped around rod.

I have never yet had this clamp slip or mar the rod.

G. A. RAND.

Freeport, Ill.

Arrangement of Boiler Feed Pipes

A great deal of useful information has appeared in POWER as to the proper point at which to enter the feed water to the boiler. My experience leads me to believe that the layout of the plant should be taken into consideration, also the nature of the feed water.

Water that contains sulphates of lime and magnesia will form a hard scale, and if not put through a process of purification before entering the boiler, will form scale in the boiler when the steam pressure is above 50 pounds. With this kind of water little or no trouble would be met with in circulating it through pipes in the boiler before discharging. But with water that contained carbonates of lime and magnesia considerable trouble would be experienced in keeping the feed pipes clear, as the carbonates precipitate at a temperature of from 190 to 212 degrees. With water containing carbonates, my idea is to get the water into the boiler as soon as possible after leaving the feed pump.

W. G. WALTERS.

Stratford, Ont.

Economic Engineering

I noted with interest Mr. Allison's criticism in the January 17 issue of my views in regard to the economic engineer and the superintendent or chief engineer.

I offered no criticism whatever of the economic engineer, neither did I express the opinion that he had not "come to stay." On the contrary, I think that the inefficiency of a good many superintendents and chief engineers has made the economic engineer a necessity, and I do not doubt for a minute that he has come to stay. But, this does not necessarily prove the inefficiency of everybody else.

Mr. Allison does not mention the chief engineer in his criticism, but deals entirely with the superintendent and regards him as the head of a business organization. Looking at the matter from that point of view, I agree heartily with Mr. Allison's views on the subject, but by referring to the editorial in the September 27 issue and also to my "argument" in the November 22 issue, it will be seen that both the superintendent and the chief engineer are considered. I understood the term "superintendent" to refer to the man who superintends the operation of the power plant, and not to the head of a business organization; sometimes he is called the superintendent and sometimes the chief engineer, and sometimes, in the case of a large plant, both are in evidence. If I understand rightly, the manager is considered the head of the organization.

Looking at the matter in this light, I still contend that the man who is "onto his job," I mean by this the man who knows his job as he ought to know it (I did not say "the man on the job"), should be just as efficient as the economic engineer.

Mr. Allison, because he considers the superintendent as an employer, accuses me of contradicting my statements by saying that I had found a great deal more unwillingness on the part of employers to furnish new equipment with which to improve the methods of operation, than unwillingness on the part of the operators to break away from old established customs.

To be sure, the superintendent is usually considered as an employer, so is the section boss on a railroad, but it does not necessarily follow that either has the power to purchase new equipment. This is generally up to the manager, who is also an employer.

A man's title does not necessarily make him more efficient than another man. The most efficient man is the one who does the job right, regardless of his title.

R. L. Rayburn.

Kansas City, Mo.

Introducing Solvents into Boilers

I read with interest Mr. Taylor's letter in the December 6 issue on the above subject. In the plant where I am employed there is an arrangement for feeding solvents into the boilers which is similar to that described by him, but I never use it except just before washing out. There is a ¼-inch pipe which connects the feed-pump suction line to a barrel on the roof. The solvent is ordinarily placed in this barrel and fed through the small pipe at a rate which is regulated so that three-quarters of a barrelful is fed in during the day's run.

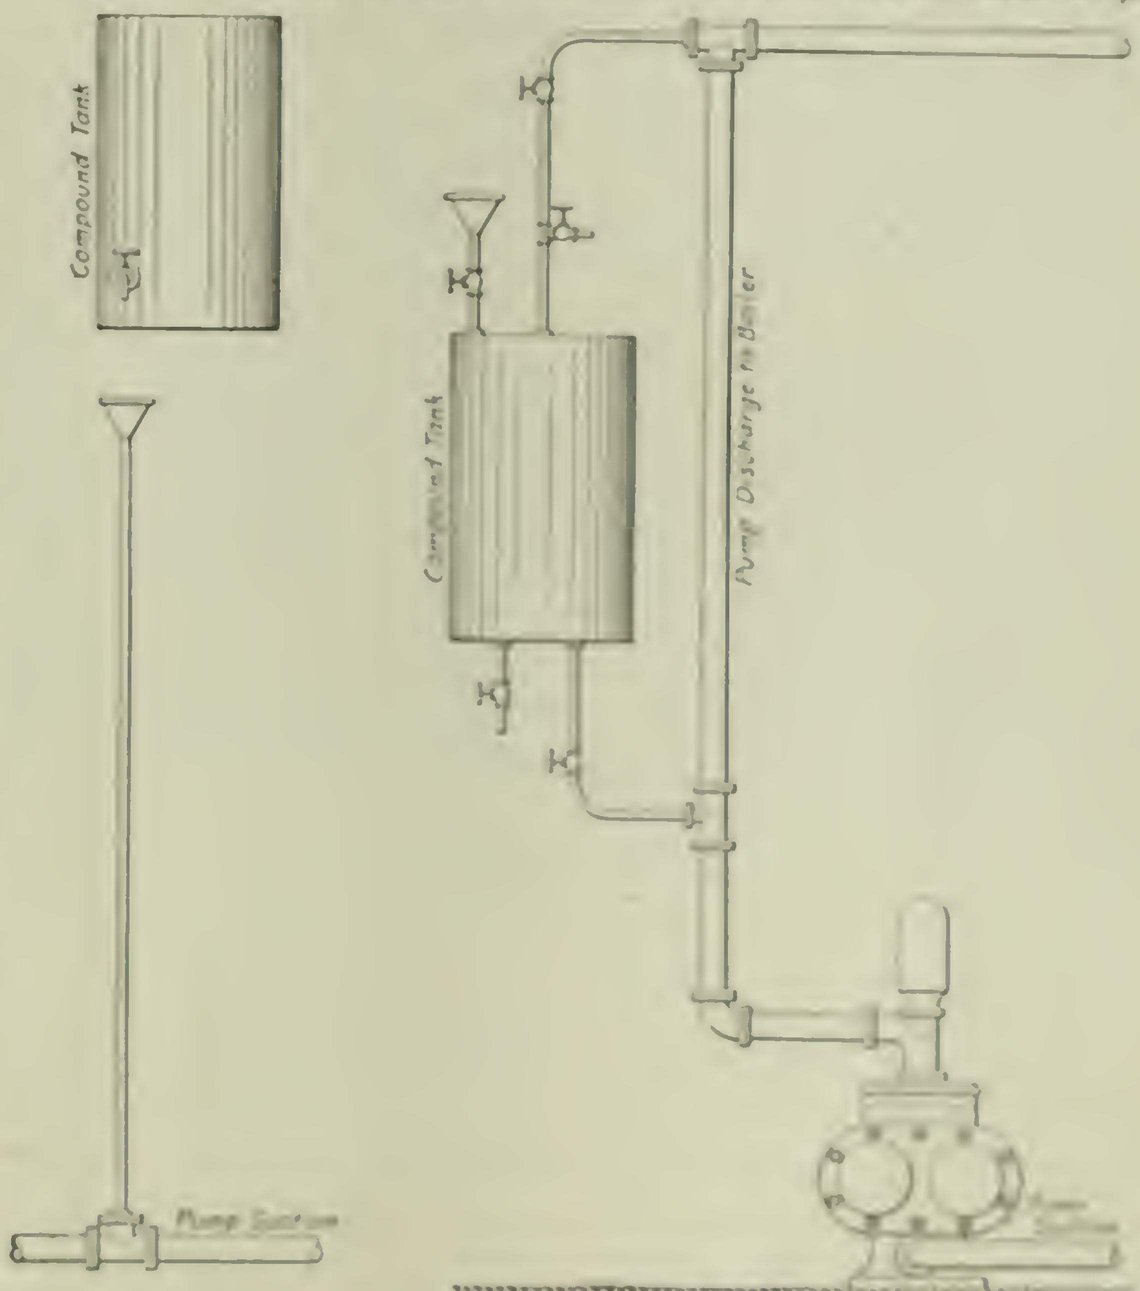


Fig. 1. Two Methods of Introducing Solvents Into Boilers Fig. 2

Just before running up the water level in the boilers at night, the balance of the solvent in the barrel is pumped into the boiler.

The object of this arrangement is to treat the water uniformly.

N. J. Keith.

Dublin, Tex.

In reply to Frank H. Williams, in the January 3 issue, in regard to introducing boiler compounds, I submit the following arrangements both of which may be rigged up from material from the scrap pile.

The device shown in Fig. 1 did not prove to be very satisfactory because the solvent passed through the pump, caused it to stick and filled up the water chambers.

The arrangement shown in Fig. 2 was substituted and gave good results. The drain valve should be a gate valve. All the piping is of ½-inch material.

William J. Martin.

Appleton, Wis.

An Engineer on Success

In the January 3 number, Mr. Eldredge writes about engine-room ethics.

No man can succeed unless he puts his whole soul into his work. With a determination to succeed he will surely rise to the top. It may take him years to do so but there is always a reward for those who keep steadfastly to their determination to win.

Many men make a mistake by not holding to one position, but moving around from one to another every few months.

The engineer who succeeds is the one who devotes his whole time and ability to the interests of his employer while on duty, and improves his spare moments by reading good engineering books or magazines.

We all have our ups and downs and the only way to come out on top is to keep up the spirit and determination to win.

George O. Griffith.

Fort Flagler, Wash.

Does the Crosshead Stop

The above title has for many a weary week adorned the pages of Power. The discussions upon the subject have been largely controversial; partaking of the nature of "Katy did" and "Katy didn't." Occasionally, there has been no reference to the subject and then I have put down my Power thinking happily, "At last that crosshead has stopped." But no! next week it crops up again as lively as ever with elaborate diagrams to show that it stops—or doesn't.

So, in self defense, I humble myself to write upon the subject. And I do hope that mine will be the last word. So here goes:

If the crosshead does not stop, it must be moving. If it moves, it has a velocity. If it has a velocity, it must have a direction. If it has a direction, please let someone who votes that the crosshead does not stop say in *just what direction the crosshead is moving at the end of the stroke.* Let him put an arrow on a diagram to show in which direction it moves. If he can prove the direction, I will yield him the palm. But, if it is impossible to find a direction, clearly there is no motion, and no further argument is needed that the crosshead does stop.

Julian C. Smallwood.

Syracuse, N. Y.

Engineer or Laborer

The advertisement copied in the editorial under the above title in Power for January 31 is enough to make every engineer in the country sit up and take notice. There are cases where a young fellow who is trying to get experience could work for such pay and be excused, but for a man who is duly qualified to take such a position is shameful. I regret that the article does not state whether or not this position was in Massachusetts; it is no more attractive than some I have seen in the daily papers in this State. Engineers in other States, who are struggling for a license law, will tell us it has a tendency to raise wages. Come and see. Here are a few specimens:

In a large office building requiring continuous service, where the engineers work seven 8-hour shifts each, the engineer does his own firing, burns screenings, operates two boilers in summer and three in winter, keeps everything in good condition and tends to the engines, generators and switchboard, all for $14 per week. This job requires a second-class license.

A first-class engineer recently made vacant a position for which he was receiving $35 per week, and another engineer with a first-class license took it for $18.

Another engineer with a first-class license took a job for $16 per week while he was looking for something bigger to turn up. Before he had been there two weeks, another engineer came along and took his position for $14.

Well, who is to blame? Why, the engineers, of course. To do each other out of a job seems to be a malady that is fast growing among engineers.

The average operating engineer is the poorest paid mechanic in the country. Other mechanics are getting good pay and they cannot do each other out of a job, because they are organized, and in organization there is strength.

There is no mistaking the fact that the engineers of this country must organize. Not only engineers but every man engaged in the generation and transmission of power should be a member of one organization. Give us a national organization of all power workers, coupled with Federal license and inspection laws, and I will venture to say that within ten years we will have the wages of the average power worker increased wonderfully, and the engineer's profession raised to such a position as to command the respect of employers.

J. A. Levy.

Greenfield, Mass.

Runaway Engines

It is surprising to note that hardly anything is being done toward reducing the number of flywheel explosions. Due to the results of such accidents not being so disastrous, perhaps, the general public and, indeed, those who are more intimately concerned with engines, are surprisingly complacent toward this type of accident. The lack of publicity as to the direct cause of flywheel explosions, due to the vigilant care of owners to baffle and prevent worthy investigation, is in a large measure responsible for fostering this indifference. A boiler explosion will occupy a very prominent space in the daily newspapers while often the reader must search minutely for mention of a flywheel explosion, and when he finds it, 99 times out of 100, the direct cause of the accident is not reported.

Why? Is it because the cause would incriminate the owner, or his servant, the engineer? That runaway engines are of frequent occurrence, though in the majority of cases stopped before damage is done, can be attested to by a large number of engineers.

When an engineer has once faced a runaway, by being obliged to stand in front of 12 tons or so of madly revolving iron, which at any moment may burst into a hundred pieces and hurl him to eternity, he generally afterward becomes most solicitous about all of the details which have to do with the safety of the flywheel. The chief cause of runaways is the governor belt, that often oil soaked, pieced, and badly spliced bit of hide to which one-half of engine builders are willing to commit the safety of valuable engines and their more or less valuable attendants.

My first experience was with a large central condenser pump with Corliss valve gear. Due to the breaking of the governor belt one afternoon it started to enliven matters by attempting to find out how fast it could go. As I descended the steps leading to the pit, I was met first by the crank-pin oil cup, and next by the oil pipe leading to it. The engine was stopped, however, without doing any further damage. My next experience was with an air pump, equipped with a throttling governor. To stop this runaway, also caused by the breaking of the governor belt, I was forced to stand on a step ladder and bend over one of the flying balance wheels to close the throttle. When stopped, the crank and wrist-pins were found to be smoking hot, and all of the foundation bolts loose. These two experiences inculcated the habit of extreme caution on my part, and taught me to seek answers to such questions as, what would I do if this, that or the other thing should happen. It is surprising how many things an engineer can do in an emergency—after full consideration under calm thought—and it will do no harm here to impress on young engineers the importance of considering the answers to these pertinent questions before an emergency arises, and not after the smoke clears.

A case to illustrate this happened some time ago. I was employed in a small textile mill erecting a line of shafting. It was my custom to spend my noon hour with the engineer, and during our conversations on engineering topics, I asked him what he would do if the engine ran away. The machine was a small slide-valve affair, equipped with a throttling governor that had no provision for stopping the engine in the event of the governor belt breaking, which, by the way, seemed to me from its condition to be imminent. His only resort at the time was to shut the stop valve on top of the boiler.

It was only a few days later that he was called upon to face the emergency. As I noticed the mill machinery speeding up, I called to the operatives to keep their looms running, and start up every loom that was idle, giving the example myself, for I had noticed that with a large percentage of the looms in operation, the speed often slackened, proving that the engine was hardly big enough to handle the mill load. But, much sooner than I expected, the racing looms slowed down. As I proceeded to the boiler room to congratulate the engineer on the remarkable agility he had shown in finding a ladder, climbing to the top of the boiler and closing the stop valve, I peeked into the engine room and beheld a most melodramatic tableau. Clinging to the lever of the 2-inch back-pressure valve that stood 10 feet above the floor and with one foot slowly but surely shutting the throttle was the engineer, while steam from several leaky gaskets was filling the place.

On being asked what had made him think of the back-pressure valve, he said that my inquiry as to what he would do when called upon to face this emergency had set him to thinking and had prompted him to try the expediency which had proved so efficacious.

Not long ago I had to deal with a very mysterious case of overspeeding on the part of a cross-compound Corliss engine, direct connected to a 1500-kilowatt alternator. I was about to stop this engine and, with a precaution that many would deem unnecessary, I had the oiler shut the throttle valve before pulling out the main switch. When this was done, we waited for the speed to slacken before releasing the steam and exhaust clutch on the high side. These clutches had been done away with on the low side as being unnecessary. To my astonishment and alarm, instead of slowing down, the engine began gradually but surely to increase its speed. Hastily I released the two clutches and, anticipating something wrong with the throttle, I picked up the starting bar and with it tightened the valve. Noting that the dashpot rods on the low side kept moving, I looked at the governor, but found it had assumed its highest plane, the spindle sleeve being tightly pressed against the top collar. Convinced that in some manner steam was being furnished to the low-pressure cylinder, I tried the low-pressure throttle, and while standing there I distinctly heard the hissing of steam, though the valve was closed tightly. Jumping over to the governor reach rod, I tapped it with the starting bar, bending it and thus shortening it, which brought the knock-off cams into action and prevented the valves from hooking. Then, as quickly as possible, the injection valve of the condenser was closed and the pump stopped. Upon investigating, I found that the low-pressure bypass valve was wide open. In order to pack the valve stem, the oiler had opened it to take advantage of the packing seat, and had forgotten to close it. It had no extension handle passing through the floor as the other valves had.

Pressure in Condensing Engine

The answer to a question in the January 17 issue under the caption, "Pressure in Condensing Engine," contains a statement that running an engine condensing is equivalent to increasing the pressure on the steam side of the piston to the extent of 10 or 12 pounds in average practice.

I think that the statement is misleading, as some would take it, that 10 or 12 pounds increase in initial pressure would give the same result, whereas it requires 10 or 12 pounds increase in the mean effective pressure.

F. M. Bennett.

Chicago, Ill.

A Practical Compression Test

"Compression or no compression" is a subject that has frequently been discussed in and out of the technical journals for the past twenty years, to my knowledge. The matter is not yet settled, although I see by some of the articles and letters in Power during the past year that some of the higher authorities in engineering are coming around to the side of no compression or, at least, very much reduced compression.

In the editorial "Two Diagrams" in the January 31 issue, the question is asked, "What is the real answer, and why does not some college laboratory find and announce it?" Must the answer come from "some college laboratory"? Can it not be found in steam plants where there is an opportunity to experiment and note results? It seems to me that it can, and to my knowledge it has been in one instance at least.

The plant, a street-railway power station, contained thirteen compound, condensing, Corliss engines of sizes varying from 500 to 1500 horsepower. The total horsepower was in the neighborhood of 8000 and for a few hours every day all of the units ran under full load. All of the engines had considerable compression in both high- and low-pressure cylinders, and were operated under a boiler pressure of 150 pounds and a receiver pressure of 15 pounds per square inch. During peak load both in the morning and the evening it was most difficult to keep up steam for even a half hour, and frequently the pressure would drop to 125 pounds, and sometimes even to 100 pounds.

After careful consideration it was decided to try reducing the compression in one of the engines, and at the same time increasing the receiver pressure. A few trials showed that the receiver pressure could be raised to 25 pounds gage. The engine was run for a day under the changed conditions and seemed to do as well, if not better, than before, as far as ordinary observation was concerned. As, apparently, the engine suffered no unfavorable effect, it was thought that a similar change could be made in the operation of all of the other ones and it could then be very soon discovered whether gain or loss resulted.

One by one, the engines were gone over, until all were changed. As the work progressed it was noticed that it was less difficult to maintain the standard 150 pounds boiler pressure. When all of the engines were finished, the peak loads were carried day after day without any trouble in the boiler rooms at all. Now, as the load conditions had not changed, as no other changes were in progress at the time and as not only one day was taken, but a number of days, it certainly seems fair to assume that the improvement was due to the reduction in compression, the increase in receiver pressure, or to both. I think that each contributed its share of the decided improvement.

I am not going to attempt any theoretical explanation, nor do I care particularly about such, just at present, but I do know, positively, that after the changes less steam was consumed to do the same amount of work in the same period of time, and every one of the engines behaved splendidly while carrying its share of the load. There was no more dropping of steam pressure with the consequent long cutoffs and the disagreeable possibility of having to shift some of the load onto some of the other stations.

From a purely practical and commercial standpoint, what difference does it make as to just exactly what caused the improvement, as long as it was effected by the expenditure of a few hours' time on the part of the station men who were on duty anyway. There is hardly any doubt that had a mistake been made in reducing the compression and in increasing the receiver pressure in so many engines, it would have manifested itself immediately.

Set some of the boys to trying the thing out for themselves, and report the results in Power. Report the exact conditions attending such tests, so that the whole truth may be known.

Charles J. Mason.

Scranton, Penn.

Belt Lacing

I was much interested in Mr. Kell's article on lacing belts in the January 10 issue. The illustrations were good, also the methods.

I wish more others would contribute articles on the same subject.

Thomas Clark.

Boston, Mass.

Inquiries of General Interest

Questions are not answered unless accompanied by the name and address of the inquirer. This page is for you when stuck—use it

One or Two Cylinders

We are now running an 18x36-inch engine which is supposed to develop 249 horsepower at one-third cutoff. The load has increased to 328 horsepower, and the engine takes steam seven-eighths of the stroke. If another side is put in the same as this, setting the crank pins on the quarter, would it take more steam to develop the same amount of power with the two engines than it does with this single one with the overload?

E. W. O.

A fair load for an 18-inch engine under average conditions of steam pressure is 175 horsepower. Two 18-inch cylinders will develop 328 horsepower on much less steam than one. The displacement up to cutoff will be about in the ratio of 8 for one cylinder and 5 for two.

Color of Ashes

What gives the fine ashes in the combustion chamber of an ordinary return-tubular boiler their reddish color?

C. O. A.

The color is due to the presence of sesquioxide of iron.

Peak Load

What is meant by "peak load"?

E. E. P.

The term refers to the heaviest load of the run. Where the load curve is plotted on a chart, the highest point reached is called the peak.

Brake Horsepower

What is the brake horsepower of an engine?

E. P. E.

Brake horsepower is the term applied to the power delivered from the flywheel or engine shaft. It is that determined by brake measurement, hence the term. It is the net horsepower as distinguished from the indicated horsepower, which is the power developed in the cylinder.

Effect of Safety Valve Opening

If the quick opening of a valve or the breaking of a pipe or fitting reduces the pressure in a boiler and causes a water hammer, why is there not a water hammer every time the safety valve blows?

E. S. O.

When a safety valve blows there is no sudden reduction of the pressure in the boiler. The opening of the valve prevents any further rise and if there is any appreciable reduction due to excessive "blow back," this reduction is accomplished slowly instead of rapidly as is the case with a broken pipe.

Compound Engine Cranks

In a cross-compound engine which will give the better results, to have the crank pins 90 or 180 degrees apart?

C. E. C.

It will make no difference in steam economy. But there will be a more uniform turning effect on the shaft with the cranks at 90 degrees.

Granulated Babbitt Metal

How can I make a granulated babbitt metal?

G. B. M.

Melt the metal in a ladle, remove the ladle from the fire and allow the metal to cool. When it begins to "set," stir briskly with a stick until it has all cooled into a granular mass. If any particular size of grain is desired, the metal may be sifted, using two screens, one of the desired size mesh to remove the large grains and one slightly smaller to allow the escape of the fine or too small grains.

Disabled Valve Gear

If the connection on one of the exhaust valves of the high-pressure cylinder of a triple-expansion Corliss engine should get broken, what should be done in order to keep on running?

O. W. L.

Block the exhaust valve open, then shorten the dashpot rod of the corresponding steam valve until the hook will not engage. This will leave the steam port closed and the high-pressure cylinder will run single acting.

Cutting Boiler in with Others

How should a boiler, in which steam has been raised, be cut in with others?

C. B. O.

As the steam pressure approaches that in the others, the draft should be checked and the pressure allowed to increase slowly until it is within a pound or two of the other pressure, when the connecting valve should be slowly opened.

Area of Steam Port

How is the size of the steam ports of an engine cylinder found?

A. S. P.

The velocity of the steam entering the cylinder should not exceed 100 feet per second. To find the area of a steam port for this velocity, multiply the piston area in square inches by its travel in feet per second. This product divided by 100 will give the required area of the port in square inches. Dividing the area of the port by its length will give the width.

Tubes, Flues and Pipes

What is the difference between tubes, flues and pipes?

T. F. P.

It is in the terms of the diameter. Tubes and flues are measured by the external diameter. Boiler-tube sizes run to 4½ inches. Above this they are called flues. Iron and steel pipe is measured by the internal diameter up to 12 inches and by the outside above this. Cast-iron pipe of all diameters is measured on the inside.

Corrosion and Remedy

What is corrosion in a boiler and how can it be prevented?

C. A. R.

It is the gradual rusting or dissolving of the metal by the water or oxygen or acid present in it. It may be prevented by analyzing the water and introducing such elements as will neutralize the corroding agents.

Total Pressure in Boiler

What is the aggregate pressure tending to burst a boiler 6x18 feet, carrying 120 pounds pressure per square inch?

T. P. B.

The total pressure on the shell is

$$3 \times 3.14 \times 18 \times 144 \times 120 = 2{,}879{,}996.8 \textit{ pounds}.$$

The pressure on the heads if supported by the tubes and stays has no bursting tendency.

Comparative Value of Wood and Coal

How does wood compare with coal in fuel value?

C. V. C.

Dry wood has a heat value per pound of about 0.4 that of carbon. There is little difference in the fuel value of the different kinds of wood, pound for pound.

POWER

The Coal Mine Operator's Profit

In the January 17 issue of Power an editorial entitled "The Consumer Pays the Bill" was published. Our contemporary, *The Black Diamond*, took exception to some of the statements made, and tried to tell the coal operators that they are not receiving enough money for the smaller sizes of anthracite coal.

According to *The Black Diamond's* own statement, sixty-two per cent. of the anthracite coal now mined is sold for domestic use, and the remaining thirty-eight per cent., which is broken up into the small sizes, is sold for steaming purposes, so that there is practically no waste of actual combustible. Not long ago these smaller sizes were thrown away and therefore represented no income. During the year 1909 there were 855,933 tons of No. 1 buckwheat, 1,330,468 tons of No. 2 buckwheat and rice and 1,172,831 tons of No. 3 buckwheat coal taken from the washeries as against 8,287,401 tons of No. 1 buckwheat, 4,283,417 tons of No. 2 and rice and 2,145,938 of No. 3 buckwheat coal taken from the mines.

Coal is being mined almost as cheaply today as it was ten or fifteen years ago, but the selling price to the consumer is higher than it has ever been, under ordinary conditions; yet *The Black Diamond* contends that the money received from the sale of the smallest sizes is not "velvet" and asserts that inasmuch as it costs just as much to mine the fine coal as it does to mine the larger sizes, the anthracite companies should charge more for the small sizes instead of less. This argument might have some merit if the prices of larger sizes had been reduced when the operators began selling the fine sizes.

If the income from sixty-two per cent. of the coal mined formerly paid a good profit over the cost of mining all of it, how much profit must there be now that all of it is sold without any reduction in the price of the larger sizes? The average price of the larger sizes at the mine last year was about two dollars and ninety-two cents per ton, and how that this formerly paid a profit on the cost of mining a little over one and one-half tons of combined large and small sizes. The average price of small sizes is one dollar and twenty-five cents per ton, or fifty cents on each ton of available fuel mined. Result: instead of receiving one dollar and seventy-five cents per ton of available fuel mined, the operators receive two dollars and twenty-five cents per ton, although the cost of mining has not increased as much as the selling price of coal since the small sizes were "dumped." If that is not fifty cents of "velvet" per ton of fuel, what is it? And who pays it, if not the consumer?

Boiler Inspection and Engineers' License Legislation

It is interesting to note that the persistent agitation on the part of the more intelligent engineers for the enactment of boiler-inspection and engineers' license laws is beginning to be felt where no laws of this nature exist. There are before the legislatures of the States of New York and Kansas concise and comprehensive propositions for the examination of engineers. And there has just passed both houses of Congress a bill providing for the annual inspection of locomotive boilers.

These are steps in the right direction and when all of the States have enacted suitable inspection and license laws a part of the coroner's occupation will have disappeared. Uniform license laws throughout the country, honestly administered, will eliminate the incompetent employee and one form of menace to life and property will disappear.

Consistent boiler-inspection requirements forbidding the installation and use of boilers of defective construction and compelling the rigid examination of all already installed will add to the length of the undertaker's vacation. The most rigid laws and the utmost vigilance in their execution will probably not entirely prevent boiler accidents, but such action will reduce them to the lowest possible number. Periodic inspections have prevented almost numberless explosions, and hundreds of others would have been prevented by the enforcing of common-sense laws. There are no boiler laws in New Hampshire. In 1908 on a boiler belonging to the town of Dartmouth, Mass., the pressure allowance was reduced by a State inspector to a point which rendered it useless to the municipality as a source of steam supply and it was sold for junk for fifty dollars to an alleged engineer who represented to the New Bedford Ice Company that the boiler was safe for a much higher pressure than that allowed by the State inspector. The boiler was taken to New Hampshire and installed for use during the ice harvest. It exploded on the first day of its use, killing the man who said it was safe.

Last summer at Laconia, a boiler in the Lakeport steam laundry exploded with fatal results. Had laws similar to those of Massachusetts been in force in New Hampshire, neither of these boilers would have failed, and the State would not be characterized as the dumping ground for worn-out Massachusetts boilers.

Sign Your Full Name

From Detroit, Mich., there comes a question about the method used to determine the efficiency of riveted seams. The question is a reasonable one and is intelligently stated. But after the question comes this plea: "Now, do not turn this down and say that you have shown this more than a hundred times during the last twenty years, but kindly and considerately remember that there are many young men just beginning to read POWER while the older readers are passing away. Editors sometimes forget that new men are coming up as the old ones go, by the thousand, and refuse to reply to a question a second time. Please do not treat this one that way."

Four times within two years this question has been answered in the columns of the paper and more than fifty times by personal letter, just as it would have been in the present instance if the writer had signed his name to the letter he so painstakingly wrote.

Sometimes a correspondent will sign a letter with his initials only and hundreds of letters have been answered where the only clues to the addresses were the post mark on the envelop and the initials which fitted a name on the subscription list.

Hundreds of letters are received, read, answered and filed at this office every working day of the year and it is not strange that a few mistakes occur. But it is strange that the most, in fact nearly all, of the unsigned letters received at this office are written by engineers. Anonymous letters are annoying, whether the omission of the signature is intentional or otherwise; but are doubly so when concealment makes it impossible to perform a service so manifestly expected, as in the instance mentioned.

Engineers are not as a rule careless; their work and training, and the responsibilities of the positions they occupy preclude this. But some do slip, and when they do, how often will they accept the suggestion that possibly or very probably the miscarriage of a project was due to negligence on their part?

This was not written wholly for the subscriber in Detroit, whose question will, in the near future, be answered in the reading columns, but for all who feel that they have not been given courteous attention. This journal is for its readers, and the whole office force from the office boy to the president is at their service and they have only to ask to receive and that quickly, if they ask aright by plainly signed letters.

Stress in Boiler Sheets

It is a well understood fact that in a cylinder under pressure the stress upon the metal per unit of section is twice as much when the section is taken parallel with the axis as when it is taken at right angles thereto; that in a cylindrical boiler, for example, this stress is twice as great upon the longitudinal as upon the roundabout joint.

This stress upon the longitudinal section has been considered by designers as the maximum stress per unit of section to which the sheet is subjected by reason of the pressure; but on page 1935 of POWER for November 1, 1910, Mr. Adler advances the idea that these two stresses acting at right angles have a component acting diagonally through the sheet greater than either of them.

This proposition seems open to argument, and we should like to have expressions of the ideas of our readers concerning it.

Suppose a sheet of boiler steel to be stressed lengthwise, as in a testing machine, up to its breaking point. Would it break under any less stress and would the direction of the line of fracture be any different if at the same time it were subjected to a crosswise stress one-half of that which was being applied lengthwise?

If a square piece of perfectly homogeneous boiler steel were submitted to tensile stresses, uniformly applied to all four sides and normal to those sides, would it break into four squares or four triangles, that is, would it break on the diameters or on the diagonals?

High Boiler Efficiency

Some time ago we published the report of a test upon the boilers of the Government plant at Panama, showing an efficieny of over eighty-two per cent. Under the terms of the contract a bonus of over seventeen thousand dollars was earned by the builders upon the strength of this test. The report was furnished us by the makers of the boilers and was signed by the testing engineer for the Government.

Since publishing the report, we have received several communications questioning the correctness of the figures, and upon taking the matter up with the makers, they admit that they are at a loss to account for some of the figures. Computed rationally, the efficiency should have been about seventy-five per cent.

Hanging On to Water Power

Another instance of the keeping of the hands of the people upon their power supply is the refusal of the House of Representatives to cede perpetual control of the water power of the St. Lawrence river to the Aluminum Company of America. The Government should either itself develop or encourage the development of water powers as fast as there is a demand for them, but under such circumstances that the people can retain their rights therein and be guarded against excessive charges.

Louisville, Ky., is also out for an international exposition in 1915. The excuse is that that year marks the fiftieth anniversary of the end of the Civil war. It is to be known as the Lincoln-Davis exposition and held at Louisville as both Abraham Lincoln and Jefferson Davis were natives of Kentucky. The real 1915 exposition will be held in San Francisco and will commemorate the completion of the Panama canal. We are big enough, however, to run two international expositions at once, if it has to be done.

Have you had or do you know of any trouble with boiler tubes recently? If so, what kind of a tube was it; iron or steel, lap or butt welded or seamless, standard thickness or under or over gage? How did it fail; in the seam or elsewhere, by thinning down or breaking a piece squarely out? What were the conditions of the tube as to cleanliness, and how much water was it evaporating per square foot of heating surface?

Camille Flammarion, who in a recent issue of the *New York American* takes a Look One Thousand Years Ahead, says that "Electricity will, of course, have taken the place of steam." Where are they going to get the electricity? At present, "juice" is not a substitute for but a product of steam power.

Pittsburg will entertain the Mechanical Engineers in May. This will be the second time in the history of the society that it has met at Pittsburg, the first being in 1884.

When are they going to try John Carroll? They are waiting for him in Philadelphia after the Boston authorities get through with him.

It is rumored that the committee on power tests of the American Society of Mechanical Engineers has turned over in its sleep.

The crosshead does stop at the end of the stroke.—*Punktum.*

Prevention of Industrial Accidents

An analysis of the principal causes of injury in industrial establishments and recommendations as to the preventative measures to be adopted.

At a recent meeting of the American Society of Mechanical Engineers, John Calder presented a paper upon "The Mechanical Engineer and the Prevention of Accidents," which was, in part, as follows:

Accident clauses have been included in the labor laws of the various States for some years, but the provision for administering these laws effectively has always been inadequate.

In study and legislation upon the subject, this country is far behind Great Britain, Germany and France, which countries more than thirty years ago began to enforce the existing laws with strictness and excellent technical judgment. The reports of the Bureau of Labor show that the yearly mortality from industrial accidents, among adult wage earners alone, in the United States is between 30,000 and 35,000. It is estimated that the nonfatal injuries reach nearly 2,000,000 annually.

Scientific study and a solution by the mechanical engineer of individual problems of safeguarding, supervision and instruction of employees, as they arise in daily routine work, will do more than all other existing agencies to bring about satisfactory results. In such matters the attitude and action of the executive are all important. However, all industrial accidents are not to be considered preventable, either by employer or employee. Furthermore, of those that may be avoided, some do not fall strictly within the province of the engineer, but are directly within the control of the injured themselves.

An analysis of many thousand industrial accidents shows them to have been due principally to the following causes: ignorance, carelessness, unsuitable clothing, insufficient light, dirty and obstructed work places, defects in machinery and absence of safeguards. Accidents due to the culpable, as well as excusable, ignorance of supervisors, engineers, millwrights, elevatormen, etc., may be reduced only by administrative vigilance in selecting and instructing these employees. As for carelessness, the average American workman is very apt to take foolish and unnecessary chances with life and limb and the only way to guard against this is by the maintenance of strict discipline in the shops, the adoption of salutary punitive measures and the elimination of the dangerous employee, in addition to an educational campaign throughout the plant.

Much eloquence has been expended from time to time on assumed inherent and deadly defects in machinery and structures used in the arts. These, while contributing to some serious and a number of minor casualties, do not approach the extent commonly alleged. It certainly does not pay any employer to keep a defective machine in operation; nor is it in the interest of the employee to use imperfect apparatus which reduces the possible earnings. On the other hand, it is by no means infrequent to find workmen who have their choice of the best material and apparatus and who possess the intelligence to apply these correctly, showing a striking disregard for their own safety; this is especially true in temporary structures, such as scaffolds, frayed ropes, etc.

The absence of safeguards, although not the most prolific cause of accidents in plants, as is commonly supposed, nevertheless closely concerns the mechanical engineer who holds the possibilities largely in his own hands. However, in many cases of injuries caused by the absence of safeguards, it has been found that these were removed or rendered ineffective by the operatives themselves. All safeguards should be so designed as not to interfere with the speed and ease of operating the machine.

Mr. Calder illustrated a number of safeguarding devices, applicable for the most part to industrial machines. Regarding power-house appliances he recommended that the edges of all stairs, platforms and gratings should have toe fenders on both sides to prevent nuts, bolts, tools and other small parts rolling off onto the machinery or striking employees. Also, a double metal railing not less than three feet high and not nearer to any moving part than twelve inches should be provided at all dangerous places, such as crank and flywheel pits and the edges of all stairways. Metal tubing and disk guards should be used for all shafting, bearings and pulleys requiring to be approached closely while in motion. Seven feet clear of every moving part is considered the least height from the floor level without guarding and, even then, where a horizontal belt drives across a frequented passage it is well to have the lower side screened to avoid injuries caused by "whipping" if the belt should break.

Discussion

The discussion of the paper was opened by Professor Hutton, president of the American Museum of Safety Devices, who showed lantern slides of numerous devices and commented upon their effectiveness. A number of the devices shown were of German design and, although practically a sure preventative against accidents, many of these were of such design as to impede the speed of the operator or make their cost prohibitive. Professor Hutton laid particular stress upon the subject of signs, pointing out that the majority of signs were ineffective for two reasons: First, owing to the number of foreigners employed in this country, it is essential that the signs be printed in several languages; second, they are usually of a cautionary nature and are not expressed forcibly enough. In this connection he called attention to the practice of the United States Steel Corporation which uses the symbol of a skull and crossbones to denote a death danger.

The next speaker, Mr. Cummings, dwelt to some extent upon the economic side of the question, showing that outside of humanitarian considerations it actually paid the manufacturer to install safety appliances. It was shown that nearly all the courts hold that if an accident occurs from any device or machine, it is not valid evidence that it is not customary to guard that machine, but it is accepted as *prima facie* evidence that the machine being dangerous, the accident should not have happened and the machine could have been guarded. Thirty-one cases were cited, happening within thirty days in the State of Minnesota, in which judgments of over $140,000 were awarded by the courts; of this only $6000 was deducted by reversed decisions.

Mr. Cummings also referred to the preventative methods adopted by the United States Steel Corporation which have reduced the number of accidents 50 per cent. Here, besides the mechanical appliances employed, much of the credit is due to the system of inspection, which makes every foreman and workman an inspector. A set of inspectors is appointed in each department for a certain period, at the end of which these men go back to their work and others take their place, and so on. However, the fact of their going back to work does not relieve them of responsibility of inspection, as they are supposed to keep continually upon the alert for defects. In this way all the men are trained.

J. W. Alexander, while conceding that machines should be made safe, believed that it was not necessary to make them foolproof. He thought that more attention should be given to working conditions, the cooperation of the workmen, clothing, etc., and suggested that a committee of engineers be appointed to collect the available data on safety appliances and standardize their use.

New Power House Equipment

What the inventor and the manufacturer are doing to save time and money in the engine room and power house. Engine room news

Diamond Tube Blower

A new soot blower, known as the Diamond, has been designed for use with water-tube boilers, and is illustrated herewith. By its use soot can be cleaned from the tubes without waiting for the boiler to cool down, and as often as the operator may desire.

Fig. 1 gives a good idea of the construction and mechanical parts of the device. Fig. 2 shows three blowers installed on one boiler having two vertical baffles, and under such circumstances

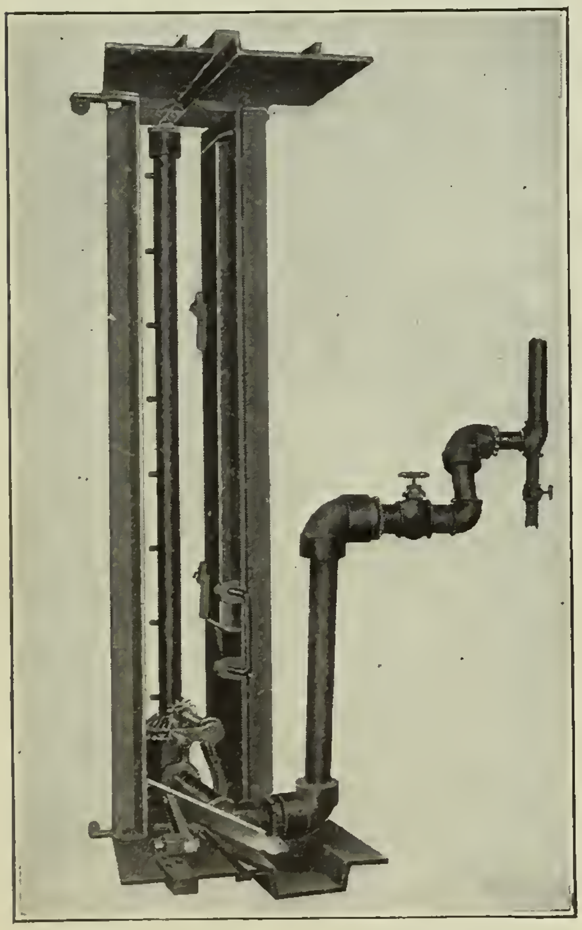

FIG. 1. DETAILS OF BLOWER

three blowers are required, one each side of the baffles. If the boiler had only one baffle, but two blowers would be necessary.

This blower is also applicable to boilers having horizontal baffles, in which case the number of blowers required is regulated by the length of the boiler, but any ordinary length can usually be covered by two blowers.

The blower is intended for use on boilers in which tubes are laid in even horizontal or nearly horizontal rows, when there is a clear passage between each row of tubes from one side of the boiler to the other, so that a jet of steam may pass through this space unobstructed for the full width of the boiler.

This blower is very simple in design, having no complicated parts to be destroyed by the effect of heat, soot or dirt.

There are three main parts to the blower: the door frame, the door and the standpipe resting on its slide. The slide operates in a groove in the top and bottom plates of the frame, and is moved in and out of the operating position by means of a vertical hand lever, as shown in Fig. 1, this lever being in a vertical position when the device is out of use, and in a horizontal position when the blower is thrown into the operating position.

When the blower is not in use it is protected by the door which closes behind the standpipe. This protects the working parts of the blower from the heat of the boiler, no parts being exposed when the blower is not in use. The door itself is protected by a filling of asbestos and cement about ½ inch thick.

When the blower is thrown into an operating position, by pressing down the lever, the standpipe is moved toward the inner side of the boiler wall so that it projects slightly beyond the inner face of the boiler setting.

In cleaning the tubes the standpipe is rotated through an arc of 180 degrees, or 90 degrees to the right and 90 degrees to the left, by the geared handle on the pinion shaft, as shown in Fig. 1.

The standpipe is provided with small jets so placed that one will come between each row of boiler tubes, and as the operator turns the handle, a jet of steam is thrown between each row of tubes from one side of the boiler to the other, and within the limits intended to be covered by one machine.

This blower is manufactured by the "Diamond" Power Specialty Company, 80-82 First street, Detroit, Mich.

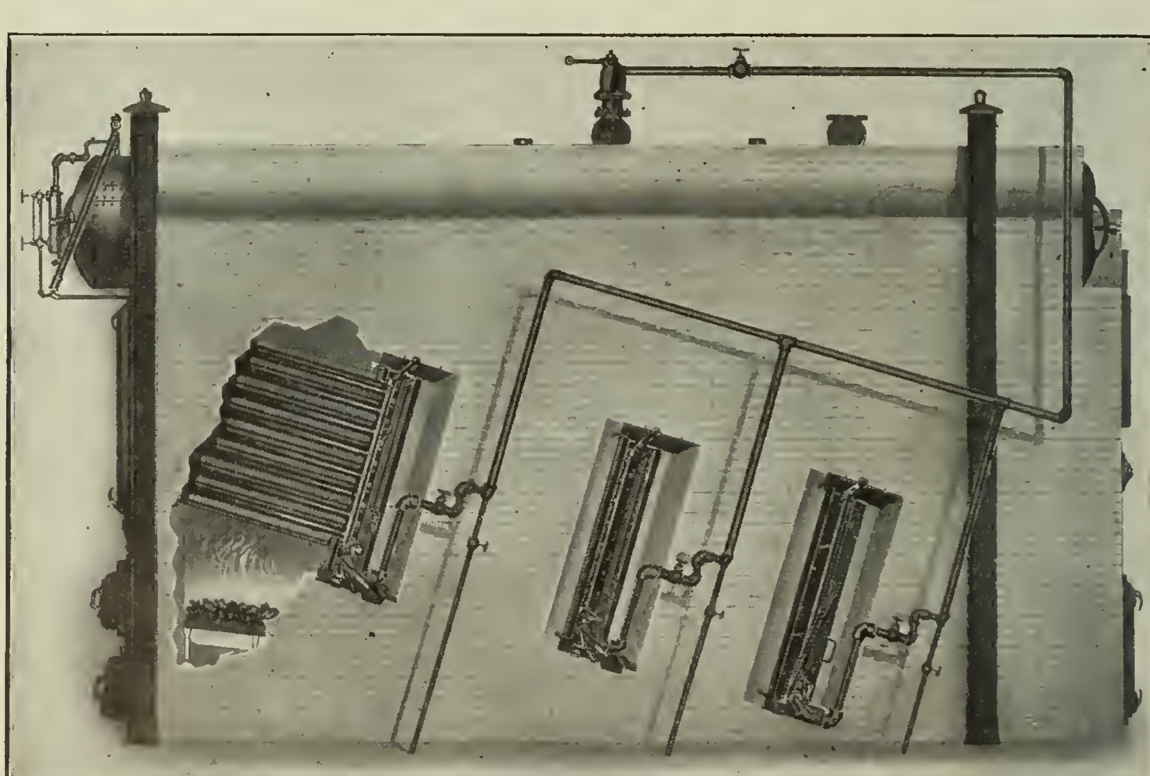

FIG. 2. APPLICATION OF BLOWER TO A BOILER

Mound No. 4 Packing Irons

These tools are for the purpose of replacing packing in the stuffing box of an engine, pump, etc.

They are forged from tool steel, and,

NO. 4 PACKING IRONS

having no sharp edges, are not liable to cut the piston rod during the process of packing.

There are four tools in each set, each 7, 9, 11 and 14 inches long, and they are nickel plated. The set is known as No. 4, and is made by the Mound Tool and Scraper Company, 7 Hickory street, St. Louis, Mo.

Court Rulings on Pittsfield Explosion

By John L. Robbins

In filing the report of the inquest on the recent boiler explosion at Pittsfield, by which seventeen lives were lost, the court found that there was violation of law in substituting a new safety valve of larger size and increased pressure for the one allowed by the State inspector, and in afterward tampering with the safety valve and thereby greatly increasing the pressure at which it was set. But it was held that no one living was responsible for it.

With a view to preventing further accidents from a like cause, it was recommended that the law be so amended as to require that all connections between the steam gage and the boiler shall be of brass or other metal that does not rust, and that all safety valves on boilers which require a licensed engineer to run them, shall be locked and a key kept in possession only of the State inspector of that district in which the boiler is located.

Long Beach Plant of the Southern California Edison Company

To insure continuity of service, the Southern California Edison Company has already invested about $2,000,000 in steam auxiliary generating plants to supplement in case of necessity their hydroelectric developments on the Kern river, the Santa Ana cañon and other water courses that derive their flow from the Sierras.

At Long Beach a steam plant is now under construction which will have a total ultimate capacity of 125,000 horsepower when entirely completed. This amount of energy will be necessary for carrying the peak loads of Los Angeles and the towns of southern California. The final cost of this plant will be about $6,000,000.

The new station, which will be located on a site adjacent to the inner harbor, will comprise two buildings having a combined floor space of nearly an acre. The generator and boiler house will have a floor area of 30,000 square feet and will be 60 feet high, while the transformer building will cover 7800 square feet and will be four stories in hight. Both structures are to be of reinforced concrete with artificial-stone base, ornamental cornice and mission-tile roof. The generator room will have a floor of imported Welsh quarry tile, with a glazed-tile wainscot. Everything considered, this will be the most handsome and best equipped steam plant west of Chicago.

The main unit will consist of a steam turbine of 12,000 kilowatts capacity.

For supplying steam to this turbine, there will be eight 750-horsepower Stirling boilers. Crude oil will be used for fuel, large concrete supply tanks being located on the west end of the property. This oil will be shipped in tank cars or may be pumped through a main which now runs by the company's property. Salt water will be used for condensing purposes.

Although only one unit will be installed at the present time, the buildings are being built of ample size for two large machines with their boilers and auxiliaries. The property on which the plant is located will allow for future growth. Frederick Sargent, of Chicago, has been retained as consulting mechanical engineer. The Edison company's engineering department is supervising the construction work and has made all of the designs and plans, except the purely architectural details which were designed by Parkinson & Bergstrom who have been retained as consulting architects.

Cost of Industrial Power

On Friday evening, March 10, the American Society of Mechanical Engineers, coöperating with the American Institute of Electrical Engineers, will hold a meeting on the cost of industrial power in the Engineering Societies building, 29 West Thirty-ninth street, New York. Papers will be presented on power costs by members of both societies. All members having intimate knowledge of cost of producing power in either central or isolated and industrial plants are invited to take part in the discussion. That there may be a proper standard for comparison it is necessary that the cost figures be itemized and the method of analysis by which each is determined, together with primary data from which determined, be given in detail. It is hoped that reliable information as to practical year in and year out operating costs will be presented so that it will be possible to differentiate between test conditions and actual operating costs. Those intending to discuss the question are requested to notify the New York meetings committee at an early date.

The Naval Dinner

On February 11, the American Society of Naval Engineers held its third annual banquet at Rauscher's, Washington, D. C. The banquet was a brilliant one and well attended by representative men of the naval, executive and army departments. Walter M. McFarland was toastmaster. Ernest W. Roberts, L. P. Padgett, Rear Admiral R. Wainwright and Col. Robert M. Thompson were on the program for toasts to the navy and Rear Admiral Melville concluded the speaking with a few brief remarks on the navy of the past and the present.

Newport Cannot Use Rhode Island Coal

Rhode Island coal may burn satisfactorily in some cases, but reports from Newport indicate that it cannot favorably compete with other coals for boiler use. Bids for supplying the city hall and overseers of the poor with fuel for the present year were requested by the board of aldermen. Rhode Island coal was offered at the lowest price and the company's agent in Newport was given a chance to take charge of the city-hall furnaces for a few days. The engineer of the plant reported that while the coal seemed to burn well enough, its heat value was apparently low and with the equipment in the plant did not raise steam as readily as other coals. An unsatisfactory report was also received from the overseers of the poor.

Oil Burning Engines for New Haven Road

It is reported in the daily press that the New Haven road is planning to try oil-burning locomotives on a more extensive scale than has been attempted by any other railroad in the East.

One locomotive has been transformed and the directors of the road will consider at their next meeting the project of converting twenty-two more locomotives.

The road has been quietly running an oil-burning locomotive daily from Boston to Provincetown, Cape Cod. The experiments show a saving of $12 a day and a speed fully as great as that of coal-burning engines.

Boiler Explosion in Philadelphia

On February 15 a boiler exploded in the basement of the candy factory of H. Nuss & Co., Philadelphia. The engineer of the plant was killed and considerable damage to the boiler room is reported.

Locomotive Explodes

A locomotive-boiler explosion is reported in the daily press to have occurred in Smithville, Tex., on February 9. Two were killed and nine injured and a property damage of $20,000 was effected. Details of the explosion will be given in an early issue.

PERSONAL

Frank Koester, previously with the Interborough Rapid Transit Construction Company, J. G. White & Co., the Guggenheim Exploration Company and the American Smelting and Refining Company, all of New York, recently opened an office at 115 Broadway, New York City, as consulting engineer. Mr. Koester is author of "Steam Electric Power Plants" and "Hydroelectric Developments and Engineering."

Arthur Ritter has succeeded Clayton W. Old as manager in charge of the New York sales office of the American Blower Company. Mr. Ritter has been connected with this company for a number of years and is well and favorably known among its clientele in the New York section.

SOCIETY NOTES

The next meeting of the Engineering Society of Wisconsin will be held in Madison on March 8, 9 and 10.

The spring meeting of the American Society of Mechanical Engineers will be held in Pittsburg, Penn., May 30 to June 2.

The national convention of the Building Owners and Managers Association will be held at Cleveland, O., on July 10, 11 and 12.

The Southern Supply and Machinery Dealers' Association, the National Supply and Machinery Dealers' Association and the American Supply and Machinery Manufacturers' Association will hold a triple joint convention in Louisville, Ky., on April 3, 4 and 5, 1911.

On the evening of March 9, 1911, the Institute of Operating Engineers will hold its second monthly meeting in its rooms in the Engineering Societies building, 29 West Thirty-ninth street, New York. William D. Ennis, professor of mechanical engineering in the Polytechnic Institute of Brooklyn, will deliver a paper on "Commercial Aspects of the Work of the Operating Engineer." Two other prominent engineers will be called upon to enter into the discussion of the paper. As this subject is one of great importance to the operating engineer, a large attendance is expected.

NEW INVENTIONS

Printed copies of patents are furnished by the Patent Office at 5c. each. Address the Commissioner of Patents, Washington, D. C.

PRIME MOVERS

INTERNAL COMBUSTION ENGINE. William J. Perkins, Grand Rapids, Mich. 983,307.

COMBUSTION ENGINE. Jakob Sulzer, Winterthur, Switzerland. 983,322.

INTERNAL COMBUSTION ENGINE. Leonard Archibald Vallillee, Buckingham, Quebec, Canada. 983,328.

TWO-CYCLE GASOLENE ENGINE. Fred Howes, Burlington, Vt. 983,369.

INTERNAL COMBUSTION ENGINE. Thos. Turnbull, Jr., Pittsburg, Penn. 983,583.

TURBINE. Byron Stevens, Oakland, Cal. 983,653.

ROTARY ENGINE. Franklin Priestley Nichols, Houston, Tex. 983,754.

BOILERS, FURNACES AND GAS PRODUCERS

STEAM GENERATOR. John N. Leach, Melrose, Mass., assignor, by mesne assignments, to Judson L. Thomson Manufacturing Company, Waltham, Mass., a Corporation of Maine. 983,296.

MECHANICAL STOKER. Edgar D. Newkirk, Canastota, N. Y., assignor to the Westinghouse Machine Company, a Corporation of Pennsylvania. 983,305.

WATER-TUBE BOILER. Amasa Worthington, New York, N. Y. 983,339.

OIL BURNER. William S. Dowell, El Reno, Okla. 983,484.

SMOKE CONSUMER. Charles D. Leonard, Rochester, N. Y. 983,503.

SMOKE-CONSUMING FURNACE. John W. McNeal, Chicago, Ill. 983,510.

GRATE. Robert Hilprecht, Lansing, Mich. 983,716.

POWER PLANT AUXILIARIES AND APPLIANCES

FEED-WATER HEATER. Francis Hodgkinson, Edgewood Park, Penn., assignor to the Westinghouse Machine Company, a Corporation of Pennsylvania. 983,282.

STARTING DEVICE FOR EXPLOSIVE ENGINES. Frederic N. Howard, Harris, R. I. 983,282.

OIL SAVER. Clark F. Rigby, Butler, Penn. 983,314.

FEED-WATER CONTROLLER. George Fleming, Chicago, Ill. 983,356.

PUMP. Byron W. Haskell, Oakland, Cal. 963,365.
